In both type 1 and type 2 diabetic patients with nephropathy, results of several earlier small trials suggested that the combination of an ACE inhibitor and an ARB is more effective in reducing BP and proteinuria than is either drug alone.[41,42] The Ongoing Telmisartan Alone and in Combination with Ramipril Global End-point Trial (ONTARGET), which included diabetic and nondiabetic patients with CV risk, failed to show improved CV outcomes from a combination of an ACE inhibitor and an ARB. Instead, it showed increased renal functional decline in some patients, a trend toward an increase in the development of ESRD that fell just short of statistical significance, and a possible increase in mortality.[43] Whereas most of the ONTARGET study population did not have overt DN, the more recent Veterans Affairs Nephropathy in Diabetes study (VA NEPHRON-D)[44] tested the effect of combination therapy with ACE inhibitor and ARBs in type 2 diabetic patients with overt nephropathy. The study showed no difference in the primary end point of CKD progression or death. There was, however, an impressive increase in hyperkalemia (6.3 vs 2.6 events/100 person-years; $P < 0.001$) and doubling of acute kidney injury events (12.2 vs 6.7 events/100 person-years; $P < 0.001$) with combination therapy compared to ARB alone. The VA NEPHRON-D study was in fact terminated early because of the unfavorable patient-risk benefit ratio.

ACE inhibitors and ARBs have also been studied in combination with a direct renin inhibitor (aliskiren). Further reductions in proteinuria have been reported with these combinations compared with the ACE inhibitor or ARB alone. However, as was seen in ONTARGET and VA NEPHRON-D study, an incremental antiproteinuric effect is not automatically translated into clinical outcome benefits. The large Aliskiren Trial in Type 2 Diabetics Using Cardio-Renal End-points (ALTITUDE) was also terminated prematurely because of findings that a combination of aliskiren and ACE inhibitors or ARBs caused considerable increase in nonfatal stroke, hypotension, hyperkalemia, and renal complications after 1½ to 2 years.[45] In summary, evidence from clinical trials suggest caution in the use of RAS antagonists in combination, which is presumably not superior to maximum tolerated dose of the monotherapies.

Dosing and Adverse Effects Associated with ACE Inhibitors and ARBs

The antiproteinuric effect of ACE inhibitors and ARBs is at least in part independent of blood pressure reduction, and in individual patients, proteinuria may continue to respond to dose escalations beyond those recommended for BP control.[46] Unfortunately, maximal dosing of ACE inhibitors or ARBs may be limited by side effects, including hyperkalemia, hypotension, and reduced GFR. In women of reproductive age, counseling about pregnancy prevention and contraceptive use should begin before ACE inhibitor or ARB is started.

Serum creatinine concentration may increase up to 30% in proteinuric patients with renal impairment after an ACE inhibitor is started. This rise in creatinine is associated with long-term renoprotection, and therefore the ACE inhibitor should not necessarily be stopped in these patients.[47] Increases in serum creatinine concentration above 30% after initiation of an ACE inhibitor should raise the suspicion of renal artery stenosis. Aggressive dose increments of ACE inhibitors or ARBs, especially in conjunction with diuresis, can precipitate acute kidney injury (AKI). In advanced CKD and aggressive sodium restriction, although ACE inhibitors and ARBs are not contraindicated, the *de novo* introduction of these agents or injudicious dose increments may precipitate the need for dialysis prematurely, so some caution is appropriate.

Other Antihypertensive and Antiproteinuric Agents

Diuretics and Low Sodium Intake

The antiproteinuric effects of RAS blockade are enhanced by sodium restriction and diuretic use. Patients receiving ACE inhibitors or ARBs should be instructed to take a low-sodium diet (e.g., <2 g sodium/day). The combination of a loop diuretic or a thiazide diuretic with agents that block the RAS may be more effective than

either type of treatment alone for lowering blood pressure and proteinuria.

Selective aldosterone receptor antagonists (e.g., spironolactone, eplerenone) have been shown to reduce proteinuria when used alone and have an additive effect on proteinuria when used with ACE inhibitor or ARB.[48] As discussed earlier, aldosterone blockade may be especially beneficial in patients demonstrating aldosterone escape. The risk of hyperkalemia, however, frequently limits the use of combined aldosterone receptor antagonists with ACE inhibitors or ARBs, especially in patients with reduced GFR.

Calcium Channel Blockers

Dihydropyridine calcium channel blockers (dCCBs; e.g., nisoldipine, nifedipine, amlodipine) may be used as additional antihypertensive agents, but they have not been shown to reduce albuminuria or to slow the progression of renal disease.[49] In the Appropriate Blood Pressure Control in Diabetes (ABCD) trial, the long-acting calcium antagonist nisoldipine was compared with the ACE inhibitor enalapril as first-line antihypertensive therapy in 470 hypertensive type 2 diabetic patients. The incidence of fatal and nonfatal myocardial infarction was significantly higher among those receiving nisoldipine compared with those receiving enalapril during a 5-year study period.[50]

Nondihydropyridine calcium channel blockers (ndCCBs; e.g., diltiazem, verapamil) have been shown in some studies to have beneficial antiproteinuric effects. A meta-analysis of randomized trials of ndCCB and dCCB in hypertensive patients with proteinuric renal disease found that at comparable BP control, ndCCB reduced proteinuria by approximately 30% as compared with baseline, whereas dCCB had no appreciable effects on urinary proteins.[51] Taken together, these findings suggest ndCCBs are reasonable agents for BP control and can be used in combination with a RAS antagonist in patients with DN.

β-Blockers

Classic β-adrenergic blockers have adverse metabolic effects and are therefore undesirable in diabetic patients, but this is no longer true for the novel β-blockers (e.g., carvedilol, nebivolol). Despite insufficient controlled evidence, β-blockade appears to be useful because of the extremely high CV risk in diabetic patients with nephropathy and can be used in combination with ACE inhibitors or ARBs but not ndCCBs to achieve optimal BP control.

Glycemic Control

Most of the evidence favoring strict glycemic control comes from studies of patients with normoalbuminuria or early stages of DN. Fewer studies addressed intensive glycemic control in patients with advanced stages of DN, in whom it may be difficult to show a benefit because the results are confounded by the effects of concomitant hypertension and CVD. Even so, evidence supports glycemic control in reducing the risk of worsening albuminuria and renal functional decline.[52,53] Furthermore, in type 1 diabetic patients with DN, glycemic control may also improve renal histology. Renal biopsy specimens from pancreatic transplant recipients in whom true euglycemia is restored showed stabilized glomerular structure at 5 years' follow-up and improved glomerular and tubular structure at 10 years after transplantation.[54]

For type 2 diabetic patients with established DN, large trials (e.g., Kumamoto study, ADVANCE, ACCORD trial) suggest that strict glycemic control may provide some renoprotection but does not protect against macrovascular complications (see section under Prevention of Diabetic Nephropathy).[4,6,7] Thus, glucose-lowering treatment must be individualized in type 2 diabetes. It should be more aggressive in young patients with short duration of diabetes, high life expectancy, and low risk of hypoglycemia. A more cautious approach is sensible in the elderly patient who has longstanding diabetes, has preexisting CV problems, gains weight with insulin, and is susceptible to hypoglycemic episodes. Current guidelines recommend lifestyle intervention first and suggest the addition of basal insulin (most effective), sulfonylurea (least expensive), or thiazolidinediones (no hypoglycemia) if HbA_{1c} values still exceed 7%.

Treatment of Dyslipidemia

Most patients with DN have dyslipidemia, characterized by low levels of high-density lipoprotein (HDL) cholesterol, high triglyceride (TG) levels, and a shift from larger toward smaller LDL cholesterol.[55] Dyslipidemia in diabetic patients may contribute to the development of glomerulosclerosis and progressive renal disease.[56,57]

In type 2 diabetic patients with non–dialysis-dependent DN, treatment with statins provides substantial CV benefit.[58,59] The recently published KDIGO Clinical Practice Guideline for Lipid Management in CKD recommends treatment with statin in adult diabetic patients with CKD who are not treated with chronic dialysis. Furthermore, existing evidence does not support a specific on-treatment LDL cholesterol target. Once a patient is placed on a maximum tolerated dosage of statin, follow-up measurement of lipid levels is usually unnecessary except in instances in which the results would modify management. In contrast, statin therapy in ESRD may come too late to translate into improved CV outcomes (see Chapters 32 and 82).[59a]

In diabetic patients, LDL cholesterol is not the sole lipid that defines CV risk. As major statin trials have demonstrated, lowering of LDL cholesterol does not prevent the majority of adverse CV events and does not bring the CV risk in diabetics down to the level of nondiabetic patients. This has been referred to as residual CV risk. Atherogenic dyslipidemia, specifically elevated TG, low HDL cholesterol, elevated apolipoprotein B, and elevated apolipoprotein C-III, are thought to be key factors associated with residual CV risk in diabetic patients.[60] In the UKPDS, elevated TG was independently associated with albuminuria in type 2 diabetic patients. Thus, interventions aimed at improving all lipid targets are required. However, it is not clear whether this is best achieved by intensification of statin therapy or by supplementation of statin therapy with a fibrate, niacin, or omega-3 fatty acids. In the ACCORD Lipid trial, routine use of combination therapy with statin plus a fibrate did not reduce CV risk in patients with type 2 diabetes.

Nonpharmacologic Interventions

Dietary protein restriction may alleviate uremic symptoms in patients at or approaching ESRD. However, it is of uncertain benefit in the treatment of DN. Small trials have shown low-protein diet (0.8 g/kg/day) to reduce proteinuria significantly with increased plasma albumin in macroalbuminuric type 2 diabetic patients.[61] A recent meta-analysis, however, concluded that although low-protein diet improved proteinuria, it is also associated with lower serum albumin concentrations and was not associated with a significant improvement of renal function in patients with either type 1 or type 2 DN.[62] Nutritionist counseling is advised for all patients with advanced CKD to avoid protein-calorie malnutrition before renal replacement therapy, which has been shown to be a strong predictor for subsequent increased morbidity and mortality during maintenance dialysis. Furthermore, all patients with DN should be given counseling on salt, potassium, and phosphate restriction as well as choice of carbohydrates and fats.

Lifestyle modifications such as smoking cessation and weight reduction can provide additive renal benefits and lower the risk of CV events in patients with established DN. There is evidence that smoking cessation ameliorates progression of microalbuminuria to macroalbuminuria and improves renal prognosis.[63] Weight reduction may also improve renal outcome. In a small RCT of obese (BMI >27 kg/m^2) diabetic and nondiabetic patients with proteinuric renal disease, patients who lost weight through dieting had marked improvement in proteinuria compared with those who lost no weight.[64]

EMERGING TREATMENTS FOR DIABETIC NEPHROPATHY

The pathophysiology of diabetes and DN is complex (see Chapter 30). A number of therapeutic agents, some experimental and others in clinical use for other indications, have been tried with the goal of preventing or treating DN. Specific new targets for therapeutic intervention include drugs that interfere with the formation and action of advanced glycation end products (AGEs) or receptor for AGE (RAGE), drugs that inhibit inflammatory cytokines, and antifibrotic agents (Table 31-1). These heterogeneous compounds are increased in diabetic patients and are associated with diabetic complications. Preclinical trials evaluating the effects of the AGE inhibitor pimagedine on renal function in diabetic animals yielded promising results. Unfortunately, early clinical trials of pimagedine were suspended because of side effects.[65] Other AGE inhibitors (e.g., pyridoxamine)[66] and AGE cross-link breaker (e.g., alagebrium)[67] have been studied, but their efficacy in preventing or treating DN remains to be established.

Bardoxolone methyl is an inducer of the Nrf2 pathway, which can suppress oxidative stress and inflammation. In the Bardoxolone Methyl Treatment: Renal Function in CKD/Type 2 Diabetes (BEAM) trial, diabetic patients with stage 3 or 4 CKD given bardoxolone methyl had significantly increased eGFR (by 6 to 10 ml/min) at 52 weeks of follow-up compared to placebo. However, bardoxolone methyl therapy also resulted in significantly increased albuminuria, weight loss, and dose-dependent adverse events, including muscle spasms and nausea. There was also a trend toward increased systolic BP with bardoxolone therapy.[68] A Phase III trial of bardoxolone methyl in DN patients was recently halted because of excess serious adverse events in the treated group.[68a]

Peroxisome proliferator-activated receptor (PPAR) agonists, such as thiazolidinediones (e.g., pioglitazone, rosiglitazone) are glucose-lowering agents that appear to have beneficial effects in animal models of DN. Pioglitazone in combination with the ARB losartan seems to offer greater renoprotection than does losartan alone in short-term studies.[69] Unfortunately, thiazolidinedione use has decreased because of higher rates of CV complications in a recent

Selected Emerging Treatments of Diabetic Nephropathy

Drug	Proposed Mechanism of Action	Clinical Trials and Comments
Pyridoxamine	Vitamin B_6 derivative known to be effective scavenger of reactive oxygen species and potent inhibitor of AGE	Small RCT found that pyridoxamine may be of benefit in patients with type 2 diabetes who have minimal renal impairment.[66]
Alagebrium	AGE cross-link breaker with antioxidative properties	Preclinical evidence in DN models suggests treatment with alagebrium has favorable effects on biochemical, structural, pathologic, and functional hallmarks of DN.[67] Clinical trial data are lacking.
Bardoxolone methyl	Inducer of Nrf2 pathway that can suppress oxidative stress and inflammation	In type 2 diabetic patients with stage 3-4 CKD, bardoxolone methyl significantly increased eGFR (by 6-10 ml/min) at 52 weeks' follow-up compared to placebo. Dose-dependent adverse events include muscle spasms and nausea.[68] Phase III trial of bardoxolone methyl in DN was recently halted because of excess serious adverse events in the treated group.[68a]
Thiazolidinediones	Peroxisome proliferator-activated receptor (PPAR) agonist; may improve endothelial function and have anti-inflammatory properties	Pioglitazone in combination with ARB losartan seems to offer greater renoprotection than losartan alone in short-term studies.[69] Use of thiazolidinediones has declined due to higher rates of CV complications reported in a large observational trial.[70]
Avosentan	Endothelin A receptor blocker	Phase III clinical trial showed antiproteinuric effect of avosentan, but terminated early after median of 4 months due to drug-related adverse events including fluid retention.[71]
Atrasentan	Endothelin A receptor blocker	In short-term study, atrasentan reduced albuminuria when used with RAS inhibitor in patients with type 2 diabetes; significant risk of peripheral edema noted in subgroup of patients receiving higher dose of atrasentan (1.75 mg).[72]
Pirfenidone	Inhibitor of TGF-β production with antifibrotic and anti-inflammatory properties	In small RCT, pirfenidone 1200 mg/day significantly increased eGFR versus placebo after 1 year; at 2400 mg/day, dropout rate too high to detect a significant change; no difference in albuminuria.[73]
Doxycycline	Matrix metalloproteinase inhibitor with antifibrotic properties	Small studies in patients with DN have shown significant proteinuria reduction with no effect on serum creatinine.[74]
Allopurinol	Purine analogue and inhibitor of xanthine oxidase that decreases uric acid formation	Limited short-term studies have shown improved blood pressure control and slowing of CKD progression after serum uric acid lowering with allopurinol.[75]
Paricalcitol	Agonist for vitamin D receptor	RCT (n = 281) found that addition of paricalcitol to RAS inhibition lowered albuminuria in type 2 patients with DN.[76]

Table 31-1 Select emerging treatments of diabetic nephropathy (DN). *AGE,* Advanced glycation end product; *RCT,* randomized controlled trial; *CKD,* chronic kidney disease; *eGFR,* estimated glomerular filtration rate; *ARB,* angiotensin receptor blocker; *CV,* cardiovascular; *RAS,* renin-angiotensin system; *TGF,* transforming growth factor.

observational trial.[70] Currently, it is premature to suggest routine therapy with a thiazolidinedione in DN patients.

The renal endothelin system is activated in patients with DN as well as in rat models of diabetes-induced damage. The antiproteinuric effect of an endothelin A receptor blocker was shown in the Avosentan on Doubling of Serum Creatinine, End stage Renal Disease and Death (ASCEND) Phase III clinical trial. Drug-related adverse events such as fluid retention led to early termination of the ASCEND trial.[71] Another endothelin A receptor blocker, atrasentan, was shown to reduce albuminuria when used in conjunction with a RAS inhibitor in patients with type 2 diabetes. Unfortunately, significant risk of peripheral edema was noted in the subgroup of patients receiving higher dose of atrasentan (1.75 mg).[72] Thus, the cumulative evidence from trials using endothelin receptor blockers shows that these drugs may lower albuminuria, but the side effects of sodium retention and peripheral edema may ultimately limit their clinical use.

Pirfenidone is an antifibrotic agent that exerts its effect through inhibition of transforming growth factor β (TGF-β) in animal studies. In a small, double-blind RCT, pirfenidone at 1200 mg/day significantly increased estimated GFR (eGFR) compared with placebo after 1 year. At 2400 mg/day, the dropout rate was too high to detect a significant change.[73] Thus, pirfenidone may have dose limitations in the treatment of DN. Doxycycline is also proposed to have some antifibrotic properties and has been shown to significantly reduce proteinuria in patients with DN.[74]

Recent epidemiologic studies suggest an independent association between asymptomatic hyperuricemia and increased risk of arterial hypertension, CKD, CV events, and mortality.[75] A small number of short-term single-center clinical studies have shown improvements in BP control and slowing of CKD progression following serum uric acid lowering with allopurinol. A Phase IV pilot study to determine whether allopurinol can be used to prevent or delay the loss of kidney function in type 1 diabetes is currently under way.

The effect of vitamin D administration has also been investigated in patients with type 2 diabetes. In a placebo-controlled RCT (n = 281), the addition of paricalcitol 2 μg/day to RAS inhibition safely lowered albuminuria in type 2 DN.[76] Limitations of the study include the use of albuminuria reduction as the primary end point and its 24-week follow-up. Further investigation is required to evaluate the relationship between vitamin D and DN.

Several other agents, including sitagliptin (a dipeptyl-peptidase-4 inhibitor), ruboxistaurin (a protein kinase C inhibitor), FG-3019 (anti–connective tissue growth factor monoclonal antibody), AST-120 (an oral adsorbent with antifibrotic properties), and several drugs currently in clinical use for other indications (e.g., pentoxifylline, fenofibrate), have all been evaluated for treatment of proteinuric renal disease, including DN. The role of micro-RNAs in the pathogenesis of DN is an emerging field and may also provide additional novel treatment approaches. There are insufficient data on any of these agents at this time for their use to be advocated in the prevention or treatment of DN. New insights into the molecular mechanisms that underlie the origin and progression of DN are emerging from large-scale genetic and molecular studies in experimental models and humans. It is anticipated that strategies for the prevention and treatment of DN will continue to improve as newer agents become available.

CHAPTER 32

Management of the Diabetic Patient with Chronic Kidney Disease

Ahmad Abou-Saleh, Stephen C. Bain, and David J. A. Goldsmith

Diabetes mellitus is the leading cause of chronic kidney disease (CKD) and end-stage renal disease (ESRD) (Fig. 32-1). Diabetes is also the most common primary diagnosis in patients receiving renal replacement therapy (RRT).[1] After the diagnosis of diabetic nephropathy (DN) has been established, the focus of care must be as follows:

- Aggressive management of diabetes and other risk factors, which are essentially the same for both type 1 and type 2 diabetes mellitus, to prevent or delay the progression of DN (Table 32-1).
- Management of the complications arising from diabetes-induced CKD, with the recognition that their presentation and management may differ from nondiabetic CKD.
- The associated morbidity and mortality from the microvascular and macrovascular complications of diabetes mellitus, especially with these rates potentially even higher in patients with DN.
- Timely institution and correct choice of RRT, with recognition of how diabetes impacts the management of ESRD.

This diabetic CKD patient population will benefit from a multidisciplinary approach, first and foremost with the involvement of nephrologists and diabetologists, but also with input from other specialists, such as cardiologists, renal or diabetes nurse specialists, podiatrists, and dieticians. Early referral to nephrology is also important to rule out other causes of renal disease, especially in patients without evidence of microvascular disease elsewhere (e.g. diabetic retinopathy) or with rapid progression of disease despite well-controlled diabetes. The primary goal in these patients should be stabilization of underlying kidney disease and preventing further progression. Regular follow-up is recommended, from a minimum of yearly appointments, to quarterly appointments in those with progressive CKD. As diabetic CKD progresses through various stages, from normoalbuminuria to microalbuminuria, frank proteinuria, and eventual deterioration in plasma creatinine levels, the risk of cardiovascular death increases (Fig. 32-2).

HYPERGLYCEMIA

Assessment

The reliability of glycosylated hemoglobin (HbA_{1c}) as a marker of glycemic control diminishes as CKD progresses. Anemia, iron deficiency, hemolysis, and reduced red blood cell (RBC) life span cause reductions in the measured HbA_{1c} regardless of actual plasma glucose levels, thus underestimating the degree of hyperglycemia. The use of erythropoiesis-stimulating agents can also interfere, generating younger RBCs with reduced exposure to plasma glucose. Therefore, using the "usual" measures for glucose averages and variability is challenging. For example, analysis of data from the Diabetes Control and Complications Trial (DCCT) showed a correlation coefficient of 0.82 with mean plasma glucose in type 1 diabetic patients,[2] whereas the correlation coefficients from various studies assessing how closely HbA_{1c} levels relate to mean plasma glucose in patients with CKD have been found to be generally much lower than this (correlation coefficients ~0.5).

Despite these limitations, HbA_{1c} remains a marker of mortality in patients with diabetes-induced CKD, even up to ESRD. The recent Dialysis Outcomes and Practice Patterns Study (DOPPS) data, looking at more than 9000 dialyzed type 1 and type 2 diabetic patients in 12 countries, found that HbA_{1c} strongly predicted mortality as levels increased beyond the range of 7% to 7.9%, which was associated with the lowest mortality rates.[3] Lower HbA_{1c} levels were associated with increased mortality as well, particularly in patients with indicators of poor nutritional status.

Other markers of hyperglycemia include glycated albumin and fructosamine, although these are less readily available than HbA_{1c} and are affected by conditions that alter protein metabolism. Newer glycated albumin assays free from the interference of other glycated molecules suggest that it may correlate more accurately than HbA_{1c} with mean plasma glucose, especially in the patient with advanced CKD.[4]

Treatment

Progressive CKD leads to changes in insulin and carbohydrate metabolism. As glomerular filtration rate (GFR) continues to decline, especially below 60 ml/min/1.73 m^2, regular review of the patient's oral antidiabetic agents or insulin doses is essential because these may need to be reduced or even stopped altogether, a result of accumulation of the drugs and their metabolites, which can have various adverse effects.

Biguanides

The only drug in the biguanide class in contemporary use is metformin, which works as an insulin sensitizer. The American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD) state that the use of metformin is safe down to an estimated GFR (eGFR) of 30 ml/min/1.73 m^2, with dose reductions advised with eGFR less than 45 ml/min/1.73 m^2, based on the guidelines issued by the UK National Institute for Clinical Excellence (NICE).[5,6] These guidelines help to minimize the risk of lactic acidosis in a population with multiple comorbidities and an increased risk of cardiovascular disease (CVD) and hospitalization. Despite this, lactic acidosis remains extremely rare in clinical trials and cohort studies on metformin therapy, with a Cochrane meta-analysis showing only 4.3 cases per 100,000 patient-years (which was actually less than the nonmetformin group).[7]

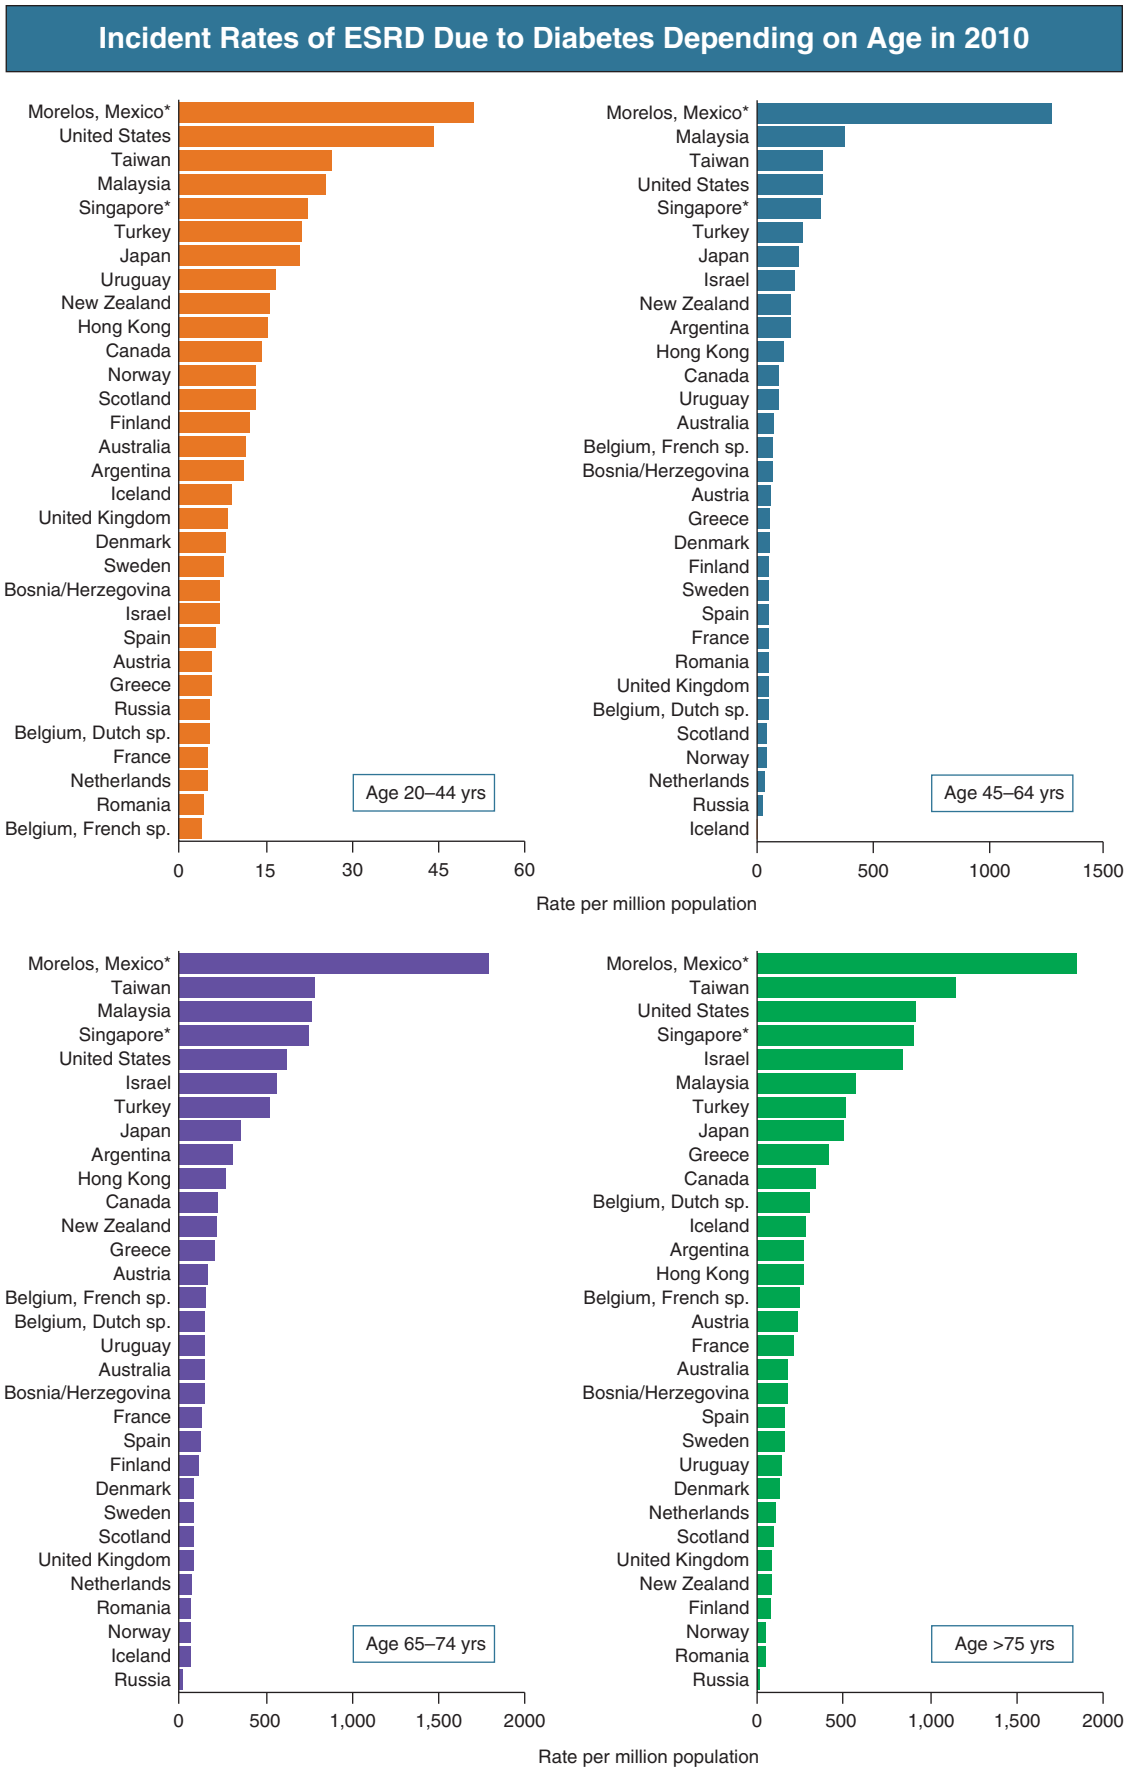

Figure 32-1 End-stage renal disease (ESRD) resulting from diabetes. Incident rates of ESRD caused by diabetes according to patient age (20-44, 45-64, 65-74, >75 years) throughout the world in 2010. Data for France include 23 regions in 2010.*Latest data for Singapore and for Morelos, Mexico are for 2009. *(Modified from reference 1.)*

Standard Care and Target Values Proposed for Diabetic CKD Patients

Parameter	CKD 3 and 4	CKD 5 and Dialysis
Metabolic Control		
Glycosylated hemoglobin	>6.5-7.5%	>7.0-8.0%
Preferred agents	Meglitinides, sulfonylureas, insulin	Insulin
Blood Pressure		
Systolic/diastolic BP	130/80 mm Hg	
Preferred agents	ACE/ARBs	?
Lipid Treatment		
LDL cholesterol	<100 mg/dl	?
Preferred agents	Statins	?
Anemia Treatment		
Hemoglobin level	11.0-12.0 g/dl	11.0-12.0 g/dl (avoid >13)
Preferred agents	Iron/ESA	Iron/ESA
Vitamin D Supplements*		
	Vitamin D_3/ 1,25-OH D_3	1,25-OH D_3/vitamin D_3
Supportive Treatment		
Smoking cessation	++	NP
Hypoglycemia awareness	++	+++
Low-dose aspirin	++	+
Exercise (daily/weekly)	+	+
Foot care	+++	+++
Prevention of falls	+	+++

Table 32-1 Standard care and target values proposed for patients with diabetes mellitus who have chronic kidney disease (CKD). *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *ESA,* erythropoiesis-stimulating agent; *LDL,* low-density lipoprotein; *?,* benefit unknown; +/++/+++, moderately/very/highly indicated. *In case of vitamin D supplements, the therapeutic approach should be reversed from native vitamin D first in CKD 3/4 to vitamin D analogues first in CKD5.

Annual Transition Rates Through the Stages of Nephropathy and to Death from Any Cause

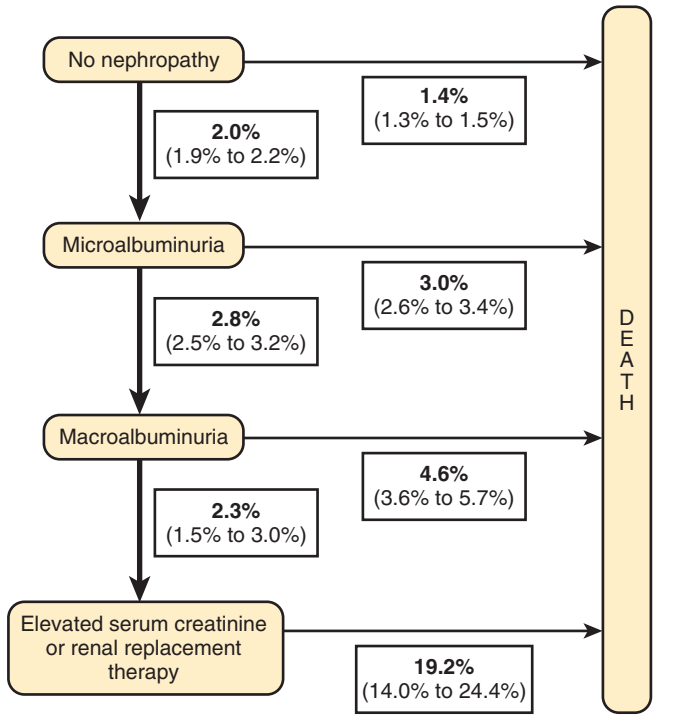

Figure 32-2 Stages of nephropathy and mortality. Annual transition rates with 95% confidence interval through the stages of nephropathy and to death from any cause in diabetic patients. *(Modified from reference 12.)*

Sulfonylureas

A class of insulin secretagogues, the older generation of sulfonylureas (tolbutamide, glibenclamide) are long acting and almost exclusively excreted by the kidneys and thus are best avoided in CKD patients. Newer agents are of shorter duration and primarily metabolized by the liver, although most metabolites are subject to renal clearance. The metabolites of gliclazide and glipizide are inert or only weakly active, so these particular sulfonylureas can be used even in patients with ESRD receiving dialysis. Their use does carry the risk of hypoglycemia, especially as GFR declines and insulin clearance decreases. Sulfonylureas are highly protein-bound but can be displaced into circulation by other drugs used in diabetic patients (e.g., salicylates, β-blockers, fibric acid derivatives), further contributing to hypoglycemia.

Thiazolidinediones

The thiazolidinediones are peroxisome proliferator-activated receptor (PPAR) modulators, which work to increase insulin sensitivity. Their use is limited by resultant weight gain and fluid retention through transcriptional upregulation of amiloride-sensitive sodium (Na^+) channels in renal tubules, which is problematic in a population already prone to CVD and heart failure. Rosiglitazone was withdrawn from the market because of the suggestion of an increased risk of myocardial infarction with its use, although pioglitazone remains in use.

Meglinitides

The main drugs in the meglinitide class, nateglinide and repaglinide, are primarily metabolized in the liver and act as insulin secretagogues. Repaglinide is safe to use in diabetic patients with advancing renal failure because it is converted to inactive metabolites and mainly excreted in bile, with less than 10% of the parent drug appearing in the urine, so no dose adjustments are deemed necessary. More than 80% of nateglinide is excreted in the urine, and thus it should only be used cautiously, if at all, in advanced CKD.

Glucagon-like Peptide-1 Analogues

Glucagon-like peptide-1 (GLP-1) analogues such as exenatide and liraglutide work by enhancing glucose-mediated insulin secretion in response to food entering the gut and maintaining the integrity of insulin-producing beta cells. The GLP-1 analogues help stimulate weight loss by appetite suppression, both centrally and by affecting gastric motility. Exenatide and liraglutide are not recommended if GFR falls below 30 and 60 ml/min/1.73 m^2, respectively.

Gliptins

The gliptin class inhibits the effect of dipeptidyl peptidase-4 (DPP4), a cellular membrane protein expressed in a variety of tissues whose function is to rapidly degrade incretin hormones such as GLP-1.

Sitagliptin is excreted mostly unchanged (70% to 80%) in the urine, requiring dose reductions as GFR drops below 50 ml/min/1.73 m^2 (50% reduction) and 30 ml/min/1.73 m^2 (75%). Newer agents such as linagliptin are primarily metabolized by the liver and excreted in the bile, not needing dose reduction in CKD. The gliptins have the advantage of being weight neutral, unlike insulin secretagogues.

Insulin

Exogenous insulin, unlike endogenously secreted insulin, which undergoes first-pass metabolism in the liver, is primarily eliminated by the kidneys through free filtration and secretion into the renal tubules, before reuptake and degradation by peritubular cells. In terms of endogenous insulin handling, the kidneys extract up to 40% of all plasma insulin down to GFR of 20 ml/min/1.73 m^2, with less than 10% extraction at ESRD.[8]

As GFR falls below 60 ml/min/1.73 m^2, insulin requirements in both type 1 and type 2 diabetic patients progressively fall, by up to 40% to 50%, regardless of residual insulin secretion in type 2 patients. This decline is especially marked as GFR falls below 20 ml/min/1.73 m^2 and approaches ESRD.[9] This helps to explain the phenomenon of hypoglycemia in nondiabetic patients with advanced CKD, although importantly, the kidney is an important site for gluconeogenesis, which can fail as CKD progresses.

Insulin resistance itself results from CKD. Uremia induces insulin resistance, thought to be caused by a defect in post–receptor signaling, with reduced glucose uptake and metabolism after insulin receptor activation peripherally. In skeletal muscle tissue, insulin-mediated glucose metabolism is mediated through phosphatidylinositol-3 kinase (PI3K-AKt) secondary messenger pathways, which are adversely affected by many factors associated with renal impairment, such as metabolic acidosis, uremia, anemia, elevated levels of proinflammatory cytokines, and low vitamin D levels.

In terms of the types of insulin used, available data favor the use of analogues, where the insulin molecule has been modified for both rapid-acting and long-acting forms so as to possess pharmacokinetics more in keeping with physiologic insulin secretion, in contrast to traditional human insulins. In a comparative study of insulin lispro versus human insulin in diabetic patients on hemodialysis, insulin was injected just after starting a 4-hour dialysis session. Insulin lispro was shown to have a faster rate of absorption with a shorter time to peak concentration (which was also of greater overall magnitude) and elimination.[10]

Another study on the pharmacodynamics and pharmacokinetics of insulin lispro versus human insulin in type 1 diabetic patients found that both attained a higher peak concentration and prolonged clearance in patients with overt DN, with an average reduction of insulin clearance by 30% to 40%.[11] However, despite higher circulating levels, human insulin was found to have a paradoxically lower peak effect with reduced overall metabolic activity in diabetic patients with DN than in those with normal GFR. Insulin lispro maintained a similar metabolic profile, regardless of whether DN was present. Insulin aspart, another rapid-acting analogue, has also been found to have a metabolic profile largely unaffected by various stages of CKD, along with long-acting analogues such as glargine and detemir.

Although there is no formal insulin regimen recommended in the setting of CKD, for type 1 diabetic patients, the basal bolus regimen of 3 daily injections of short-acting insulin with meals combined with 1 or 2 injections of long-acting insulin, as used in DCCT, is the standard treatment regimen, with the added benefit of greater flexibility over a regimen with fewer injections. Type 2 diabetic patients, when requiring insulin, usually start on once-daily or twice-daily, long-acting or intermediate-acting insulin, if necessary moving onto mixed formulations (fixed percentages of short-acting and longer-acting insulins) or the basal bolus regimen as in type 1 patients. Again, as CKD progresses, this may need regular adjustment.

HYPERTENSION

The most common blood pressure (BP) target, set by the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (KDOQI) and other major societies, was a BP below 130/80 mm Hg for patients with CKD caused by diabetes mellitus,[12] with the cutoff derived from observational studies such as the MRFIT study and the Okinawa Screening Programme, with risk of developing ESRD beginning to increase significantly beyond the 130/80 mm Hg target (see Chapter 80).

Despite this, there is a lack of strong evidence from randomized controlled trials (RCTs) to support this target in secondary prevention of renal disease, with systemic review of relevant trials showing no benefit for tight BP control on renal outcomes such as the rate of decline of GFR and progression to ESRD.[13] Some benefit was found in patients with frank proteinuria, but this required more antihypertensive agents, with a slightly increased risk of adverse events. This must be taken with the caveat that the numbers of patients involved were quite small and the trials short in duration, possibly limiting their ability to detect differences.

The recent Kidney Disease: Improving Global Outcomes (KDIGO) guidelines on managing hypertension in CKD patients with diabetes reflects this information, with a more conservative target of 140/90 mm Hg or less in patients with GFR below 60 ml/min/1.73 m^2, but with normal urinary albumin excretion rates, based on the conclusion that insufficient high-quality evidence from RCTs is available to recommend a lower target based on observational studies.[14] However, KDIGO also recommends a lower target of 130/80 mm Hg or less in patients with CKD and microalbuminuria or macroalbuminuria, because of the enhanced risk of CVD. Lower BP targets than this (e.g., systolic BP <120 mm Hg in ACCORD trial) are of uncertain benefit, possibly with increased risk of adverse events, and are not recommended.

The recommended first agents of choice in the DN population are either angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), with evidence of significant reductions in both cardiovascular (CV) and all-cause mortality, especially if albuminuria is present. They have also been shown to have protective effects on renal outcomes in preexisting DN (progression to ESRD and doubling of serum creatinine), with a possible effect independent of BP lowering.

Long-term use of ACE inhibitors and ARBs is associated with lower hemoglobin (Hb) levels, with losartan doses of 50 to 100 mg shown to reversibly lower Hb by about 1 g/dl, thought mainly to result from lower levels of angiotensin II, known to have a proerythropoetic effect on RBC precursors.[15] Anemia as a result of renin-angiotensin-aldosterone system (RAAS) inhibition does not mitigate their renoprotective effects.

Patients with diabetic CKD will usually require more than one antihypertensive agent to achieve BP targets.[16] Aldosterone antagonists can reduce target organ damage as well as surrogate end points such as proteinuria and left ventricular hypertrophy (LVH). The addition of spironolactone to an ACE inhibitor exerts a greater renoprotective effect on DN than dual ACE inhibitor/ARB therapy. Given the risk of hyperkalemia, spironolactone must be used cautiously. Aliskiren improves albuminuria in short-term studies, although the ALTITUDE study showed an increased rate of adverse events when aliskiren was combined with RAAS blockade. The use of other

antihypertensive agents, such as calcium channel antagonists and thiazide-like diuretics (e.g., indapamide), has also been shown to be beneficial in reducing the risk of CVD in diabetic patients, with some evidence of benefit in the diabetic CKD population. β-Blockers, although beneficial in the setting of CVD as add-on therapy, may mask hypoglycemia and are not usually used as first-line therapy.

There are no guidelines recommending specific drug classes after use of an ACE inhibitor or ARB. Medical management should thus be tailored to the patient's comorbidities.

HYPERLIPIDEMIA

Given the elevated risk of CVD in diabetic patients, it is generally recommended that hyperlipidemia be treated (see Chapter 82). KDOQI recommends that all patients with diabetes mellitus and CKD 1 to 4 should receive treatment if low-density lipoprotein cholesterol (LDL-C) is greater than 100 mg/dl, with a target of less than 70 mg/dl. NICE UK guidelines, however, stipulate a total cholesterol less than 4 mmol/l and LDL-C less than 2 mmol/l for optimal prevention of microvascular and macrovascular complications of diabetes.[6,12]

In nondialysis CKD patients, a beneficial effect on lowering cholesterol was finally confirmed by the SHARP RCT, which included more than 9000 patients with a wide range of CKD but no prior history of CVD. They were randomized to either a combination of simvastatin and ezetimibe or to placebo. A 17% reduction in CV outcomes was found for every 0.85 mmol/L reduction in LDL-C (in nonhemorrhagic strokes, coronary revascularization events), with similar results in all subgroups, regardless of whether diabetic or nondiabetic.[17]

In diabetic patients on dialysis, the evidence is less clear, with the AURORA and 4D trials not showing significant reductions in CV events or mortality despite LDL-C falling by up to 42%. Subgroup analysis of the SHARP trial also found a nonsignificant reduction in primary CV end points for the cohort of patients on dialysis.

In terms of lipid-lowering agents available, statins are first-line agents. If insufficient, other drugs can be added, depending on the nature of the hyperlipidemia, with ezetimibe added to treat LDL-C, or fibric acid derivatives for hypertriglyceridemia. Other types can be added if the previous treatment is insufficient or if the patient is intolerant of statins or other medications. For statins, as renal function declines into CKD 4, dose reductions may be necessary if rosuvastatin or simvastatin is used; this is not necessary for atorvastatin or pravastatin. Multiple trials of statins in hemodialysis patients have not reported significantly increased adverse events relating to liver function or muscle enzymes. Dose reductions in fibric acid derivatives may be required as well. There is no need for dose adjustment for bile acid sequestrants, niacin, or ezetimibe.

ANEMIA

Anemia is common in patients with DN and acts as a risk multiplier for all-cause mortality in patients with diabetes mellitus and CKD, and as an independent risk factor for LVH, CVD, and heart failure (see Chapter 83).

A prospective 5-year study of type 2 diabetic patients in Australia found that 13% were already anemic, with an additional 13% developing anemia at the end stage.[18] The best predictors of developing anemia were significant albuminuria, baseline renal function, and preexisting macrovascular disease. Diabetic patients have lower Hb levels at every stage of renal impairment than patients with CKD from other causes; one study found a prevalence of 41% in diabetic versus 17% in nondiabetic CKD patients, and this fall can be seen even before renal function begins to decline.[19] As a result, diabetic patients should be screened for anemia when GFR begins to decline below 60 ml/min/1.73 m^2. Patients with DN have increased levels of proinflammatory cytokines (from low-grade systemic inflammation), which causes resistance to the effects of erythropoietin (EPO) in various tissues of the body, as well as impairing the efficient use of iron in the generation of new erythrocytes. Other contributing factors include autonomic neuropathy, use of ACE inhibitors or ARBs, and possible microvascular damage in the bone marrow impairing responses to EPO as well.

Earlier studies on anemic patients with ESRD requiring RRT found that the use of erythropoiesis-stimulating agents (ESAs) to correct low hemoglobin led to increased quality-of-life scores and reduced frequency of blood transfusions, but current data do not suggest that this can be extrapolated to earlier stages of CKD. In the CHOIR and CREATE studies, non–dialysis-dependent CKD patients receiving ESAs were randomized to higher or lower Hb targets, with the higher target Hb greater than 13 g/dl. In these studies, use of larger doses of ESA in the higher-Hb target group was associated with increased quality-of-life scores, but led to an increased incidence of CV events. This would suggest ESA resistance itself is a marker for poorer outcomes. Progression to ESRD had a higher incidence in the high-Hb group in CREATE but not CHOIR.

The TREAT study was a landmark study in the use of ESAs for correcting anemia secondary to CKD in type 2 diabetic patients. Over a median follow-up of 29 months, type 2 patients with GFR or 20 to 60 ml/min/1.73 m^2 and Hb of 11.0 g/dl or lower were randomized either to treatment with darbepoetin alfa, to achieve a target Hb of 13 g/dl (mean achieved value 12.5 g/dl), or to a control group with rescue darbepoetin treatment only if Hb fell below 9.0 g/dl (mean value 10.6 g/dl). The treatment group had fewer CV revascularization procedures but had significantly increased risk of both fatal and nonfatal nonhemorrhagic strokes. Those treated also had an increased risk of arteriovenous thromboembolic events compared with the placebo group, and no effect on progression to ESRD was noted.[20] In fact, the TREAT cohort showed (despite BP/glycemic/lipid control measures), a 31% progression to dialysis and death.

The KDIGO guidelines recommend that for CKD patients not receiving RRT, ESAs should only be used if Hb levels drop below 10.0 g/dl, with other factors such as the rate of decrease and presence of symptoms to be considered before initiation (for adult hemodialysis patients, given the faster rate of fall of Hb, ESAs are recommended when Hb is 9.0 to 10.0 g/dl, to avoid the need for transfusions).[21] It is also recommended that Hb not be maintained above 11.5 g/dl. Other measures to correct anemia, such as intravenous iron and improved dialysis technique, should be considered especially if patients are asymptomatic, only moderately anemic, or have a history of previous stroke (see Chapter 83).

ANTIPLATELET AGENTS

It is well known that hyperglycemia has a procoagulant effect on platelet aggregation independent of insulin levels, and hyperinsulinemia itself carries an inhibitory effect on fibrinolysis, with these two phenomena in tandem significantly increasing the risk of thrombosis. Platelet reactivity is known to increase as CKD progresses into stage 3 and beyond. ADA guidelines recommend the use of antiplatelet therapy as primary prevention in diabetic patients at significant risk of CVD with risk factors such as albuminuria, hypertension, and hyperlipidemia (see Chapter 84). This stipulates that almost all patients with DN should receive antiplatelet therapy.

Although DN patients are at an increased risk of CVD compared to other patient groups, dual-antiplatelet therapy has not shown any benefit. *Post hoc* analyses of data from the CHARISMA and CREDO trials found that there was no benefit in adding clopidogrel to aspirin in patients with dual-antiplatelet therapy in patients with DN and may actually lead to worse outcomes independent of bleeding risk.

A recent Cochrane review on the use of antiplatelet agents in CKD patients found that although CVD was reduced, all-cause mortality was not, with an increased risk of both minor and major bleeding events, with the recommendation that antiplatelet therapy only be used in those at higher risk of CVD. This would surely include diabetic patients, even at earlier stages of CKD. There was also little evidence to suggest any preference for one agent over another.

BONE DISEASE

It has been suggested that disordered mineral metabolism and bone disease occur across the whole range of CKD, even in patients with normal renal function (see Chapter 85). Markers of altered bone metabolism, such as hyperphosphatemia, elevated fibroblast growth factor 23 (FGF-23) and reduced Klotho concentrations, have been linked to an increased risk of progression to ESRD, CVD, and mortality.[22] Observational follow-up studies on both type 1 and type 2 diabetic patients found that those with vitamin D levels below the 10th centile had a significantly increased risk of CV or all-cause mortality independent of other CV risk factors.[23]

Bone disease in diabetic patients with ESRD on dialysis is usually a low-turnover (adynamic) state, with lower overall levels of parathyroid hormone than in their nondiabetic counterparts. Adynamic bone disease in turn is a recognized risk factor for cardiovascular calcification (see Chapters 82 and 85), as is diabetes itself. In non–dialysis-dependent CKD, evidence suggests that secondary hyperparathyroidism occurs at an earlier stage in diabetic patients.

Preventive and therapeutic approaches to CKD-related bone and mineral disease do not differ substantially between diabetic and nondiabetic patients (see Chapter 85). However, given the increased prevalence of low-turnover bone disease in diabetic patients with CKD, care should be taken to avoid calcium loading. These patients also appear to accumulate aluminum more readily and are more susceptible to aluminum-induced bone disease. Aluminum-containing phosphate binders should always be avoided in the diabetic patient with advanced CKD.

EXTRARENAL COMPLICATIONS OF DIABETES MELLITUS

Even the asymptomatic diabetic patient with advanced CKD must be monitored at regular intervals for timely detection of microvascular and macrovascular complications, with at least yearly ophthalmologic examination along with assessing the patient, both clinically and through the use of appropriate investigations if necessary, for CVD (see Chapter 82).

In particular, problems related to the diabetic foot are a major cause of hospital admission and nontraumatic amputation (Fig. 32-3). For this reason, at least yearly inspection of the feet and examination of peripheral pulses and sensation is an essential part of the diabetic patient's consultation, along with general foot care (Box 32-1). Diabetic microvascular disease of the foot is frequently complicated by diabetic and uremic polyneuropathy, both of which respond poorly to conventional treatment (see Chapter 86).

Figure 32-3 The diabetic foot. Gangrenous ulcers in a diabetic caused by a combination of large-vessel and small-vessel disease and neuropathy.

Prevention of Diabetic Foot Complications

- Identification of patients at risk
- Education about foot care
- Regular examination of the feet at clinic
- Provision of appropriate footwear
- Provision of podiatry services

Box 32-1 Therapeutic measures to prevent diabetic foot complications

In the diabetic patient, due to a combination of neuropathy and poor peripheral blood supply, foot ulcers can develop suddenly with a rapid rate of enlargement, with potential bone involvement. If osteomyelitis is present, ulcers can be intractable and difficult to treat medically, often requiring very long courses of antibiotics. Patients with ulcers may need vascular intervention in the form of angioplasty, stenting, or bypass surgery as part of their treatment. Amputation may also be necessary, however, especially for refractory infections from methicillin-resistant *Staphylococcus aureus* (MRSA) or other multiresistant organisms.

Diet and Malnutrition

Diabetic patients with CKD are often severely catabolic and tend to develop malnutrition (see Chapter 87). This risk is particularly high during periods of intercurrent illness and fasting but may also be the result of ill-advised recommendations to restrict protein intake. Anorectic obese patients with type 2 diabetes and advanced CKD often undergo massive weight loss, leading to normalization of fasting glucose concentration and even of hyperglycemia after a glucose load. Low muscle mass because of wasting is an important reason for misjudging the severity of renal failure, leading, for example, to delayed start of RRT. Therefore, creatinine clearance should be measured, or at least GFR should be estimated, rather than relying on serum creatinine.

Prevention and Treatment of Cardiac Disease

In diabetic patients, the likelihood of death from CVD greatly exceeds that of reaching ESRD, and thus the population of diabetic patients on dialysis represents a "positive selection." Similar observations have been made in the DCCT/Epidemiology of Diabetes Interventions and Complications (EDIC) trial in type 1 diabetic patients[23] and in particular in the Steno-2 population, in whom 27 deaths (14 from CVD) occurred during a mean follow-up of 7.8 years, whereas

mean GFR decreased by about 30 ml/min/1.73 m^2, and no patient reached ESRD.[24,25]

Once a diabetic patient has reached ESRD, CV mortality rate is still excessive. This may relate to the fact that in diabetics, coronary heart disease is often amplified by the coexistence of more severe LVH, congestive heart failure, disturbed sympathetic innervation, and microvascular disease. How and when best to intervene in the progressive course of CVD in diabetic patients with CKD has not been precisely defined. In the absence of data, recommendations for the formal workup of coronary heart disease in diabetic patients with CKD should be no different from those for nondiabetic CKD patients.

In nondialysis patients, both coronary intervention and bypass surgery can be associated with significant risk of acute renal deterioration, which must be weighed against the potential outcome benefits in the individual patient. In general, to preserve residual renal function, bypass grafting might be favored in nondialysis CKD stages, whereas interventional stenting procedures might be assumed to be more appropriate for dialysis patients with limited life span, if risks of cerebrovascular complications are assessed and treated adequately (see Chapter 82).

DIALYSIS AND TRANSPLANTATION

Diabetes mellitus is the most common cause of ESRD in developed countries. Diabetes is also an independent risk factor for developing ESRD from nondiabetic causes, possibly from accelerated atherosclerotic disease. The most recent data reports from the U.S. Renal Data System (USRDS) show that patients with ESRD either on dialysis or with renal transplant as a result of diabetes have the highest annual mortality compared with ESRD patients requiring RRT secondary to any other cause.[1] The main cause of death is again CVD. Infections are the other important contributor to increased mortality in diabetic patients. Other contributing factors are impaired immunity, malnutrition, lower limb ulceration, hospitalization, and long-term indwelling catheters.

Diabetic patients receiving dialysis are also at increased risk of foot complications, with higher amputation rates. Diabetic eye disease is also highly prevalent in this population.

The management of hyperglycemia in the patient receiving renal replacement therapy can present many challenges. Note that even in nondiabetic patients receiving RRT, plasma glucose concentrations can be abnormal and unpredictable, if glucose-free dialysates are used, with about 80% of all episodes of hypoglycemia and mean nadir glucose levels occurring within 24 hours of a session of hemodialysis.[26] The usual systemic symptoms that occur in response to hypoglycemia may well be attenuated by the prevalence of neuropathy. Thus it is recommended that glucose-containing dialysates be used.

The general metabolic milieu in ESRD patients, as previously outlined, predisposes to increased insulin resistance. During and after dialysis, this can be temporarily reversed through correction of uremia, acidosis, and phosphate handling, leading to greater efficacy of antidiabetic treatments. Importantly, the pharmacokinetics of the various treatments are altered during dialysis, coupled with impaired renal gluconeogenesis and insulin clearance.

Symptomatic uremia and fluid overload occur in diabetic patients at higher GFR than in ESRD from other causes. Earlier initiation of dialysis was thought to have survival benefit over later initiation, with the better control of volume-dependent hypertension especially relevant in the patient with ischemic heart disease, heart failure, and strokes. However, the IDEAL study comparing early to late initiation (with 34% of both groups having diabetes as the primary cause of ESRD) found no significant benefit with adverse events (e.g., CVD, sepsis) or for survival[27] (see Chapter 81).

The best modality of RRT for survival and rehabilitation of the patient with diabetes-induced ESRD is living-related renal transplantation, with better courses of neuropathy and retinopathy, although not for CVD and ischemic heart disease.[28] Prior USRDS data showed 5-year survival rates of 29% in diabetic patients starting dialysis versus 75% and 85% with cadaveric and living-donor renal transplants, respectively.[29] Ideally, the transplant should be timed to avoid an interim period of dialysis, preferably at a stage where uremic symptoms are minimal. For patients with type 1 diabetes, the ideal form of transplantation is simultaneous pancreas and kidney transplantation (SPKT); the additional restoration of normoglycemia carries a significant survival advantage over isolated kidney transplants, although with the caveat of higher rates of allograft rejection and hospitalization[30] (see Chapter 110). Another option is sequential living-donor kidney transplantation, followed by deceased-donor pancreas transplants, reducing the waiting time to transplantation. Although there were concerns with this approach due to possible worse outcomes in terms of survival and the pancreas graft itself, outcomes have improved in recent years.[31]

For diabetic patients, in whom there are advantages and disadvantages to either form of dialysis, outcomes in terms of survival and CV mortality/morbidity are similar in hemodialysis and peritoneal dialysis (PD).[32] Some evidence suggests that PD has an initial advantage in terms of survival, but this decreases over time. Younger diabetic patients have better survival with PD as well, with PD potentially serving as a staging interval while preparing for transplantation (Table 32-2).

Hemodialysis

Hemodialysis as RRT is associated with a general improvement in morbidity from retinopathy, neuropathy, and peripheral vascular disease (although to a lesser degree than patients with renal transplant or on CAPD). If hemodialysis is the chosen modality, vascular access should be prepared for 3 to 6 months, given that atherosclerotic disease in these patients poses a challenge to the vascular surgeon, with calcific atherosclerosis causing inadequate arterial inflows and problems with venous runoff. Early failure of fistulas resulting from impaired maturation is also more common in diabetic patients.

The process of hemodialysis is not without its risk, especially in a population with a preexisting burden of CVD. Regular hemodialysis, with its rapid removal of fluid and solutes in combination with exposure to an extracorporeal circuit, can precipitate hypotension, arrhythmias, and heart failure, with a general deterioration in CV status caused by the recurrent circulatory stress. This is compounded by the presence of diabetic autonomic neuropathy, with impaired compensatory reflexes such as increasing peripheral vascular resistance and reflex tachycardia. As a result, there is an increased frequency of intradialytic hypotension in diabetic patients in response to rapid fluid shifts across different compartments. Such hypotension can precipitate myocardial ischemia (although conversely, hypotension can result from silent infarction). Systolic dysfunction is common, but the diastolic dysfunction of diabetic cardiomyopathy associated with reduced left ventricular compliance and filling can also contribute to this phenomenon. With lower blood pressures, underdialysis can occur with reduced access blood flow.

Patients also have a higher incidence of hypertension requiring medical therapy despite amelioration of volume-dependent hypertension with dialysis. Paradoxical rises in BP during dialysis sessions

Comparison of Dialysis Options for the Diabetic Patient				
	Peritoneal Dialysis		Hemodialysis	
Parameters	*Advantages*	*Disadvantages*	*Advantages*	*Disadvantages*
Technique	No need for vascular access; better preservation of residual renal function	Low technique survival rate; high hospitalization rate; higher rate of infections	Better technique survival rate; lower hospitalization and infection rate	Frequent difficulty in obtaining good vascular access
Blood pressure	Good control, slow ultrafiltration, and fewer episodes of cardiovascular instability			Difficult control; more frequent hypotensive episodes (esp. in patients with autonomic neuropathy)
Nutritional factors	Fewer dietary restrictions	Excessive weight gain, poor nutrition		Difficulty with fluid and dietary restrictions
Biochemical and metabolic control	Steady-state biochemical parameters	Worsening of blood glucose control and hyperlipidemia; increased insulin requirements	Efficient solute and water extraction	
Social factors	Maintains independence		Better medical surveillance	In most diabetic patients, cannot be performed at home

Table 32-2 **Advantages and disadvantages of peritoneal dialysis versus hemodialysis options for the diabetic patient**

can occur, possibly from activation of RAAS and increased peripheral vascular resistance from reduced intravascular plasma volumes (clinically inapparent hypervolemia can also contribute); ACE inhibitors can attenuate this effect. Other agents, such as calcium channel antagonists and central vasodilators (e.g., clonidine), can be used in tandem. The tendency to high intradialytic weight gain is related to the degree of hyperglycemia with resultant thirst and excessive fluid intake.

Peritoneal Dialysis

Given the slower ultrafiltration rate in PD compared with hemodialysis (see Chapter 96), PD carries less hemodynamic instability and mitigates the risk of hypotension or precipitating CVD with large fluid shifts or BP changes, which is especially relevant in diabetic patients with preexisting CVD burden or autonomic neuropathy. Also, PD is associated with better preservation of residual renal function and urine output along with increased clearance of advanced glycation end products, one of the pathways by which diabetic complications occur. Issues with vascular access, such as thrombosis, local infection, and transfer of blood-borne diseases, are also avoided.

Another advantage of PD is better outcomes for retinopathy, with stabilization and reduced rates of progression, possibly from less heparin and CV instability. Various reports of improvement in peripheral neuropathy are thought to result from increased clearance of middle molecular proteins thought responsible for uremic neuropathy.

Intraperitoneal insulin (soluble human insulin) can be injected through the connecting tubing before starting dialysis or can be added to dialysate bags. Note that requirements are often higher than when subcutaneous injections of insulin are used, because intraperitoneal insulin is adsorbed onto plastic surfaces of the delivery systems, and bioavailability does depend on the solution used as well. This has the advantage of being more physiologic because intraperitoneal insulin is absorbed through portal circulation, with decreased amplitude of glucose excursions and improved mean plasma glucose, predominantly by inhibition of hepatic gluconeogenesis. However, soluble human insulin does carry a risk of subcapsular hepatic steatosis, linked to the dosage of intraperitoneal insulin used.

Peritoneal dialysates contain supraphysiologic concentrations of glucose, which can diffuse down a concentration gradient into the bloodstream, with up to 80% of glucose from the dialysate potentially absorbed. This can obviously worsen glycemic control, and hyperlipidemia, leading to weight gain or worsening of obesity. In some patients a vicious cycle can occur, in which patients with poor diabetic control and the resultant thirst and fluid consumption require dialysate solutions with higher glucose concentrations to off-load the volume excess. While glucose degradation products in PD solutions are known to cause leukocyte apoptosis, no difference in PD-related catheter infections seems to exist between diabetic and nondiabetic patients.

Non–glucose-containing solutions (e.g., icodextrin) avoid both the risk of hyperglycemia and the damaging effects of glucose degradation products, leading to better ultrafiltration volume, blood pressure control, and preservation of residual function (see Chapter 97). Note that some metabolites of icodextrin can act as substrate for the glucose dehydrogenase present in blood glucose meters, resulting in potential overestimation of blood glucose levels. Up to 15% of patients can experience skin reactions to icodextrin, which can be serious in up to one third of all cases.[33]

As peritoneal clearance declines over time as a result of progressive peritoneal membrane impermeability or fibrosis, longer dialysis sessions are needed. Malnutrition can result from large protein loss in the dialysate, as well as high glucose loads and increased intra-abdominal pressures, reducing appetite.

SECTION VI

Hypertension

CHAPTER 33

Normal Blood Pressure Control and the Evaluation of Hypertension

William J. Lawton, Gerald F. DiBona, Ulla C. Kopp, and Friedrich C. Luft

NORMAL BLOOD PRESSURE CONTROL

Systemic arterial blood pressure (BP), or the pressure of the blood within the arteries exerted against the arterial wall, is produced by the contraction of the left ventricle (producing blood flow) and the resistance of the arteries and arterioles. *Systolic* blood pressure (SBP), or *maximum* BP, occurs during left ventricular systole. *Diastolic* blood pressure (DBP), or *minimum* BP, occurs during ventricular diastole. The difference between SBP and DBP is the pulse pressure.[1] The mean arterial pressure (MAP) is clinically defined as the DBP plus one third of the pulse pressure.

Blood flow, *Q*, as defined by Ohm's law, varies directly with the change in pressure, *P*, across a blood vessel and varies inversely with the resistance, *R*, defined as $Q = P/R$. Rearrangement shows that pressure varies directly with blood flow and resistance, $P = QR$. Ohm's law suffices for an overall view of the circulation. However, for a more detailed picture of the resistance to flow in any given vessel, the relationship of Hagen-Poiseuille should be applied, as follows:

$$Q = \Delta P \times (\pi r^4/8L) \times (1/\eta)$$

Here, *r* is the radius of the pipe, *L* is its length, and η is the coefficient of viscosity. Thus, as the lumen of a vessel decreases, the pressure increases to the fourth power of the radius for the same blood flow. In other words, a 50% reduction in radius results in a 16-fold increase in pressure to maintain equivalent flow.

Normal BP is controlled by cardiac output and the total peripheral resistance and is dependent on the heart, the blood vessels, the extracellular volume, the kidneys, the nervous system, humoral factors, and cellular events at the membrane and within the cell (Fig. 33-1). Cardiac output is determined by the stroke volume in liters per minute (l/min) and the heart rate. In turn, stroke volume is dependent on intravascular volume regulated by the kidneys as well as on myocardial contractility. Myocardial contractility involves sympathetic and parasympathetic control of heart rate, intrinsic activity of the cardiac conduction system, complex membrane transport and cellular events requiring influx of calcium that lead to myocardial fiber shortening and relaxation, and effects of humoral substances (e.g., catecholamines) on stimulating heart rate and myocardial fiber tension.

Total peripheral resistance is regulated by baroreflexes and sympathetic nervous system (SNS) activity, response to neurohumoral substances and endothelial factors, myogenic responses, and intercellular events mediated by receptors and mechanisms for signal transduction.[2] Baroreflexes are derived from (1) high-pressure baroreceptors in the aortic arch and carotid sinus and (2) low-pressure cardiopulmonary baroreceptors in ventricles and atria. Aortic baroreceptor nerve fibers travel via the vagus nerve (cranial nerve X), and carotid sinus fibers travel via the glossopharyngeal nerve (cranial nerve IX). These receptors respond to stretch (high pressure) or filling pressures (low pressure) and send tonic inhibitory signals to the brainstem. If BP increases and tonic inhibition increases, inhibition of sympathetic efferent outflow occurs and decreases vascular resistance and heart rate. However, if BP decreases, less tonic inhibition occurs, and heart rate and peripheral vascular resistance (PVR) increase, thereby increasing BP.

The brainstem cardiovascular centers are localized in the dorsomedial medulla. Neural afferents from cranial nerves IX and X are integrated in the nucleus tractus solitarius (NTS). From here, vasoconstriction and increased heart rate are mediated through the caudal and rostral ventrolateral medulla by the SNS. NTS efferents communicate with the nucleus ambiguus (vagal nucleus) to decrease heart rate through the vagus nerve. Also, the central neural control of renal function modulates renal blood flow, glomerular filtration rate (GFR), excretion of sodium and water, and renin release. These factors in turn regulate intravascular volume, vascular resistance, and BP.[3]

Inhibitory reflexes also originate in the kidney. Increases in urine flow rate increase renal pelvic pressure, which stretches the renal pelvic wall, leading to activation of mechanosensory nerves in the renal pelvic wall. Activation of these sensory nerves decreases renal sympathetic nerve activity and induces diuresis and natriuresis, an inhibitory renorenal reflex response.[4] The responsiveness of the renal sensory nerves is modulated by dietary sodium. A high sodium intake enhances the responsiveness of the afferent renal mechanosensory nerves in rats, thereby achieving sodium balance during increased dietary sodium intake.[5] Rats lacking intact afferent renal innervation only achieve sodium balance at the cost of increased MAP. Afferent renal denervation leads to salt-sensitive hypertension.[6]

Numerous vasoactive substances have effects on blood vessels, the heart, the kidneys, and the central nervous system (CNS) to regulate BP (Table 33-1). The renin-angiotensin-aldosterone system (RAAS) regulates volume and PVR (Fig. 33-2). Angiotensin II (Ang II) constricts vascular smooth muscle; stimulates aldosterone secretion; potentiates SNS activity; stimulates salt and water reabsorption in the proximal tubule; stimulates prostaglandin, nitric oxide (NO), and endothelin release; increases thirst; and stimulates vascular remodeling and inflammation. Increased renal angiotensin activity has also recently been linked with salt-sensitive hypertension, even in the volume-expanded state, and may have a role in blocking pressure natriuresis, in part by increasing renal sympathetic nerve activity and local oxidative stress.[7] Aldosterone stimulates sodium channels in distal renal tubular epithelium, leading to sodium retention and potassium excretion. It also exerts inflammatory and fibrotic effects through the mineralocorticoid receptor in vascular cells and in the heart. Plasma concentrations of renin and aldosterone are both inversely related to salt intake and are influenced by various medications.

A second major effector system is the SNS. Sympathetic nerve endings release the vasoconstrictor (norepinephrine) that binds the

Vasoactive Substances that Modulate Blood Pressure		
Group	**Compound**	**Cellular Effects**
Catecholamines	Norepinephrine, epinephrine, dopamine	Adrenergic receptors (α_1, α_2, β_1, β_2) causing protein phosphorylation and increased intracellular calcium through G proteins linked to ion channels or second messengers (cyclic nucleotides, phosphoinositide hydrolysis)
Renin-angiotensin system (RAS)	Angiotensin II (Ang II)	Angiotensin receptors (AT_1, AT_2, AT_4) causing increased intracellular calcium and protein phosphorylation through second messenger, phosphoinositide hydrolysis, and activated protein kinases Aldosterone stimulation
Mineralocorticoids	Aldosterone	*Genomic:* Binds to cytoplasmic mineralocorticoid receptor (MR), translocates to nucleus, modulates gene expression, and signals transduction and effectors (S_gK, CHIF, K_i-Ras), which increases transport proteins (increasing ENaC number and open probability) *Nongenomic:* Effects through separate membrane or cytosolic proteins
Kallikrein-kinin system	Bradykinin	Bradykinin receptors (B_1, B_2), B_2-G protein coupling cause activation of phospholipase C, increased inositol phosphates, and intracellular calcium
Arachidonic acid products	Prostaglandins: prostaglandin E, prostacyclin, thromboxanes Lipoxygenase enzyme products: leukotrienes, hydroxyeicosatetraenoates	Nine prostaglandin receptors coupled to G proteins: (e.g., PGI_2 [Receptor IP], PGE_2 [Receptors EP_1, EP_2]); PGF_{2a} (Receptor FP)
Endothelium-derived factors	Endothelium-derived relaxing factor (nitric oxide) Endothelins (ET-1, ET-2, ET-3)	Increased levels of cyclic guanosine monophosphate cause activation of protein kinases G proteins activate phospholipase C and L-type calcium channels Class 2 G protein–coupled receptor
Natriuretic peptides	Atrial, brain, and C-type	Activation of three receptor types; further effects mediated by cGMP
Posterior pituitary hormones	Arginine vasopressin	Vasopressin receptors (AVPR 1A; AVPR 1B) mediated by second messenger system, phosphatidyl inositol/calcium; AVPR2 effects via adenylate cyclase (cAMP)
Cyclic vasoactive peptides	Urotensin II (UT II)	UT II binds to G protein receptor GPR 14
Other substances	Acetylcholine, adenosine, insulin, neuropeptide Y, serotonin, sex hormones (estrogens, progesterone, androgens), glucocorticoids, other mineralocorticoids, substance P, vasopressin, renalase, heme oxygenase 1	

Table 33-1 Vasoactive substances that modulate blood pressure.

α-adrenergic receptor (adrenoceptor) on vascular cells, renal cells, and other cells (e.g., adipocytes). Epinephrine increases heart rate, stroke volume, and SBP through α- and β-adrenoceptors. The hormone is released from the adrenal medulla. Increased sympathetic tone has long-term influences on cardiovascular regulation and may cause hypertension.[8] In the kidneys, sympathetic nerves mediate renin release. Furthermore, innervation of each individual nephron affects sodium reabsorption. Thus, the SNS regulates both effective circulating fluid volume and PVR.

The kallikrein-kinin system counters the RAAS and produces vasodilator kinins, which stimulate prostaglandins and NO (see Fig. 33-2). Prostaglandin E and prostacyclin block the vasoconstriction by Ang II and norepinephrine. Two endothelium-derived factors have opposite effects on the blood vessels: NO is a vasodilator, whereas the endothelins are vasoconstrictors. Natriuretic peptides that include atrial (ANP), brain (BNP), and C-type induce vasodilation and natriuresis and inhibit other vasoconstrictors (renin-angiotensin system [RAS], SNS, endothelin). Renalase is a flavin adenine dinucleotide–dependent amine oxidase that is secreted by the kidney, circulates in the blood, and modulates cardiac function and systemic BP by metabolizing catecholamines.[9] Heme oxygenase (HO) is another important intrarenal and systemic BP modulator and inhibits oxidants, resulting in decreased BP.[10] Endogenous digitalis-like factors, which inhibit cell surface Na,K-ATPase and include an ouabain-like factor and marinobufagenin, also appear to regulate BP, cardiovascular (CV), and renal function.[11] Urotensin II is a locally expressed vasoconstrictive cyclic vasoactive peptide that stimulates proliferation of vascular smooth muscle cells and fibroblasts, inhibits insulin release, and modulates GFR. Despite urotensin II having these actions, high plasma urotensin II levels predict reduced CV complications in patients with chronic kidney disease (CKD, stages 2 to 5).[12,13]

Other mediator systems recently discovered include leptin, which in obese persons may increase BP by activating the CNS through a melanocortin pathway.[14] Uric acid may also be important by activating the RAS, inducing intrarenal oxidative stress, blocking endothelial NO, and directly affecting the vasculature.[15] Recent studies suggest a role for T cells in primary hypertension, possibly in response to heat shock protein 70, which may cause intrarenal vasoconstriction through release of Ang II and oxidants.[16] Chemoreceptors in the brain medulla and in the carotid and aortic bodies respond to changes in carbon dioxide and oxygen tension, resulting in renal vasoconstriction and dilation of the CNS and coronary vasculature.[17] Pain can also activate the SNS, although deep pain from crush injuries, testicular trauma, joint disruption, or abdominal distention leads to decreased sympathetic and increased parasympathetic outflow and decreased BP.[17] Postreceptor signaling events also regulate PVR. For example, the small guanosine triphosphatase Rho and its effector, Rho-associated kinase (Rho-kinase), stimulate vascular constriction and may have a role in cerebral artery spasm.[18]

Guyton and Hall[1] provide a model of the BP regulation in which CNS mechanisms (e.g., baroreflexes) provide short-term regulation of the circulation (seconds to minutes), with the RAAS and fluid shifts altering BP over minutes to hours and the kidneys responsible for long-term adjustments in BP, predominantly by regulating extracellular fluid volume[1] (Fig. 33-3). Indeed, the critical role for the kidney in the long-term control of BP received strong support from kidney cross-transplantation experiments[19] and bilateral nephrectomy in patients with end-stage renal disease (ESRD) and severe hypertension. However, activation of CNS and renal SNS pathways are now recognized as important in long-term BP control, in part by the later effects on the kidneys.[20] Renal sympathetic denervation by radiofrequency ablation through the renal arteries leads to substantial reduction in blood pressure in patients with resistant hypertension (see Chapter 38).[21,22] Furthermore, both intrarenal and extrarenal mechanisms are involved in the long-term regulation of blood pressure.[23]

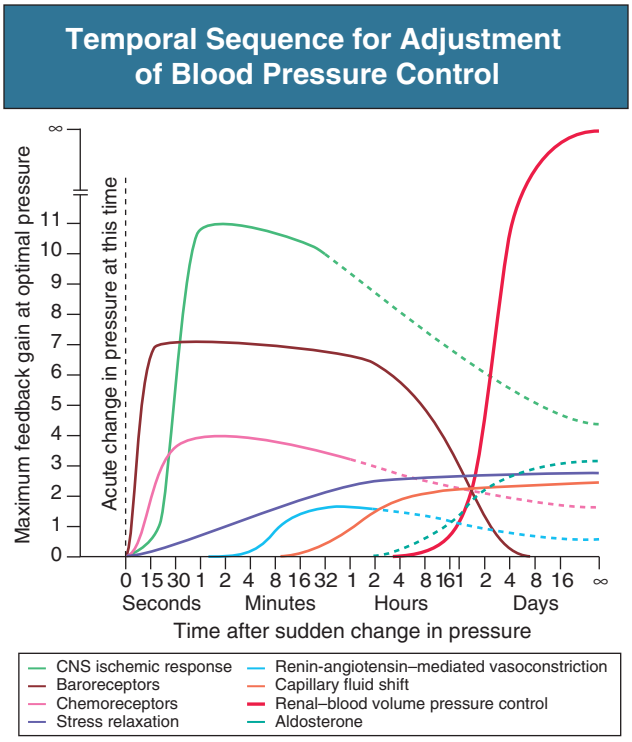

Figure 33-3 Temporal sequence for adjustment of blood pressure control. Degree of activity, expressed as feedback gain, of several arterial blood pressure control systems at various times after a sudden change in arterial BP. DEFINITION OF HYPERTENSION

Blood pressure is normally distributed in the general population. Thus any definition of hypertension is arbitrary. Hypertension is usually asymptomatic, and most symptoms, if present, are more from the sequelae of hypertension or its treatment. Hypertension may be defined by its associated morbidity and mortality, as increases over arbitrary cutoff points, or by thresholds defining therapeutic benefit.

Blood Pressure in Relation to Morbidity and Mortality

The first approach defines hypertension by relating BP levels to the risk of morbidity and mortality. The association of SBP and DBP with CV and renal complications is continuous over the entire BP range.[24] Death from both coronary heart disease and cerebrovascular accident (stroke) increases progressively and linearly from BP as low as 115 mm Hg SBP and 75 mm Hg DBP upward in all age groups ranging from 40 to 89 years (Figs. 33-4 and 33-5). For every increase of 20 mm Hg SBP or 10 mm Hg DBP, the mortality from both coronary heart disease and stroke doubles. On the basis of these data, the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7 Report) introduced the term *prehypertension* for those with BP ranging from 120 to 139 mm Hg SBP or 80 to 89 mm Hg DBP.[25] After the 2003 JNC 7, the Writing Group of the American Society of Hypertension (WG-ASH) proposed a new definition of hypertension not based on BP values alone but considering hypertension as a complex cardiovascular disorder that includes target organ damage, early disease markers, and CV risk factors[26] (Table 33-2). This risk-based approach seeks to identify individuals with an increased likelihood of future CV events at any BP level. The WG-ASH stage 1 includes the prehypertension category in JNC 7. It should be noted that JNC 8 has recently been published but focuses on BP management and not on classification.[26a]

Elevation of Blood Pressure by Arbitrary Cutoff Points

A second approach defines hypertension by the frequency distribution within a population. This statistical approach arbitrarily designates values above a certain percentile as "hypertensive" and is used in defining hypertension in children. The values defining hypertension vary according to age, gender, body size, and race.[27] This frequency distribution method is not helpful for determining a value for initiation of antihypertensive treatment but is useful in epidemiologic studies, for example, defining the prevalence of hypertension in various age groups or the changing prevalence

WG-ASH Definition and Classification of Hypertension

Class	BP Elevation		CV Disease*	CV Risk Factors	Early Disease Markers	Target Organ Disease
Normal	Normal or rare	or	None	None or few	None	None
Hypertension						
Stage 1	Occasional intermittent	or	Early	Several	Usually present	None
Stage 2	Sustained	or	Progressive	Many	Overtly present	Early signs present
Stage 3	Marked and sustained	or	Advanced	Many	Overtly present with progression	Overtly present with or without CV disease events

Table 33-2 Working Group–American Society of Hypertension (WG-ASH) definition and classification of hypertension. *Cardiovascular *(CV)* disease determined by constellation of risk factors, early disease markers, and target organ disease.

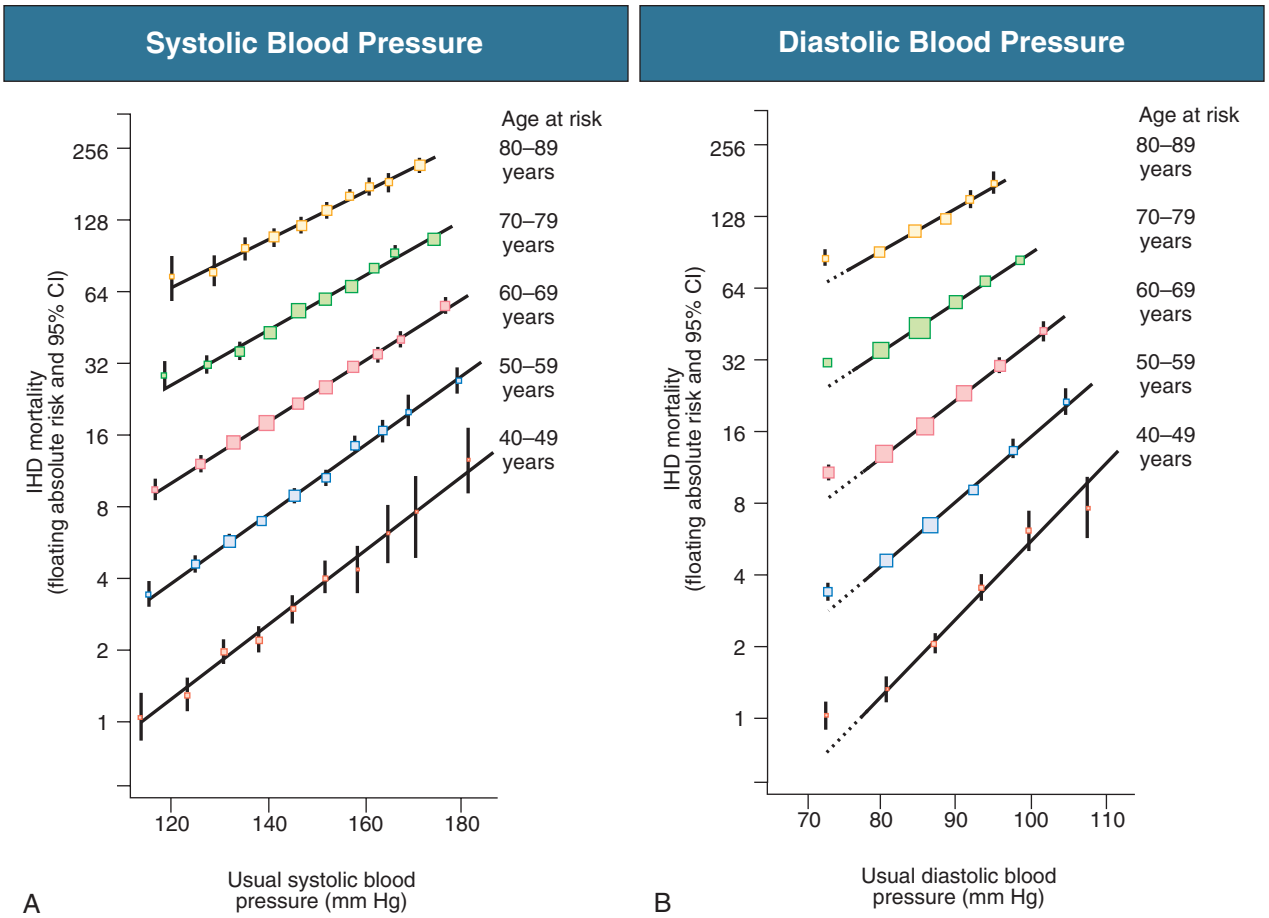

Figure 33-4 Ischemic heart disease (IHD) mortality rate in each decade of age versus usual blood pressure at start of that decade. A, Systolic blood pressure. **B,** Diastolic blood pressure. Floating absolute risk is a relative risk score that corrects for a baseline group, in this case the absolute death rate within a particular community. The size of the squares correlates inversely with the variance of the data collected for that data point. *CI,* Confidence interval. *(From reference 24.)*

of hypertension in a given population over time. The prevalence of hypertension in adults in the United States, defined as BP of 140/90 mm Hg or higher, has increased progressively from 11% of the population in 1939 to 29.3% in 2004.[28] The reported prevalence of hypertension in six European countries is 44%, and 66.3% in those older than 60.[29]

Threshold of Therapeutic Benefit

The third concept for defining hypertension is derived from randomized controlled trials (RCTs) that have demonstrated reductions in mortality and morbidity. As a result of clinical RCTs, consensus has been reached on intervention levels for moderate and severe hypertension but not for lower levels of hypertension. The Hypertension Optimal Treatment (HOT) study showed benefits of lowering BP to 138/83 mm Hg in hypertensive patients in the absence of diabetes mellitus, CKD, coronary heart disease risk, or target organ damage.[30] For patients with these complications, a treatment goal below 130/80 mm Hg is recommended (JNC 7).[25]

Operational Definitions

The European Society of Hypertension (ESH) divides "normotension" into three categories (optimum, normal, high-normal) and describes hypertension as mild, moderate, or severe[31] (Table 33-3). The ESH also provides values for automated 24-hour BP measurements, divided into daytime and nighttime.

In the United States, JNC 7 defined hypertension for individuals 18 years and older.[25] The committee settled on normal, prehypertension, and stage 1 and stage 2 hypertension (Table 33-4). For children, JNC 7 considers that BP at the 95th percentile or higher at each age is elevated.

Clinicians evaluate hypertensive patients and treatment goals on the basis of overall CV risk factors, not by BP alone. Age, gender, and ethnicity are important nonmodifiable risk factors, whereas cholesterol, high-density lipoprotein (HDL) cholesterol, smoking, control of diabetes, obesity, and left ventricular hypertrophy (LVH) are potentially modifiable[32] (Fig. 33-6). The cluster of risk factors that increase CV risk and are often associated with hypertension is termed the metabolic syndrome (Table 33-5). Decreased renal function and proteinuria are recognized as independent CV risk factors, including even microalbuminuria.[33] JNC 7 recommendations include follow-up of BP findings in a given individual (Table 33-6).

Special Definitions

Prehypertension (High-normal or Borderline Hypertension) Prehypertension is defined as SBP of 130 to 139 and DBP of 85 to 89 mm Hg. An earlier definition of "borderline hypertension" defined individuals whose BP was sometimes above 140/90 mm Hg but would decrease to levels below this with rest. Estimates of prehypertension or borderline hypertension have ranged between 12% and 30% of the adult population. Individuals with prehypertension have a threefold greater likelihood for development of sustained hypertension. Borderline hypertension may represent an

Blood pressure readings are in millimeters of mercury (mm Hg). *Consensus classification proposed by the European Society of Hypertension/European Society of Cardiology guidelines (see reference 32). †Classification proposed at the Eighth International Consensus Conference on Ambulatory Blood Pressure Measurement (Sendai, Japan, October 2001). ‡Mean of 95th percentiles in patients who on conventional BP measurement were normotensive in large-scale studies.

JNC 7 Classification of Blood Pressure for Adults

BP Classification	SBP (mm Hg)	DBP (mm Hg)
Normal	<120	and <80
Prehypertension	120-139	or 80-89
Stage 1 hypertension	140-159	or 90-99
Stage 2 hypertension	≥160	or ≥100

Table 33-4 JNC 7 classification of blood pressure for adults (2003). *SBP,* Systolic blood pressure; *DBP,* diastolic blood pressure.

Common Definitions for Metabolic Syndrome

Criterion	NCEP ATP III (≥3 criteria)
Abdominal obesity Men Women	Waist circumference >40 inches (>102 cm) >35 inches (>88 cm)
Hypertriglyceridemia	>150 mg/dl (≥1.7 mmol/l)
Low HDL Men Women	 <40 mg/dl (<1.03 mmol/l) <50 mg/dl (<1.30 mmol/l)
Hypertension	≥130/85 mm Hg or taking antihypertensive
Impaired fasting glucose or diabetes	100 mg/dl (5.6 mmol/l) or taking insulin or hypoglycemic medication

Table 33-5 Common definitions for the metabolic syndrome. *NCEP ATP III,* National Cholesterol Education Program–Adult Treatment Panel III. *(From reference 25.)*

Follow-up Based on Initial BP Measurement for Adults

Initial Blood Pressure (mm Hg)*		
Systolic	***Diastolic***	**Follow-up Recommendation**
<130	<85	Recheck in 1 year.
130-139	85-89	Recheck in 1 year; provide information about lifestyle modification.
140-159	90-99	Confirm within 2 months.
160-179	100-109	Evaluate or refer to source of care within 1 month.
≥180	≥110	Evaluate or refer to source of care immediately or within 1 week, depending on clinical situation.

Table 33-6 Recommendations for follow-up based on initial blood pressure (BP) measurements for adults. *If systolic and diastolic categories are different, follow recommendations for the shorter time for follow-up. The schedule for follow-up should be modified according to reliable information about past BP measurements, other cardiovascular risk factors, or target organ disease.

Absolute Risk of Cardiovascular Disease by Systolic Blood Pressure

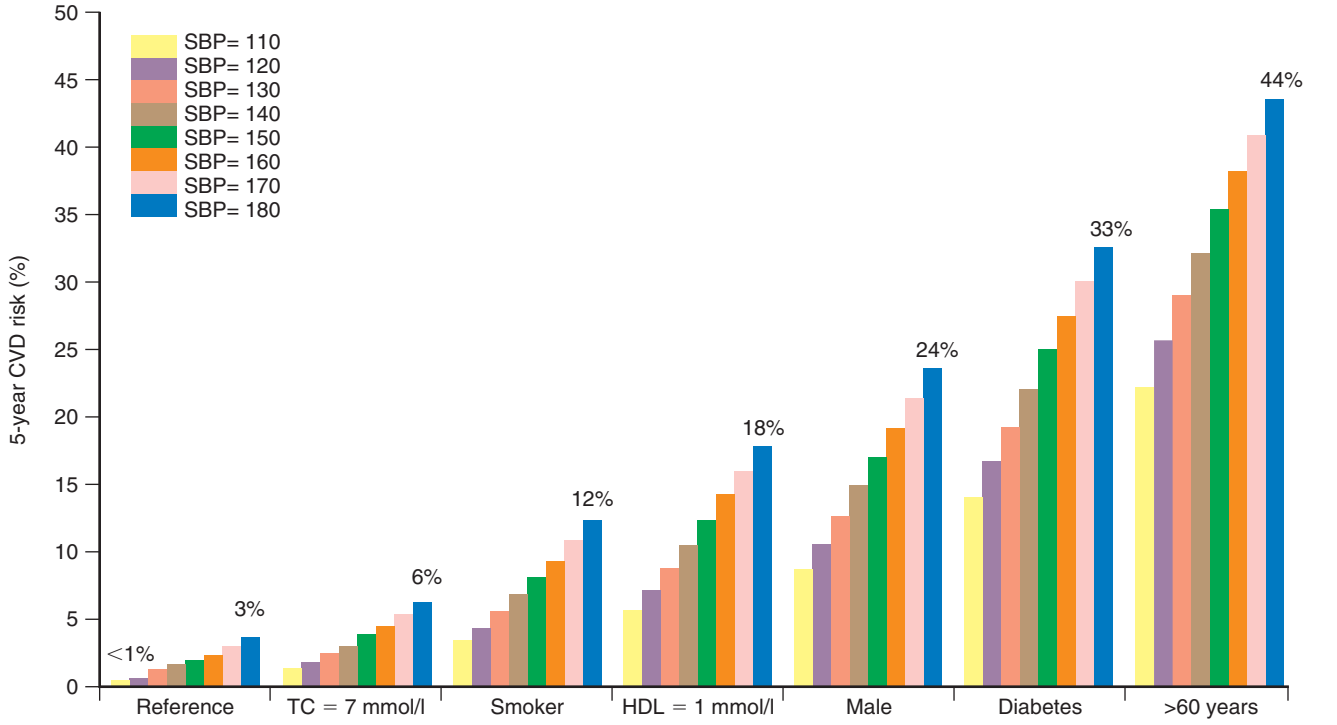

Figure 33-6 Absolute risk of cardiovascular disease during 5 years in patients by systolic blood pressure at specified levels of other risk factors. Reference category is a nondiabetic, nonsmoking woman age 50 with total cholesterol *(TC)* level of 4 mmol/l (155 mg/dl) and high-density lipoprotein *(HDL)* level of 1.6 mmol/l (62 mg/dl). Risks are given for systolic blood pressure *(SBP)* levels of 110, 120, 130, 140, 150, 160, 170, and 180 mm Hg. In the other categories, additional risk factors are added consecutively; for example, the diabetes category is a diabetic 50-year-old male cigarette smoker with TC level of 7 mmol/l (270 mg/dl) and HDL level of 1 mmol/l (39 mg/dl). *CVD,* Cardiovascular disease. *(From reference 32.)*

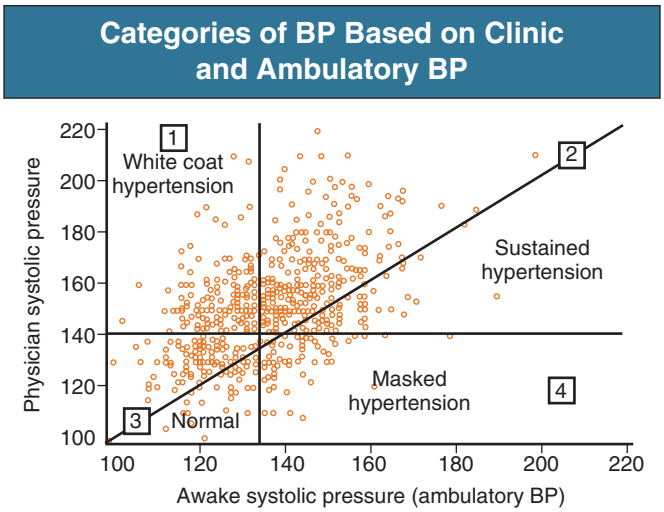

Figure 33-7 Plot of clinic systolic and daytime ambulatory blood pressure. BP plot defines four groups: normal, white coat hypertension, sustained hypertension, and masked hypertension. *(From reference 37.)*

exaggeration of normal physiologic responses to stress. Individuals with prehypertension may have a greater frequency of obesity, abnormal lipids, and other CV risk factors, with twice the CV events compared with those with BP below 120/80 mm Hg.[34] Because all BP is "labile" (variable) and generally varies on a diurnal cycle, the term "labile hypertension" is not helpful and should not be used.

White Coat Hypertension "White coat" hypertension is defined as BP that is normal during usual daily activities but is hypertensive in a clinical setting (Fig. 33-7). Normal pressures outside the physician's office are determined by measurement with standard techniques or by ambulatory BP recordings. White coat hypertension can be seen at all ages, including elderly persons. The white coat phenomenon is seen less frequently when a nurse or technician takes the BP rather than a physician. White coat hypertension is present in approximately 20% of hypertensive persons. Guidelines are available to assist in assessing patients with isolated clinic hypertension or isolated ambulatory hypertension.[35]

Although some studies suggest this hypertension is benign, in the long term, others suggest that white coat hypertension is characterized by increases in left ventricular mass index at levels intermediate between normotensive and persistently hypertensive persons.[36] White coat hypertensive patients have impaired diastolic function and higher levels of catecholamines, plasma renin activity, aldosterone, and low-density lipoprotein (LDL) cholesterol. Patients with white coat hypertension may also be at increased risk for development of persistent hypertension.[36] Thus each patient with white coat hypertension needs evaluation for CV risk factors and continued follow-up.

Masked Hypertension Masked hypertension is defined as BP that is lower in the office or clinic compared with ambulatory BP (see Fig. 33-7). In one study, the 10-year risk of stroke and CV mortality in patients with masked hypertension was similar to that of those with sustained hypertension.[36]

Sustained Hypertension Sustained hypertension, also called *persistent hypertension,* defines individuals whose BP level is elevated both inside and outside the clinic setting, including at home and during usual daily activities. Office BP readings are frequently higher in sustained hypertensive patients compared with their ambulatory BP.[37]

Pseudohypertension Pseudohypertension is defined as "a condition in which the cuff pressure is inappropriately higher when compared to the intra-arterial pressure because of excessive atheromatosis and/or medial hypertrophy in the arterial tree."[38] Pseudohypertension can be suspected by the "Osler maneuver," in which the BP cuff is inflated above the SBP (detected by auscultation). If either the brachial or the radial artery remains palpable, when pulseless, the patient is considered to be Osler maneuver positive. In general, patients with pseudohypertension have intra-arterial DBP measurements 10 to 15 mm Hg below indirect BP cuff diastolic measurements. None of the definitions specifically addresses the SBP. If a patient is suspected of having pseudohypertension, confirmation by intra-arterial pressure measurement may be considered, with therapeutic goals based on the intra-arterial findings.

Isolated Systolic Hypertension Arteriosclerosis, characterized by remodeling and stiffening of large elastic arteries, is the most significant manifestation of vascular aging.[39] The increased stiffening is believed to originate from a gradual mechanical senescence of the elastic network, alterations in cross-linking of extracellular matrix components, fibrosis, and calcification of elastic fibers. Stiffening of large arteries reduces their capacitance and accelerates pulse wave velocity, thus contributing to a widening of pulse pressure and increased prevalence of isolated systolic hypertension with age. Perhaps as a consequence, the increase in SBP continues throughout life, in contrast to DBP, which increases until age 50 and decreases later in life (Fig. 33-8). Diastolic hypertension is more common before 50 years, either alone or in combination with elevated SBP. After age 50, SBP is more important than DBP.

Isolated systolic hypertension (ISH) is defined as SBP of 140 mm Hg or higher and DBP of 90 mm Hg or lower. The prevalence of ISH increases with age and affects most individuals older than 60. In the Framingham study, elevations in SBP determined a greater risk of both "heart attacks" and strokes compared with elevations of DBP. Indeed, JNC 7 assigned SBP a higher level of importance than DBP.[25] Several clinical trials have clearly demonstrated that treatment of ISH reduces the CV event rate.[40] Nevertheless, controversy exists as to the choice of antihypertensive agent. Elderly hypertensive patients should be treated aggressively to the same target BP identified for younger patients. However, treatment should be initiated with lower antihypertensive doses to bring the pressure down more slowly in elderly patients, with monitoring for orthostatic hypotension, impaired cognition, and electrolyte abnormalities.

Resistant Hypertension Resistant hypertension is defined as BP that is not at treatment goal despite optimal doses of three antihypertensive drugs, including a diuretic. Some clinical trials suggest that resistant hypertension may occur in 30% of hypertensive patients. Older age and obesity are strong risk factors. Secondary hypertension is more common in resistant hypertension, with primary aldosteronism present in 18% to 23% of patients, and renal artery stenosis in 24%.[21,41]

Hypertensive Urgencies and Emergencies Accelerated hypertension is severe diastolic hypertension (usually >120 mm Hg) in the presence of grade III retinopathy (arteriolosclerotic changes of arteriolar narrowing and nicking plus hypertensive changes of flame-shaped hemorrhages and soft exudates).[42] In the past, "malignant" hypertension referred to severe diastolic hypertension and grade IV retinopathy (grade III plus papilledema). Because the prognosis for untreated severe hypertension in patients with grade III or IV retinopathy is so poor, there is little clinical rationale for using the two terms separately. More recently, accelerated hypertension with hypertensive retinopathy is defined as a *hypertensive urgency* if treatment is required to decrease BP within hours, whereas *hypertensive emergency* refers to clinical conditions in which severe hypertension must be lowered within minutes. Emergencies include acute

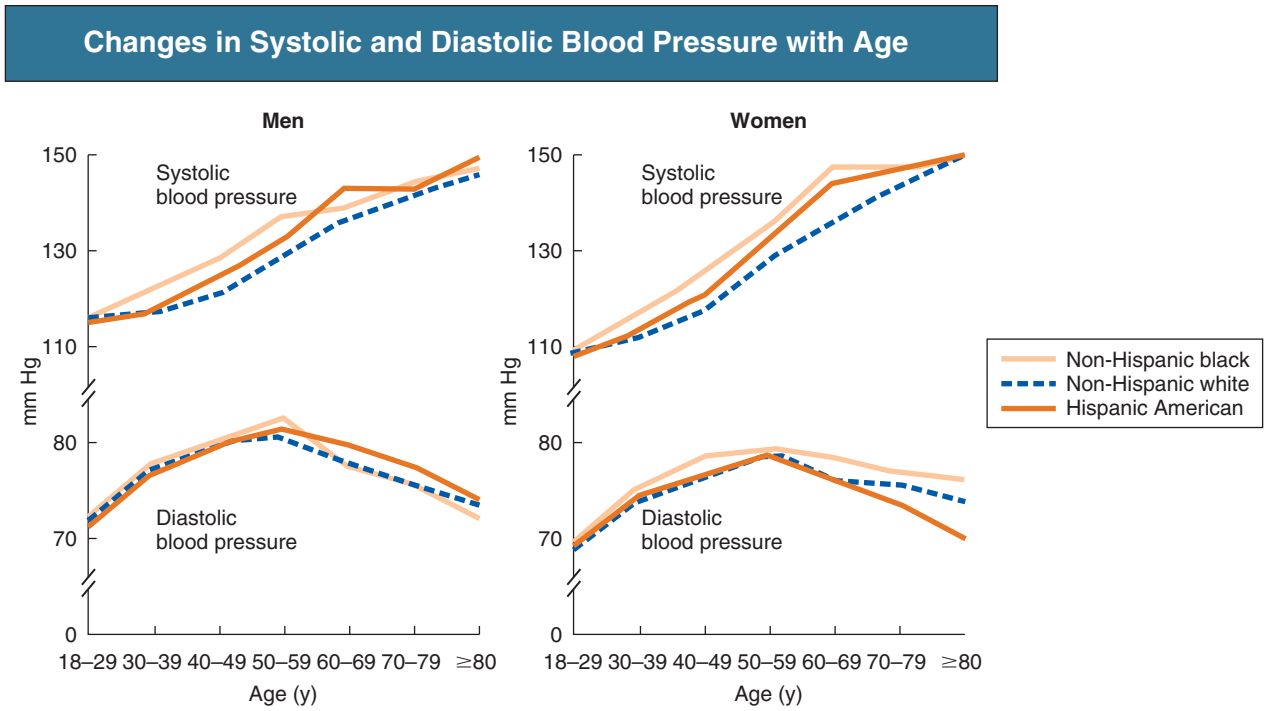

Figure 33-8 Changes in systolic and diastolic blood pressure with age. Systolic blood pressure and diastolic blood pressure by age and race or ethnicity for men and women older than 18 years in the U.S. population (NHANES III, 1988-1991). *(From reference 50.)*

dissection of the aorta, acute left ventricular failure, intracerebral hemorrhage, and crises caused by pheochromocytoma, drug abuse, and eclampsia (see Chapter 37).

Hypertension in Children and Adolescents Pediatric hypertension is defined by average SBP or DBP at or above the 95th percentile for gender and age, measured on at least three occasions. The reported causes of hypertension in children vary. Most preadolescent hypertension is thought to have renal causes, although some children may have BP levels above the 95th percentile because of an earlier growth spurt and large size. In adolescent children, mild hypertension is likely to be primary hypertension, with risk factors including a family history of hypertension and obesity, the latter now an evolving epidemic.[43] More severe hypertension in adolescents is usually of renal cause. Primary aldosteronism and thyroid disease seem to be rare.

Hypertension in Pregnancy Hypertension may occur in more than 5% of all pregnancies and in approximately 5% of women taking oral contraceptives. Definitions and implications of hypertension in pregnancy are discussed in Chapters 44 and 45.

Classification by Cause of Hypertension

In 90% to 95% of patients with hypertension, the etiology is unknown and labeled as "primary" (or essential) hypertension (see Chapter 34). Table 33-7 shows the more common causes of secondary hypertension. Acquired causes include renal parenchymal disease (2% to 6% of all hypertensive patients), renovascular hypertension (1% to 4%), and all endocrine hypertension (traditionally thought to be 1%, including primary aldosteronism, pheochromocytoma, and Cushing syndrome). More recent studies have shown an increasing prevalence of primary aldosteronism, ranging from 2% to 13% in stage 1 to stage 3 hypertension. Other causes include coarctation of the aorta (0.1% to 1.0%) and obstructive sleep apnea and obesity. An often overlooked cause of hypertension is drug induced (1%), including oral contraceptives, decongestants or sympathomimetic agents, nonsteroidal anti-inflammatory drugs (NSAIDs), and illicit drugs. There are also a number of rare monogenic causes of hypertension (see Chapter 49).

EVALUATION OF HYPERTENSION

Blood Pressure Measurement

Arterial BP is usually measured in the brachial artery by the cuff-based sphygmomanometer, in which the arterial pressure is recorded by detecting sounds that are generated (auscultatory method) or by recording vascular pulsations (oscillometric method) after decompression of a compressed artery. Box 33-1 lists guidelines for BP measurement. Unfortunately, if it is not properly used, the method can be inaccurate. The most common reason for inaccuracy is an inappropriate cuff size, because the accuracy of these measurements is influenced by the size of the inflatable bladder relative to the girth of the compressed limb. To provide uniform compression of the underlying artery, the length of the bladder should be at least 80% of the upper arm circumference, and the width of the bladder should be at least 40% of the upper arm circumference. A simple bedside maneuver to check the appropriateness of the cuff size consists of aligning the cuff so that its long axis is parallel to the long axis of the arm. The bladder width should then be sufficient to encircle half of the upper arm circumference. No change in cuff size is necessary if the cuff width encircles more than half the upper arm, because large cuffs on thin limbs do not produce considerable errors in the BP measurement. Table 33-8 provides accepted bladder dimensions for varying arm sizes.

Another potential error in BP measurement relates to the auscultatory method, which relies on the ability to hear the Korotkoff sounds. The human ear has a sound threshold of about 16 Hz. The Korotkoff sounds occur at slightly above this level (25 to 50 Hz). Thus the human ear is almost deaf to the sounds it must hear to

Acquired Causes of Secondary Hypertension	
Condition/Disorder	**Diseases: Comments**
Renal disorders	Renal parenchymal disease, including acute and chronic glomerular diseases, chronic tubulointerstitial disease, PKD, diabetic nephropathy, and obstructive uropathy Renovascular disease: renal artery stenosis caused by atherosclerosis or fibromuscular dysplasia; arteritis; extrinsic compression of renal artery Other renal causes: renin-producing tumors, renal sodium retention (Liddle syndrome)
Endocrine disorders	Adrenocortical disorders: primary aldosteronism, congenital adrenal hyperplasia, Cushing syndrome Adrenomedullary tumors: pheochromocytoma (also extra-adrenal chromaffin tumor) Thyroid disease: hyperthyroidism, hypothyroidism Hyperparathyroidism with hypercalcemia Acromegaly Carcinoid tumors
Exogenous medications and drugs	Oral contraceptives, sympathomimetics, glucocorticoids, mineralocorticoids, NSAIDs, calcineurin inhibitors, tyramine-containing foods and monoamine oxidase inhibitors, EPO, ergot alkaloids, amphetamines, herbal remedies, licorice (mimics primary aldosteronism), ethanol, cocaine and other illicit drugs, abrupt withdrawal of clonidine
Pregnancy	Preeclampsia and eclampsia
Coarctation of the aorta	
Neurologic disorders	Sleep apnea Increased intracranial pressure: brain tumors Affective disorders Spinal cord injury: quadriplegia, paraplegia, Guillain-Barré syndrome Baroreflex dysregulation
Psychosocial factors	Hostility, time-urgency/impatience, depression, anxiety, occupational stress
Intravascular volume overload	
Systolic hypertension	Loss of elasticity of aorta and great vessels Hyperdynamic cardiac output: hyperthyroidism, aortic insufficiency, anemia, arteriovenous fistula, beriberi, Paget disease of the bone
Obesity	White adipose tissue has endocrine function: leptins; adiponectin; cytokines; chemokines; Ang II; other adipokines

Table 33-7 Secondary hypertension: acquired causes. *Ang II,* Angiotensin II; *EPO,* erythropoietin; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *PKD,* polycystic kidney disease.

Accepted Bladder Dimensions for Varying Arm Sizes			
Patient	**Arm Circumference Range at Midpoint (cm)**	**Bladder Width (cm)**	**Bladder Length (cm)**
Newborn	6	3	6
Infant*	6-15	5	15
Child*	16-21	8	21
Small adult	22-26	10	24
Adult	27-34	13	30
Large adult	35-44	16	38
Adult thigh	45-52	20	42

Table 33-8 Accepted bladder dimensions for varying arm sizes. *To approximate a bladder width to arm circumference ratio of 0.4 more closely in children, additional cuffs are available. There is some overlap in the recommended ranges for arm circumference to limit the number of cuffs. It is suggested that the larger cuff be used if it is available. *(From reference 51.)*

measure BP. The bell-shaped stethoscope head should be used to measure BP.

The oscillometric method is based on the principle of plethysmography to detect pulsatile pressure changes in a nearby artery. When an arm cuff is inflated, pulsatile pressure changes in an underlying artery produce periodic pressure changes in the inflated cuff. The oscillometric method thus measures periodic pressure changes, oscillations, in an inflated cuff as an indirect measure of pulsatile pressure in an underlying artery.

There are three types of sphygmomanometers. Because of environmental concerns, the standard mercury manometer has been abandoned in many countries, with recent goals to have mercury-free health care throughout the world in 2020.[44] The second type is the aneroid manometer. There are also numerous semiautomatic oscillometric electronic recording manometers. The manufacturers must ensure accuracy, and in many countries, the local hypertension societies have arranged for certification of these devices. The technical capabilities of the devices have increased greatly. Physicians must be aware that many patients purchase devices and measure their own BP. These devices should be inspected and checked for accuracy by the physician.

Ambulatory BP monitoring uses a noninvasive system. The BP is determined by auscultation with use of either oscillometry, which measures variations in pressure within the cuff, or a microphone placed under the cuff and over the brachial artery. The ambulatory BP device can be programmed to record at frequent intervals during the daytime (e.g., every 10 minutes) and less frequently at night during sleep (e.g., every 30 minutes). The ambulatory BP equipment might not provide accurate readings in patients with large upper arms caused by obesity or increased musculature, and the equipment may be inaccurate during vigorous activity. The equipment generally records BP during a 24-hour period. Although most patients adjust to the repetitive measurements throughout the day, some patients may have a startle response with each BP recording. Most patients

Guidelines for Measurement of Blood Pressure

Patient Factors

Caffeine should not be taken for up to 1 hour before the BP measurement.

Cigarettes should not be smoked for at least 15 minutes before the BP reading.

The standard BP measurement should be made with the patient not talking and seated comfortably, back and arm supported, and legs uncrossed. The cuff must be at the level of the heart, and the arm should be bared.

The urinary bladder should be empty.

On an initial examination, BP should also be checked in the supine position after 5 minutes of rest, in the standing position after 2 minutes, and initially in both arms, especially in patients who are diabetic, older than 65 years, or receiving antihypertensive therapy. Use the higher value if the arms have differing BP readings.

If sequential BP readings are taken in the same position, at least 30 seconds must elapse between BP readings. In patients younger than 30 years, check BP in one leg.

To establish a diagnosis of hypertension, obtain BP readings on three different occasions, at least 1 week apart.

Equipment

The length of the bladder with the cuff should encircle at least 80% of the arm.

The width of the cuff should be equal to two thirds of the distance from the antecubital space to the axilla and should be 40% of the arm circumference. The best cuff for most adults is the 15-cm-wide cuff with a bladder of 33 to 35 cm in length. The distal edge of the cuff should be 2.5 cm (1 inch) above the antecubital fossa. For leg BP, thigh cuff length should encircle 80% of the thigh, and width should be 40% of the thigh circumference. For leg BP, the patient should be prone and popliteal artery sounds measured by auscultation. For automated equipment, the sensor should be over the brachial (or radial or popliteal) artery.

In extremely obese patients, BP may be more accurate when measured in the forearm, palpating and auscultating the radial artery.

For infants, ultrasound equipment may need to be used. The bell of the stethoscope is preferred.

Technique

The initial systolic BP should be checked by palpating the disappearance of the radial or brachial pulse before auscultation, and the cuff then deflated.

The second BP check requires cuff inflation 20 to 30 mm Hg above the palpable systolic level.

Deflate the cuff at a rate of 2 to 4 mm Hg per second.

Record the Korotkoff sound I (appearance of sound) as the systolic BP and record the Korotkoff sound V (silence, 2 mm Hg below the last sound) as the more reproducible diastolic BP. If the sounds do not disappear, record the muffled sound (phase IV) as the diastolic BP.

The sounds may be augmented by the patient raising the arm and opening and closing the hand 10 times before inflating the BP cuff.

Do not stop between systolic and diastolic BP readings; deflate the cuff, wait at least 30 seconds, and then reinflate. On each occasion, record at least two BP readings. If the BP readings vary by more than 5 mm Hg, take additional BP readings until two are within 5 mm Hg.

In children, the same standards apply for cuff size; Korotkoff sound V should be used. If the child is uncooperative, the systolic BP may be determined by palpation.

Box 33-1 Guidelines for measurement of blood pressure (BP): patient factors, equipment, and technique.

are able to sleep, although some have their sleep disturbed by the BP recording, and therefore determination of nocturnal fall in BP is inaccurate.

There are disadvantages to use of the ambulatory BP equipment. Trained personnel must place the monitoring equipment. Calibration of ambulatory BP equipment must be recorded at the beginning and end of the ambulatory BP session. For calibration, three to six readings must be taken at each time, and the SBP and DBP measurements must both agree within 5 mm Hg. The end calibration is critical to ensure proper functioning of the ambulatory BP monitor throughout the 24-hour period. The cuff inflation may interfere with activities, work, or sleep. The cuff may cause discomfort or skin irritation, or it may malfunction and fail to deflate, causing pain and interruption of recording. The data correlating ambulatory BP with target organ disease are limited. Standards for assessment of data and their use in therapeutic decision making are limited. In addition, equipment is expensive, and its use is limited by lack of, or unpredictable, reimbursement by health insurance systems in a number of countries.

Variability of Blood Pressure

Wake-Sleep Cycle and Office Versus Home Blood Pressure

Blood pressure varies considerably among individuals and may vary significantly throughout the day. This variation causes considerable difficulty in identifying individuals who are hypertensive, especially in terms of the preceding classification schemes. The differing BP values are caused by both biologic variation (variations of pressures within a given individual) and variation in the measurement itself. Errors in measurement can be minimized by attention to the proper technique for recording BP, as noted previously. Biologic variation is addressed by repeated BP measurement at a given visit (at least two pressures taken at least 30 seconds apart, or additional BP measurements if there is a difference of 5 mm Hg between repeated measures). In most patients with milder forms of hypertension, repeated measurements during different clinic visits over time are recommended to find the true BP.

Readings of BP at home, and outside the clinic or office setting, are recommended to assess the severity and frequency of hypertension and BP control during treatment. The instruments used at home must be checked against a standard on a regular basis, and the techniques for correct BP measurement must be taught to the patient. This includes having the brachial artery at the level of the heart when BP is measured. Levels measured at home are generally lower than those measured in the clinic or office. Patients should be discouraged from very frequent home BP measurement and from frequent adjustment of medications, which may result in unnecessary emergency department visits and hospital admissions for symptomatic hypotension or uncontrolled hypertension. It is worthwhile to ask the patient to keep a daily calendar and to measure BP under controlled conditions two or three times daily, such as while sitting

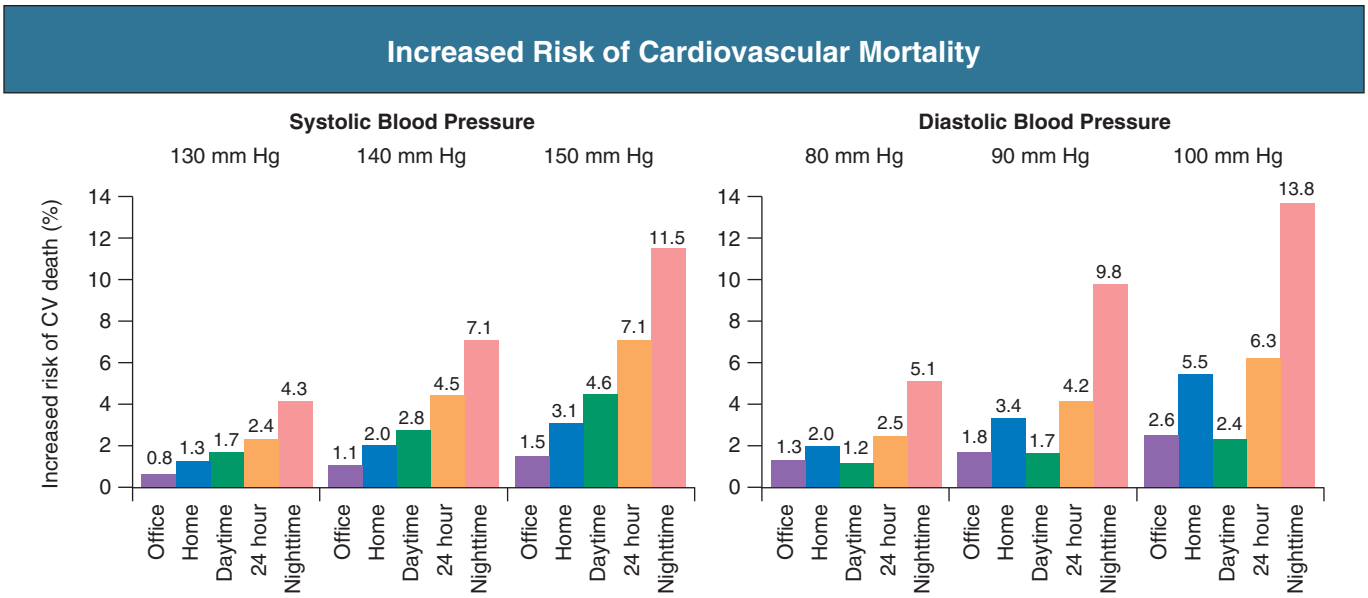

Figure 33-9 Increased risk of cardiovascular mortality. Risk of CV death (%) for 10 mm Hg increase in office, home, and ambulatory blood pressure readings at various initial BP values at 11 years. *(From reference 46.)*

quietly in the morning, afternoon, and evening. If three fourths of the measurements achieve goal value or better, office control is generally also achieved.

Biologic variation during the day is related to physical and mental activity and emotional factors. There is also diurnal variation, with a decrease in BP during sleep (averaging 20%) secondary to a decrease in sympathetic activity; similar reductions in BP occur after hospital admission and bed rest. The normal diurnal pattern includes an increase in BP before awakening that has been associated with increased incidence of myocardial infarction, stroke, and sudden death in the first few hours after awakening.[45] Those with the usual pattern of BP decrease during sleep are known as nocturnal "dippers." Individuals whose BP does not fall during sleep are called "nondippers." The failure to decrease BP during sleep has been associated with increased incidence of LVH and suggests secondary hypertension.

Home and Ambulatory Blood Pressure

Because of the variability in BP that occurs throughout the day, home BP and ambulatory BP monitoring are used to define BP more clearly. Home BP monitoring is advised for all patients to help identify white coat hypertension and borderline hypertension and help monitor response to therapy, including identification of hypotension as well as hypertension. This is particularly important in patients with CKD, who are more likely to have white coat hypertension and masked hypertension. The instructions to each patient must be individualized, but home BP monitoring may be advised two or three times daily while the patient is awake. These BP values must be self-recorded and reviewed. The prognostic value of ambulatory and home BP was compared with office BP in several population studies, and the risk of death increased more with a given increase in home or ambulatory BP than in office BP.[46] The overall ability to predict death, however, was not greater for home and ambulatory than for office BP, although it was somewhat increased by the combination of office and outside-of-office values. SBP was almost invariably superior to DBP, and night BP was superior to day BP in CV mortality risk (Fig. 33-9). Ambulatory BP monitoring is recommended over home BP recording in a few settings[47] (Fig. 33-10 and Box 33-2).

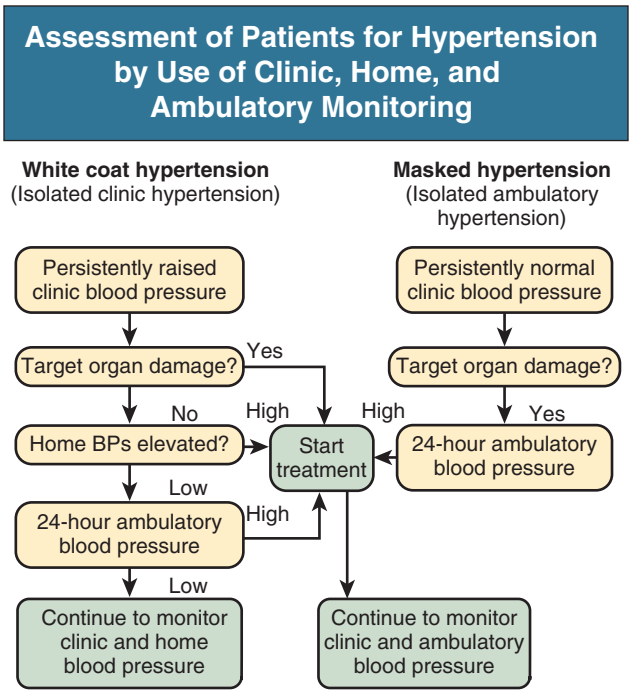

Figure 33-10 Guidelines for patient assessment: clinic, home, and ambulatory monitoring of blood pressure.

Risk Factors for Hypertension

A number of factors are known to be associated with an increased risk of primary hypertension.[48] These are discussed in detail in Chapter 34.

Evaluation for Primary Versus Secondary Hypertension

The medical history, the physical examination, and a limited number of laboratory tests provide critical information in deciding which individuals require further evaluation for secondary hypertension and target organ disease (Tables 33-9 and 33-10). All hypertensive

Indications for Ambulatory Blood Pressure Measurement
White coat hypertension
Evaluation of apparent drug resistance
Hypotensive symptoms
Autonomic dysfunction
Episodic hypertension
Evaluation of nocturnal decreases in BP as a prognostic factor for target organ disease (e.g., left ventricular hypertrophy, ischemic optic neuropathy)
Evaluation of BP changes in patients with paroxysmal nocturnal dyspnea and nocturnal angina
Carotid sinus syncope
Pacemaker syndromes
Safety of withdrawing antihypertensive medication
Assessment of 24-hour BP control in patient receiving once-daily medication
Borderline hypertension with target organ damage
Evaluation of antihypertensive drug therapy in clinical trials

Box 33-2 Indications for ambulatory blood pressure (BP) measurement.

persons should be assessed for CV risk factors, including total cholesterol, HDL and LDL cholesterol, fasting triglycerides, renal function, and proteinuria, and for the presence of diabetes mellitus or the metabolic syndrome.

If the history, physical examination, or screening laboratory studies suggest secondary hypertension, additional studies are warranted. If renal parenchymal disease is suspected, quantitative studies to assess GFR and urinary protein excretion should be performed. Renal ultrasound is useful to evaluate renal size and echogenicity (to help assess chronicity) and to evaluate for obstructive uropathy. Renal artery stenosis should be suspected in the patient with severe hypertension and abnormal renal function or with asymmetric renal size or a renal ultrasound with abnormal Doppler flow studies. If primary aldosteronism is suspected because of hypokalemia, the ratio of plasma aldosterone to plasma renin activity may be useful. If the ratio is above 25 to 30, and plasma aldosterone concentration is greater than 20 ng/dl, the diagnosis should be pursued further.

In the extended results of patients undergoing surgery,[49] resolution of hypertension after adrenalectomy for primary aldosteronism was independently associated with a lack of family history of hypertension and with preoperative use of two or fewer antihypertensive agents. Further evaluation for other forms of secondary hypertension is listed in Table 33-10.

Evaluation for Primary Versus Secondary Hypertension			
Classification	**Medical History**	**Physical Examination**	**Laboratory Studies**
General information and evaluation of target organs	Duration and course of hypertension Prior workup and treatment Diet/lifestyle: salt intake, tobacco, caffeine	Evaluation of volume status, optic fundi, heart, lungs, peripheral vessels, and nervous system	Complete blood count, fasting glucose, lipid profile (includes HDL, LDL, cholesterol, triglyceride), uric acid Consider echocardiogram
Primary (essential or idiopathic) or secondary?	Family history: hypertension, cardiovascular and renal diseases Symptoms of target organ disease (related to eyes, central nervous system, cardiorespiratory, and peripheral vascular)	See Table 33-10 for signs suggestive of secondary hypertension	See Table 33-10 for additional laboratory studies to rule out secondary hypertension

Table 33-9 Evaluation for primary versus secondary hypertension. *HDL,* High-density lipoprotein; *LDL,* low-density lipoprotein.

Evaluation for Secondary Hypertension			
Target Organ/System	**Medical History**	**Physical Examination**	**Laboratory Studies**
Kidney			
Renal parenchymal	History of renal disease (including glomerulonephritis, nephrotic syndrome, calculi, urinary tract infection) Symptoms include nocturia, frequency, dysuria, hesitancy, urgency, incomplete emptying, dribbling, hematuria, pyuria, flank pain	Tenderness in costovertebral angles; palpable kidneys, edema	BUN, serum creatinine; urinalysis, urine culture if indicated; 24-hr urine for protein and creatinine clearance if indicated; consider microalbuminuria measurement, or random urine protein-creatinine ratio
Renovascular hypertension		Epigastric bruit; other vascular bruits	Renal ultrasound with duplex Doppler flow study; consider angiography or magnetic resonance angiography
Endocrine			
Primary aldosteronism	Muscle weakness, cramps		Serum potassium: consider serum aldosterone/plasma renin activity ratio; 24-hr urine aldosterone, Na^+, K^+, creatinine

Table 33-10 History, physical examination, and initial laboratory evaluation for secondary hypertension. A more detailed discussion is provided in other relevant chapters. Pregnancy-associated hypertension is discussed in Chapters 44 and 45. *BUN,* Blood urea nitrogen; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *VMA,* vanillylmandelic acid. *Medical history, physical examination, and laboratory tests are either obvious or beyond the scope of the discussion.

Evaluation for Secondary Hypertension			
Target Organ/System	**Medical History**	**Physical Examination**	**Laboratory Studies**
Cushing syndrome	Weight gain, cosmetic changes	Body habitus: body fat, striae	Morning serum cortisol after dexamethasone suppression
Pheochromocytoma	Headaches; vasomotor symptoms, (inappropriate sweating, pallor); cardiac symptoms (awareness, tachycardia, palpitations)	Paroxysmal or intermittent hypertension (50% of patients)	Single-voided urine for metanephrine and creatinine; consider 24-hr urine for VMA, metanephrines, and catecholamines; if positive, proceed with magnetic resonance imaging or thin-section computed tomography of the adrenals
Carcinoid	Flushing		24-hr urine 5-hydroxyindoleacetic acid excretion
Hyperthyroidism	Weight loss, tachycardia, palpitations, sweating, heat intolerance	Palpable thyroid	Total and free thyroxine
Hypothyroidism	Weight gain, dry skin, cold intolerance, hair loss	Palpable thyroid	Total and free thyroxine
Hyperparathyroidism	Nausea, vomiting, bone pain, nephrolithiasis		Serum calcium, intact parathyroid hormone
Acromegaly	Change in size of head, hands, or feet (adult)	Appearance	Growth hormone (GH) level
Medication			
	Review of prescribed and over-the-counter medications (especially oral contraceptives, NSAIDs, sympathomimetic agents [cold and allergy drugs], illicit or recreational drugs, including alcohol, herbal remedies)		
Coarctation of the Aorta			
	Onset or detection of hypertension in childhood or adolescence	Simultaneous palpation of radial and femoral arteries to detect pulse lag in femorals; leg blood pressure	Chest radiograph for heart size, configuration of aorta, rib notching; consider aortography
Neurologic Disorders			
Sleep apnea	Obesity; weight gain; daytime somnolence; snoring, poor sleep habits (frequent awakening, not rested on arising); early-morning headache	Obesity; narrowed airway in hypopharynx; redundant pharyngeal tissue	Formal sleep study (polysomnography)
Increased intracranial pressure	Headache; neurologic symptoms	Papilledema	↑Cerebrospinal fluid pressure
Affective disorders*			
Spinal cord injury*			
Psychosocial Factors			
	Family and support structure, occupation, education, stressors		
Volume Overload			
	Excess salt and water intake (may be iatrogenic with excess parenteral fluid)	Increased jugular venous distention, pulmonary rales, presacral and peripheral edema, hepatomegaly	Chest radiograph
Isolated Systolic Hypertension			
		Pseudohypertension (positive Osler maneuver); cardiac and vascular examination (evaluate for aortic insufficiency, arteriovenous fistula)	

Table 33-10 History, physical examination, and initial laboratory evaluation for secondary hypertension—cont'd.

CHAPTER 34

Primary Hypertension

Richard J. Johnson, George L. Bakris, and Bernardo Rodriguez-Iturbe

DEFINITION

Primary (essential) hypertension is defined as blood pressure (BP) greater than 140/90 mm Hg without an identifiable cause. Several readings at different times, following the American Heart Association (AHA) and other guidelines, are necessary to document the diagnosis of primary hypertension. Variability in BP results from several factors, but under normal circumstances, a natural circadian rhythm generates the most significant increase in BP in the morning (6 to 10 AM). BP falls during sleep, secondary to a decrease in sympathetic nervous system (SNS) tone and reduced activity of other neuroendocrine systems. There are also minute-to-minute variations in BP (Fig. 34-1). Transient elevations in BP, reaching 150 mm Hg systolic, occur in the majority of normotensive individuals in any given day, especially during exercise.[1] However, BP that is 140/90 mm Hg or greater for more than 50% of the day is considered *hypertensive.* Chapter 33 describes the method and interpretation of BP measurements, including the use of ambulatory BP monitoring.

Primary hypertension is classified according to severity (Table 34-1). Stages in hypertension have been adapted by both the Joint National Committee (JNC 7)[2] and European Society of Hypertension and European Society of Cardiology (ESH/ESC) guidelines to allow a prognosis to be associated with different levels of BP elevation. The prognosis has been adapted from epidemiologic studies that demonstrate a linear relationship between the risk of cardiovascular events and sustained elevations of arterial pressure.

When only the systolic BP is elevated (systolic BP >140 and diastolic BP <90 mm Hg), the term used is *isolated systolic hypertension.* The former terms "borderline" or "high-normal" hypertension (defined as BP of 130 to 139/85 to 89 mm Hg) are now classified as *prehypertension* (defined as BP ≥120 to 139/80 to 89 mm Hg). *White coat hypertension* is an increase of more than 20 mm Hg in systolic BP noted only in the physician's office above that seen at home or another setting. In contrast, *masked hypertension* is BP that is normal in the office but elevated by more than 20 mm Hg when measured by ambulatory BP measurement.

Other terms used to describe specific clinical presentations include *hypertensive emergencies,* associated with acute end-organ damage requiring immediate treatment, usually in a critical care setting, and *hypertensive urgencies,* when BP needs correction in hours or a few days (see Chapter 37). In hypertensive emergencies, the reduction of BP will halt, prevent, or reverse decreasing glomerular filtration rate (GFR). These terms have replaced "malignant hypertension" and "accelerated hypertension." *Resistant hypertension* is defined as hypertension that remains above 140/90 mm Hg despite use of three maximally dosed antihypertensive medications of different classes, including a diuretic.

ETIOLOGY AND PATHOGENESIS

The kidney has a key role in the pathogenesis of hypertension. Guyton and colleagues[3] proposed that the kidney in patients with hypertension has a physiologic defect in sodium excretion. Whereas in most individuals an increase in sodium intake is related to an increase in pressure associated with prompt excretion of the salt load, this "pressure-natriuresis" relationship is abnormal in the hypertensive patient (Fig. 34-2). In some hypertensive patients, especially those under age 40, the response to a salt load is similar to that in normal individuals but is shifted rightward, such that higher pressures are required for a specific salt load, called *salt-resistant hypertension.* In contrast, most hypertensive patients, especially older and African American individuals, have both a rightward shift and a change in the slope, such that BP increases more for the same sodium load, called *salt-sensitive hypertension.* Additional evidence of a renal defect in sodium handling is the observation that kidney transplantation transfers the susceptibility for hypertension in response to salt in various rat strains. Dietary sodium content also correlates with the prevalence of hypertension in various populations, and intervention studies with salt restriction or loading have shown that the BP response in many hypertensive patients is salt sensitive. The basis for this renal defect in hypertension remains controversial, but three major hypotheses have been proposed.

Genetic (Polygene) Hypothesis

Pickering proposed that hypertension results from the expression of multiple genetic polymorphisms (polygene hypothesis), and Lifton later extended this hypothesis by stating that the cumulative effects of these polymorphisms act to favor sodium retention by the kidney, which would be accentuated in a Westernized society in which there is excessive salt intake (>10 g/day). The observation that numerous monogenic forms of both hypertension and hypotension are mediated by specific mutations involving renal sodium transport, especially involving the epithelial sodium channel (see Chapter 49), supports this hypothesis (Table 34-2). Currently, more than 20 genes have been identified in which mutations or polymorphisms influence blood pressure.[4] Many of these involve sodium transport in the distal tubule or the collecting duct. Some heterozygous mutations, such as the Na-K-2Cl cotransporter *SLC12A1,* the inward rectifier K^+ channel *KCNJ1* (carrier state for Bartter syndrome), and the heterozygous mutation of the Na-Cl cotransporter *SLC12A3* (carrier state for Gitelman syndrome), confer protection from hypertension.[5] Whereas genetic polymorphisms influence BP, most studies suggest that genetic mechanisms account for only 20% to 30% of primary hypertension, indicating that other mechanisms are more important in driving the hypertensive response.

Congenital (Low Nephron Number) Hypothesis

In 1989, Barker and associates[6] reported an increased risk for hypertension in individuals with low birth weight (LBW), and LBW was also found to increase the risk later for diabetes and obesity. Mothers of LBW infants frequently have hypertension, obesity, preeclampsia, or malnutrition, and these maternal factors also carry an increased risk for hypertension in the infant. This has led to interest in the role of "fetal programming" (e.g., from epigenetic changes) in the causation of hypertension. Brenner and colleagues[7] have postulated that LBW might lead to hypertension because of impaired renal development, leading to lower nephron number. Maternal malnutrition in laboratory rats predisposes to small babies, low nephron number, and the future predisposition for hypertension. A study of Caucasians with primary hypertension found almost 50% fewer nephrons than in age- and gender-matched controls.[8] Studies in African

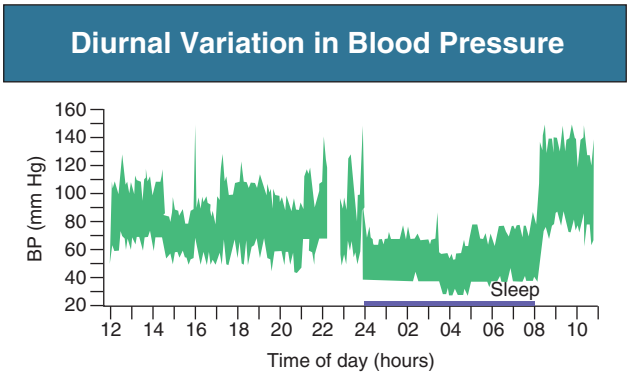

Figure 34-1 Blood pressure variability in normotensive individual. In most normal individuals, systolic blood pressure *(BP)* reaches 150 mm Hg at least once daily. *(From reference 1.)*

Classification of Blood Pressure

BP Classification	Systolic BP (mm Hg)		Diastolic BP (mm Hg)
Normal	<120	and	<80
Prehypertension	120-139	or	80-89
Stage 1 hypertension	140-159	or	90-99
Stage 2 hypertension	≥160	or	≥100

Table 34-1 Classification of blood pressure (JNC 7). *(From reference 2.)*

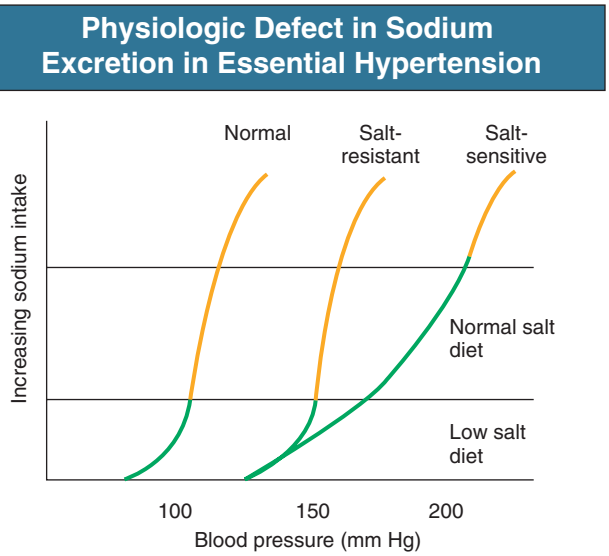

Figure 34-2 Physiologic defect in sodium excretion in primary hypertension. Evidence suggests that in patients with primary hypertension, a higher blood pressure is required to excrete an individual sodium load. In salt-resistant hypertension, the pressure-natriuresis curve has a rightward but parallel shift; with salt-sensitive hypertension, it is both a shift to the right and a change in slope. *(Modified from reference 4.)*

Monogenic Diseases Associated with Alterations in Blood Pressure

Condition	Gene	Inheritance	Site	Manifestations
Glucocorticoid-remediable aldosteronism (GRA)	Chimeric ACTH-responsive promoter with aldosterone synthase	AD	Collecting duct	Hypertension, metabolic alkalosis
Mendelian hypertension exacerbated by pregnancy	MR gain of function	AD	Collecting duct	Hypertension, worsened by pregnancy (progesterone)
Liddle syndrome	Gain-of-function of β or γ subunit of ENaC	AD	Collecting duct	Hypertension, metabolic alkalosis
Pseudohypoaldosteronism type 1 (PHA1)	ENaC loss of function MR loss of function	AR AD	Collecting duct	Neonatal hypotension, acidosis, salt wasting
Gitelman syndrome	Na-Cl cotransporter loss of function	AR	DCT	Low BP, salt wasting, metabolic alkalosis
Bartter syndrome	4 gene mutations: Na-K-2Cl, K channel, C1 channel, Barttin	AD or AR	Thick ascending limb	Low BP, salt wasting, metabolic alkalosis
Metabolic syndrome	Mitochondrial transfer RNA	Maternal	?	Hypertension, hypercholesterolemia, hypomagnesemia
Pseudohypoaldosteronism type 2 (PHA2) or Gordon syndrome	WNK1 and WNK4 serine-threonine kinases	AD	DCT and collecting duct	Hypertension, ↑K, metabolic acidosis

Table 34-2 Monogenic diseases associated with alterations in blood pressure. *ACTH,* Adrenocorticotropic hormone; *AD,* autosomal dominant; *AR,* autosomal recessive; *BP,* blood pressure; *DCT,* distal convoluted tubule; *ENaC,* epithelial sodium channel; *MR,* mineralocorticoid receptor; *WNK,* "with no lysine" kinase.

Americans, however, could not confirm the relationship between low nephron number and hypertension.

Individuals with LBW also have endothelial dysfunction early in life that likely predisposes to development of hypertension. Some studies suggest this may be caused by uric acid, which is also elevated in LBW infants and children before the development of hypertension. Regardless, LBW cannot be the primary risk factor. For example, one study found that although LBW infants have a 25% risk for developing hypertension as an adult, high-birth-weight infants have a 20% risk.[9] Thus, low birth weight and low nephron number likely reflect risk factors for development of hypertension rather than the underlying mechanism.

Acquired Renal Injury Hypothesis

Primary hypertension is frequently associated with renal arteriolosclerosis and hyalinosis with variable degrees of glomerulosclerosis and ischemic tubular injury. Renal function is usually normal or only slightly depressed, whereas renal vascular resistance is high and renal blood flow is low because of intense vasoconstriction of the afferent arteriole. Whereas the microvascular and inflammatory changes may reflect hypertension-associated injury, evidence suggests that these changes may also have a role in the development and maintenance of salt-sensitive hypertension.

Salt-sensitive hypertension can be induced by other means that usually involve renal vasoconstriction (Box 34-1). Ischemia stimulates the influx of macrophages and T cells, resulting in oxidative stress, activation of the intrarenal renin-angiotensin system (RAS), and a decrease in local nitric oxide (NO). It is highly likely that the inflammation also activates renal sympathetic nerves. A recent study suggests that rather than responding nonspecifically, the infiltrating T cells may be reacting with specific antigens induced by the local vasoconstriction, particularly heat shock protein 70 (HSP-70).[10] Blocking the intrarenal T cell infiltration or infusing T cells that have been tolerized to HSP-70 can block experimental salt-sensitive hypertension in different models.[11] Rats born with low nephron number also develop renal microvascular disease and intrarenal T cell accumulation, and administering mycophenolate mofetil (MMF) also reduces BP in these animals. MMF has also been reported to lower blood pressure in hypertensive patients with psoriasis.

Triggers of Salt-Sensitive Hypertension in Experimental Animals

- Angiotensin II infusion
- Inhibition of nitric oxide synthesis (treatment with L-NAME)
- Catecholamine infusion
- Diet-induced hypokalemia
- Hyperuricemia induced by uricase inhibition
- Reduced nephron number through maternal malnutrition
- Induction of nephrotic syndrome with use of bovine serum albumin
- Page kidney
- Lead-induced hypertension
- Cyclosporine nephropathy
- Genetic models of hypertension (Dahl salt-sensitive rat, spontaneously hypertensive rat)

Box 34-1 Mechanisms that can trigger salt-sensitive hypertension in experimental animals through the induction of microvascular injury and/or interstitial inflammation.

Role of Renal Injury in Sodium Retention

Renal T cell infiltration is associated with local oxidative stress and angiotensin II (Ang II) generation that results in renal vasoconstriction and an impaired pressure-natriuresis response. This may be augmented by afferent arteriolar remodeling and peritubular capillary loss, which also maintain renal ischemia. Activation of renal afferent sympathetic nerves, likely secondary to the local inflammation, also impairs sodium excretion. The consequence of this condition is a right shift of the pressure-natriuresis curve with a change of the slope, characteristic of salt-sensitive hypertension[12] (Fig. 34-3).

Although T cells in the kidney play a role in impairing pressure natriuresis, there are also countering mechanisms to reduce the hemodynamic impact of sodium excretion. In particular, the skin can act as a subcutaneous reservoir for sodium as a result of hypertonic accumulation of sodium proteoglycans that activates local macrophages to release vascular endothelial growth factor C (VEGF-C), which stimulates lymphangiogenesis.[13] The increase of lymph capillaries attenuates the hemodynamic effects of sodium retention. Depletion of the mononuclear phagocyte system blocks lymphangiogenesis and induces salt-sensitive hypertension.

How Does Salt Retention Lead to Hypertension?

An acute infusion of saline administered to animals with experimentally induced hypertension initially raises blood volume and cardiac output, but the increase in cardiac output is transient and is replaced by a rise in the systemic vascular resistance (SVR). Guyton and colleagues[3] called this process "autoregulation," postulating that the vasoconstriction was an adaptive response resulting from the need to reduce unnecessary increments in tissue perfusion.

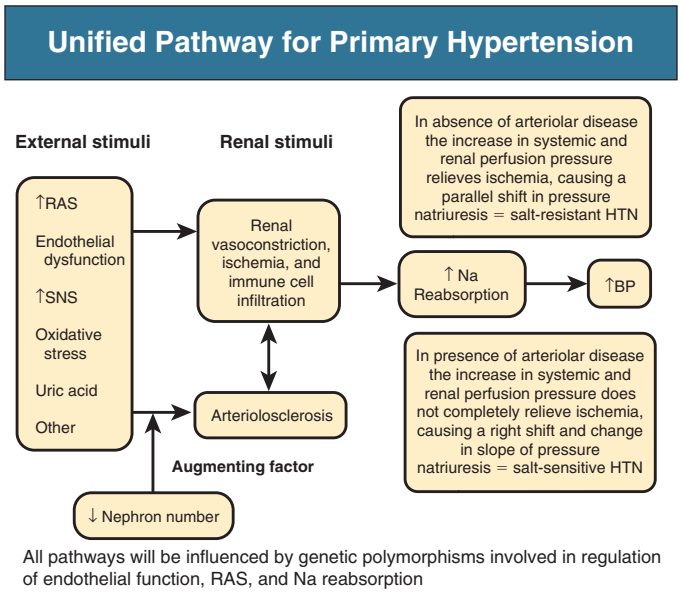

Figure 34-3 Unified pathway for primary hypertension. Hypertension *(HTN)* may be hypothesized as occurring in two phases. The first phase is mediated by renal vasoconstriction caused by stimuli such as a hyperactive sympathetic nervous system *(SNS),* hyperuricemia, endothelial dysfunction, or an activated renin-angiotensin system *(RAS).* This results in a salt-resistant form of hypertension. While hypertension may remain salt-resistant, we hypothesize that in many patients, progressive renal microvascular disease and tubulointerstitial inflammation will develop, with a switch to a salt-sensitive phenotype and an increased risk for microalbuminuria. *BP,* Blood pressure.

Several mechanisms may account for the rise in SVR. First, volume expansion increases circulating endogenous cardiotonic steroids, which function as Na^+,K^+-ATPase inhibitors. For example, ouabain is a digitalis-like factor that is released from the hypothalamus, hippocampus, and pituitary and stimulates the SNS, and marinobufagenin is a digitalis-like factor released from the adrenal cortex. These factors block Na^+,K^+-ATPase in the kidney, thereby facilitating the excretion of sodium, but at the expense of also blocking Na^+,K^+-ATPase in the vascular smooth muscle, resulting in increased intracellular calcium with vascular smooth muscle contraction and systemic vasoconstriction.[14] Circulating nitric oxide synthase (NOS) inhibitors are also present in some patients with primary hypertension. A small increase in serum sodium concentration from salt ingestion may also stimulate release of vasoconstrictive substances such as vasopressin, which may have a role particularly in African Americans.[15] Activation of the SNS also occurs in salt-sensitive hypertension in response to a salt load.[16] A possible explanation is that, in the setting of tubulointerstitial injury and intrarenal ischemia, the salt load triggers an intense renal afferent SNS activity that stimulates central nervous system (CNS) sympathetic output.[16] The importance of the renal sympathetic nerves in activating the CNS/SNS has become more evident after the introduction of renal artery denervation as a means for treating resistant hypertension (see Chapter 38).

Other mechanisms that could contribute to increased SVR are loss of vasodilatory substances from the kidney (e.g., kallikrein, medullipin) or simply the loss of systemic capillaries (microvascular rarefaction).

Pathogenic Mechanisms Driving the Current Epidemic of Hypertension

As discussed under Epidemiology, there has been a marked rise in the prevalence of hypertension in the last century. The rise in hypertension corresponds with the introduction of Western diet and lifestyle and with the dramatic increase in obesity. Obesity may cause hypertension through multiple mechanisms, including subtle renal injury, effects of hyperleptinemia or hyperinsulinemia, hyperuricemia, coexistence of endothelial dysfunction, and activation of the SNS.[17] Chronically elevated leptin levels, which are common in obese persons, can activate the SNS in the CNS through pro-opiomelanocortin neurons that activate melanocortin-4 receptors.[18]

Another proposed mechanism is an elevated uric acid level, possibly driven by intake of fructose-containing sugars. Experimental studies have reported that elevated uric acid can mediate hypertension in association with the development of subtle renal injury, and small clinical trials have reported a benefit on BP of reducing uric acid in adolescents with either prehypertension or primary hypertension.[19] Some studies also have implicated a hyperactive SNS in early hypertension, particularly in young or borderline hypertensive patients.[20] Postulated mechanisms include a defect in baroreceptor sensitivity and an increase in SNS response to emotional or work-related stress. Activation of either the systemic or the local RAS is also common in hypertension. Whereas plasma renin activity is elevated in 20% of patients, renin activity is either normal (50%) or low (30%) in the majority. However, normal renin activity may be inappropriately high in relation to the total body sodium.

In addition, some hypertensive patients have elevated plasma aldosterone, especially if the RAS is inhibited with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), known as *aldosterone breakthrough*.[21,22] Typically, such patients are obese and have hyperinsulinemia or some degree of endothelial dysfunction. Their aldosteronism is driven by a mechanism other than Ang II or hyperkalemia.

EPIDEMIOLOGY

Primary hypertension is epidemic. In the United States, the prevalence has increased from 5% to 11% of the population in the early 1900s to 31% (72 million people) in 2010[23] (Fig. 34-4). Although some of the increase in hypertension reflects an increasingly aging population, there is also an increase in primary hypertension in the pediatric population. By 2025, an estimated 1.56 billion people worldwide will have primary hypertension. The increase in hypertension correlates with increasing frequency of obesity, type 2 diabetes, and chronic kidney disease (CKD), suggesting a strong interrelationship.

Among the several major risk factors for hypertension, family history is the most important (Table 34-3). First, the risk for primary hypertension increases with age, and a normotensive person at age 55 has a 90% chance of being hypertensive at age 80.[2,24] This age-related increase in prevalence of hypertension has been observed in most Western countries but has not been uniformly observed in all populations. Second, hypertension is more common in men,

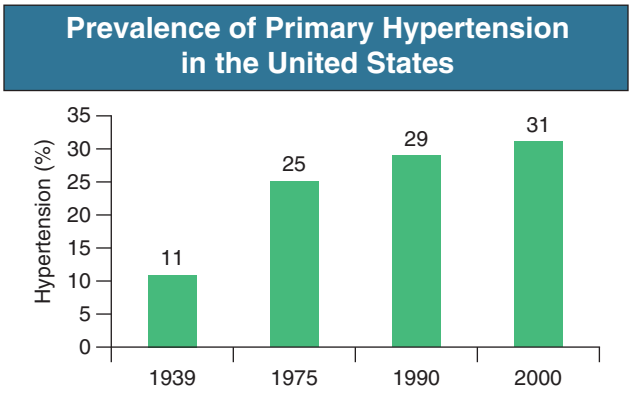

Figure 34-4 Epidemic of hypertension. The prevalence of primary hypertension (defined as BP >140/90 mm Hg) in the United States increased from 11% in 1939 to 31% of the population in 2000.

Risk Factors for Primary Hypertension

Genetic	Family history Polymorphisms (adducin, endothelial nitric oxide synthase, angiotensinogen, β2-adrenoceptor, human G protein β3 subunit)
Congenital	Low birth weight, low nephron number, maternal hypertension, maternal preeclampsia, maternal malnutrition
Physical	Obesity, older age, African American, African Caribbean, some Bantu-speaking peoples in Africa, increased heart rate (>83 beats/min), increased emotional stress
Diet/toxin	Increased sodium intake, low potassium intake, low dairy products intake, heavy alcohol intake, low level lead or cadmium intoxication
Metabolic*	Elevated uric acid, insulin resistance, elevated hematocrit
Other	Low socioeconomic status, urban versus rural

Table 34-3 Major risk factors for primary hypertension. *Laboratory-based parameters.

although the prevalence in women is similar to and slightly exceeds that of men after age 55. Certain racial groups are at increased risk of developing hypertension much earlier in life, particularly African Americans and Filipino Americans in the United States and various minority populations throughout the world (e.g., Pima Indians, Australian aborigines, Maoris). Risk factors for hypertension include strong family history, obesity, insulin resistance, hyperuricemia and/or gout, sleep disorders including sleep apnea, and persistent high-stress living environments either at work or home. Certain physical features, such as elevated heart rate or an increased BP response to exercise, are also predictive, as is elevated hematocrit.

Genetic factors also contribute, as discussed earlier. Although the inheritance patterns do not follow mendelian genetics for a single gene locus, evidence suggests that 20% to 30% of hypertension may have a genetic basis, because of the cumulative effect of multiple susceptibility genes (the polygene hypothesis). A recent genome-wide association screen found 29 polymorphisms that could account for approximately 13% of primary hypertension, with several of the polymorphisms linked with natriuretic peptide and NO signaling.[25] Others have noted polymorphisms involving immune system and oxidative stress mechanisms (HSP-70 variants, xanthine oxidase, and extracellular superoxide dismutase), vasoactive mediators (angiotensinogen, endothelial NOS, prostacyclin synthase, β_2-adrenoceptor, 20-HETE synthase [*CYP4F2* gene], G protein β3), mediators of vascular smooth muscle tone (calcium-dependent potassium channel, *KCNMA*), or mediators controlling renal sodium transport (α-adducin and 11β-hydroxysteroid dehydrogenase type 2, aldosterone synthase, WNK kinases).[19]

Hypertension is more likely to occur if the mother has a history of hypertension, obesity, preeclampsia, or malnutrition. These risk factors are all associated with intrauterine growth retardation and low birth weight, both of which predispose to future hypertension, as well as diabetes and obesity.

Dietary and other environmental factors may contribute to the risk for hypertension. Obesity, with or without features of insulin resistance and the metabolic syndrome, is a major risk factor for hypertension and parallels the rise in hypertension in these countries. Epidemiologic and interventional studies have linked salt intake and low potassium intake with persistent BP elevation, leading to earlier development of hypertension, and although the relationship is best demonstrated in older patients and in African Americans, it is true across the world. Increasing potassium intake lowers BP in both experimental and human studies. More recently, intake of added sugars (e.g., sucrose, high-fructose corn syrup) has been found to predict higher BP. Certain toxins, most notably low-level lead and cadmium intoxication, are also associated with increased frequency of hypertension.

CLINICAL MANIFESTATIONS

Evaluation of a patient with hypertension requires a careful history and physical examination, an evaluation of risk factors for hypertension, a search for potential secondary causes, and an evaluation for end-organ damage.

Blood pressure should be measured on at least three occasions to confirm persistent hypertension using the techniques described in Chapter 33. Home BP monitoring or 24-hour ambulatory BP monitoring is recommended to determine if the hypertension occurs only in the physician's office (white coat hypertension) and rarely to identify masked hypertension, in which BP elevations occur only outside the physician's office. White coat and masked hypertension can be associated with end-organ disease, including left ventricular hypertrophy (LVH) and microalbuminuria; diagnosis should be followed by assessment of cardiovascular (CV) risk factors and frequent reevaluation of BP.

The history should investigate the onset and duration of hypertension and the presence of a family history of hypertension or cardiorenal disease. The history should identify risk factors for hypertension (obesity, diabetes, physical activity, gout, alcohol, smoking, diet, emotional or work-related stress, over-the-counter and prescribed medications) and any hypertension-related morbidity. Hypertension is often asymptomatic, but studies have found that even childhood-associated hypertension can be associated with impaired memory and mental performance, and hypertension remains a major risk factor for vascular dementia. Good BP control improves mental performance and decreases the risk of developing dementia.[26,27] Hypertension, especially stage 2 (see Table 34-1), may also be associated with headache, classically occipital and pulsatile. In hypertensive emergency, encephalopathy may rarely occur, with an acute decline in mental status and seizures. Also rarely, patients may lose vision from papilledema. Stage 2 hypertension also places individuals at acute risk for myocardial infarction (MI), congestive heart failure (CHF) with pulmonary edema, aortic dissection, cerebrovascular accident (stroke), and renal failure.

Physical examination includes BP measurement in both arms and a careful cardiac examination. Attention should be focused on both the large vessels (by both palpation and listening for bruits) and the retina to grade the severity of disease in the microvasculature (Fig. 34-5). Laboratory tests should include hematocrit, electrolytes,

Figure 34-5 Different grades of hypertensive retinopathy. Kinyoun, University of Washington.)*

creatinine (and estimated GFR), calcium and phosphate (to look for primary hyperparathyroidism), fasting lipid profile (cholesterol and triglycerides), uric acid, and urinalysis. A chest x-ray film and electrocardiogram should be performed to assess cardiac size and to look for aortic dilation.

Additional tests include assessment of 24-hour urine sodium and potassium excretion. Urinary Na^+ and K^+ excretion correlates with intake if the patient is in steady state (desirable values are <100 mmol/l Na^+ and >100 mmol/l K^+ in 24 hours). A spot urine albumin-creatinine and an echocardiogram may uncover additional evidence of end-organ damage (Fig. 34-6). Note that a spot urine albumin-creatinine is recommended only for those with diabetes or stage 2 or higher CKD. Echocardiography is not recommended for routine use in patients with hypertension because of its cost, although appropriate for those with cardiac problems.

PATHOLOGY

Primary hypertension is characterized by disease of the preglomerular arterial vessels, primarily the afferent arteriole and interlobular artery. The classic lesion, seen in 90% of patients, is arteriolosclerosis, in which smooth muscle cells of the media in the afferent arteriole are replaced by connective tissue[28] (Fig. 34-7). Often, hyaline material (plasma proteins) accumulates in the subintima (hyalinosis). In addition to the arteriolar disease, there is often evidence of glomerular and tubulointerstitial ischemia with shrinkage of the glomerular tuft, tubular atrophy, and interstitial fibrosis. Occasionally, glomerulosclerosis and severe tubulointerstitial injury are seen. In cases of hypertensive emergency, a proliferative arteriolopathy occurs, occasionally with fibrinoid necrosis. Concentric layers of connective tissue and cells may give an onion-skin appearance to the intima, which may progress to a total obliteration of the lumen.

Pearlman, University of Washington.)*

DIAGNOSIS

The diagnosis of primary hypertension requires the elimination of secondary etiologies, of which the more common include medications (nonsteroidal anti-inflammatory drugs, corticosteroids, sympathomimetics, oral contraceptives), recreational drugs (excessive alcohol intake, cocaine), intrinsic renal parenchymal disease, renovascular disease, and primary aldosteronism from adrenal hyperplasia or tumors. Table 33-10 provides a more complete list along with the recommended evaluation for secondary causes.

NATURAL HISTORY

The major long-term risk of hypertension is cardiovascular disease (CVD), which can be separated into pressure-related (stroke, CHF), atherosclerotic (MI), and renal (CKD) etiologies. Hypertension is the most common cause of stroke and CHF, and the risk increases linearly with BP[29] (Fig. 34-8). Other rarer pressure-related morbidities include aortic dissection and cerebral and aortic aneurysms. Increased systolic, diastolic, and pulse pressure all confer risk, although the systolic BP and the pulse pressure (in particular when associated with low diastolic BP) are the more important determinants of risk for the pressure-related morbidities. This increased risk depends on age (increases with age), gender (greater in males), ethnic origin (greater in African Americans), and other conditions (especially diabetes).

Cardiac consequences of poor hypertension control begin with concentric LVH associated with supernormal systolic function. Over time, impaired diastolic dysfunction may occur, as manifested by slow diastolic filling, which reflects decreased diastolic relaxation.

This may progress to CHF. Almost 90% of patients with CHF have a history of hypertension.

Hypertension also confers risk for atherosclerotic-associated morbidities, including coronary heart disease,[29] peripheral vascular disease, and carotid atherosclerosis with or without cerebral emboli. In addition to an increased prevalence of hypertension, African Americans also have a 50% greater risk for heart disease.

Kidney Disease

Most patients with newly diagnosed primary hypertension have normal renal function or stage 1 (GFR >90 ml/min/1.73 m^2 with microalbuminuria) or stage 2 CKD (GFR 60 to 90 mL/min/1.73 m^2) with elevated renal vascular resistance.[30] Despite relatively normal renal function, renal biopsy, if done, usually shows arteriolosclerosis and hyalinosis (see Fig. 34-7).

Prior to use of effective antihypertensive agents, proteinuria developed in up to 40% of hypertensive patients, and as many as 18% developed renal impairment over time. Microalbuminuria, which is a marker of vascular disease and CV risk, occurs in 15-30% of patients, whereas non-nephrotic proteinuria is uncommon and nephrotic-range proteinuria is rare.[31] Microalbuminuria is associated with salt-sensitive hypertension, the loss of nocturnal dipping in BP, and increased target organ damage, especially LVH. Elevations in serum creatinine develop in 10% to 20% of patients with poorly controlled BP, and the risk is greater in African Americans, elderly persons, patients with hyperuricemia, and those with higher systolic BP (>160 mm Hg).[32,33] In 2% to 5% of those with poorly controlled systolic BP (>160), progression to renal failure will occur over the subsequent 10 to 15 years (Figs. 34-9 and 34-10). Despite the relative infrequency for hypertension to progress to end-stage renal disease (ESRD), hypertension is recorded as the second most common cause of ESRD after diabetes in the United States and Europe. Furthermore, almost all patients with diabetes have hypertension when they start dialysis.

The incidence of ESRD in African Americans with hypertension is fourfold to sixfold greater than in Caucasians.[34] Renal biopsies of African Americans with hypertension show more severe hypertensive injury, with more prominent vascular changes and increased frequency of segmental and global glomerulosclerosis. Although some of these vascular changes may relate to the presence of certain transforming growth factor β (TGF-β) polymorphisms or the higher uric acid levels that are common in this population, recent studies suggest that the increased frequency of glomerulosclerosis may be caused by a polymorphism in apolipoprotein L1 *(APOL1),* the product of which is expressed in the podocyte.[35] The mechanism by which *APOL1* polymorphisms increase the risk for progression of renal disease is unclear but may relate to effects on the podocyte.

Effect of Antihypertensive Therapy on Natural History of Hypertensive Cardiovascular Disease and Kidney Disease Progression

The specific pharmacologic approach to treatment of hypertension is discussed in Chapter 35, whereas the effect of antihypertensive therapy on CV and renal outcomes is discussed here. According to a recent report, only 71% of patients with hypertension in the United States are receiving treatment, and only 48% have their BP under adequate (<140/90 mm Hg) control.[36] Although age-adjusted mortality for stroke and coronary artery disease has been significantly reduced since the early 1980s as a result of better BP control (and better treatment of other risk factors such as hyperlipidemia), heart disease and stroke remain the first and third leading causes of death in Western countries. This emphasizes the importance of identifying and treating patients with hypertension.

Antihypertensive therapy reduces CV complications in patients with stage 2 hypertension, although there are less data to support this for stage 1 hypertension (Table 34-4).[37] The reduced risk is most significant for stroke and CHF, but also occurs for MI. In all trials to date, the group with the best overall BP control has the best outcome.[38] One exception comes from the recent ACCOMPLISH trial, where both groups had similar BP control, but the group initially randomized to an ACE inhibitor with a calcium antagonist had a 20% CV risk reduction compared to the ACE inhibitor plus diuretic group.[39] Note that almost all people with some level of kidney disease will require two or more medications. Diuretics (e.g., chlorthalidone) provide greater initial reductions in BP than most antihypertensive agents and are required in those with stage 3 CKD but are not considered agents of first choice for treatment of primary hypertension by any except U.S. guidelines.

The effect of antihypertensive therapy on the progression of renal disease secondary to hypertension is more controversial. In the Multiple Risk Factor Intervention Trial (MRFIT), in which diuretics and β-blockers were primarily used to control BP, slowing or stabilization of renal function was not seen in African American men, but was seen in all other racial groups studied.[40] In the African American Study of Kidney Disease, use of an ACE inhibitor (ramipril) was more effective at slowing CKD progression than either the dihydropyridine calcium channel blocker amlodipine (Fig. 34-11) or metoprolol.[41,42] However, both studies and others failed to show superior protection with tight BP control compared to conventional BP targets in patients with renal disease secondary to hypertension.[42,43] Masked hypertension may be a confounder to these results; a subanalysis of ambulatory BP showed inadequate 24-hour BP control in more than 70% of the cohort. Masked hypertension and nondipping (i.e., lack of BP decrease with sleep) were the two most common reasons for poor BP control.[44]

Further studies are being performed regarding the dosing and timing of antihypertensive treatment to evaluate changes in overall BP control. In contrast, *post hoc* analyses of trials show that patients with diabetic renal disease, or with proteinuric (>300 mg/day) renal disease, including that caused by hypertension, appear to benefit from lower BP goals in terms of renal protection. Based on current evidence, achieved BP levels should be less than 140 mm Hg systolic for nonproteinuric hypertensive renal disease and less than 130/80 mm Hg in those with diabetes and hypertension.[45] However, because all three of the prospective randomized CKD outcome trials have failed to show a benefit, the updated Kidney Disease: Improving Global Outcomes (KDIGO) guidelines recommend a BP goal of less than 140/90 mm Hg in those with CKD, as backed with the highest level of evidence. The previous goal of less than 130/80 mm Hg in the presence of very high albuminuria (>300 mg/day) has much lower level of evidence and is not endorsed.[46]

Some studies also suggest that thiazide diuretics are associated with worsening of renal function in patients with hypertension. In the European Working Party on High Blood Pressure in the Elderly trial, a significantly higher incidence of impaired renal function was found in those receiving diuretics than with placebo.[47] In the Systolic Hypertension in the Elderly trial, serum creatinine increased significantly in those treated with thiazide diuretics compared to placebo.[48]

Effect of Antihypertensives on Cardiovascular Outcomes in Hypertension

Outcome	No. of Trials	Effects Model	RR (95% CI)	*P* Value for Heterogeneity
Coronary heart disease	24	Fixed Random	0.86 (0.80-0.93) 0.87 (0.80-0.94)	.55 .55
Stroke	23	Fixed Random	0.69 (0.64-0.74) 0.68 (0.61-0.76)	.004 .004
CHF	7	Fixed Random	0.54 (0.45-0.66) 0.60 (0.49-0.74)	.66 .80
Major CVD events	28	Fixed Random	0.78 (0.74-0.81) 0.73 (0.62-0.87)	<.001 <.001
CVD mortality	23	Fixed Random	0.84 (0.78-0.90) 0.84 (0.78-0.90)	.10 .10
Total mortality	25	Fixed Random	0.90 (0.85-0.95) 0.90 (0.85-0.95)	.58 .59

The analysis was based on 42 clinical trials that included 192,478 patients randomized to seven major treatment strategies, including placebo. *CHF,* Congestive heart failure; *CVD,* cardiovascular disease; *RR,* relative risk; *CI,* confidence interval. *(From reference 37.)*

Ramipril Is Superior to Amlodipine in Reducing Renal Events in Hypertensive African Americans with Renal Impairment

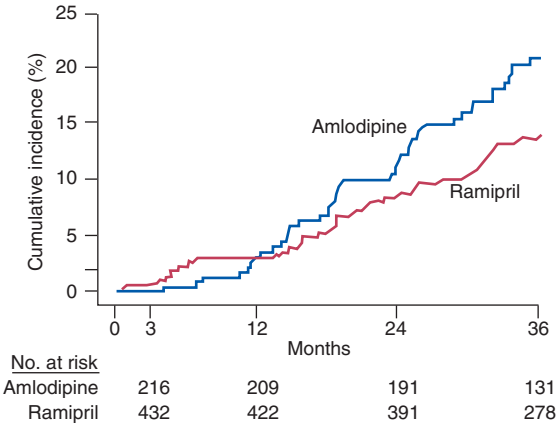

Figure 34-11 Ramipril is superior to amlodipine in reducing renal events in hypertensive African Americans with mild to moderate renal impairment. The angiotensin-converting enzyme (ACE) inhibitor ramipril resulted in fewer renal end points (proteinuria, decline in renal function, ESRD, death) compared with the dihydropyridine calcium channel blocker amlodipine, in the African American Study of Kidney Disease. *(From reference 41.)*

In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the chlorthalidone-treated group showed statistically worse renal function than either the amlodipine or the lisinopril group, at both 2- and 4-year end points.[49] This could likely be accounted for by volume depletion in many cases, but diuretics have been shown to induce mild renal injury in various animal models, possibly because of hypokalemia, hyperuricemia, and stimulation of the renin-angiotensin-aldosterone system (RAAS) related to decreased renal perfusion pressure.[50]

Can Primary Hypertension Spontaneously Remit?

In those under age 60, as many as 15% to 20% of patients with prehypertension may become normotensive spontaneously. Furthermore, in patients with established hypertension who have good BP control for 5 years under treatment, as many as 20% to 40% can be withdrawn from therapy successfully, especially if they have stage 1 hypertension and adhere to salt restriction and weight reduction. This suggests that the processes that mediate hypertension are at times reversible.

CHAPTER 35

Nonpharmacologic Prevention and Treatment of Hypertension

Brian Rayner, Karen E. Charlton, and Estelle V. Lambert

Lifestyle changes, including a combination of increased fat and refined carbohydrate intake and reduced physical activity, have resulted in an epidemic of obesity, type 2 diabetes mellitus, and hypertension. The epidemic is evident worldwide and often is greatest in underserved and indigenous populations. Adoption of healthy lifestyles is critical for both the prevention of high blood pressure (BP) and its management. According to the Seventh Report of the Joint National Committee on Prevention, Evaluation, and Treatment of High Blood Pressure (JNC 7 Report),[1] lifestyle interventions lower BP, enhance efficacy of antihypertensive medication, and lower overall cardiovascular (CV) risk. The lifestyle changes that are widely agreed to lower BP and CV risk are (1) smoking cessation, (2) weight reduction, (3) moderation of alcohol intake, (4) physical exercise, (5) reduction of salt intake, (6) increase in fruit and vegetable intake, and (7) decrease in saturated and total fat intake.[1] Interventions may have efficacy similar to that of single-drug therapy (Table 35-1). However, lifestyle changes should not delay the initiation of drug therapy in patients at higher CV risk.

PREVENTION

The importance of primary prevention has been underscored by the recognition that (1) the treatment of hypertension is expensive, (2) the control of BP in hypertensive individuals does not restore CV risk to normal, and (3) the majority of hypertensive individuals do not reach goal BP readings. The most important individuals to target are those with *prehypertension* (defined by JNC 7 as 120 to 139/80 to 89 mm Hg; see Chapter 33).[1] Individuals with prehypertension have increased prevalence of early vascular damage, increased risk of incident hypertension, and increased risk of CV events compared with those who have optimal BP levels (<120/80 mm Hg).[2] The JNC 7 Report recommends lifestyle changes in all patients with prehypertension to prevent hypertension and to reduce CV risk.[1]

The contribution of body weight, physical inactivity, and dietary factors to the prevalence of hypertension in Europe and the United States has been quantified in a meta–regression analysis.[3] Being overweight made the largest contribution to hypertension, with population-attributable risk percentage (PAR%) between 11% (Italy) and 25% (United States). PAR% was 5% to 13% for physical inactivity, 9% to 17% for high sodium intake, 4% to 17% for low potassium intake, and 4% to 8% for low magnesium intake. The impact of alcohol was small (2% to 3%) in all populations. PAR% varied among populations for inadequate intake of calcium (2% to 8%) and inadequate intake of fish fatty acids (3% to 16%).

WEIGHT LOSS

Obesity is epidemic throughout the world, and 65% of the adult population in the United States is either *overweight*, with body mass index (BMI) of 25.0 to 29.9, or *obese*, with BMI of 30 or higher.[4] Obese individuals have a threefold increased prevalence of hypertension. Possible mechanisms for obesity-induced hypertension include overactivity of the sympathetic nervous system (SNS), hyperinsulinemia (which may increase renal sodium reabsorption), increased leptin, hyperuricemia, activation of the renin-angiotensin system (RAS), and sleep apnea. Abdominal or visceral obesity is a greater predictor of both hypertension and CV risk than is a predominant lower body fat distribution. *Abdominal obesity* is defined as a waist circumference greater than 88 cm (>35 inches) in women and greater than 102 cm (>40 inches) in men. These reference values were developed in Caucasian populations, and differing criteria may be more appropriate for other ethnic groups.

In obese hypertensive patients or those with high-normal BP, weight loss of as little as 4 to 5 kg (~9 to 11 lb) is often associated with a significant reduction in BP. Weight loss is one of the most effective nonpharmacologic interventions to reduce BP.[5] A meta-analysis has demonstrated that a weight reduction of 5.1 kg reduced systolic BP by 4.4 mm Hg and diastolic BP by 3.6 mm Hg.[6] A rule of thumb is that for every kilogram lost, there is a reduction of 1 mm Hg in both systolic and diastolic BP. To minimize the risk of relapse and to maintain sustainability of the weight loss program, the initial target should be 5% to 10% of current weight, or 1 to 2 BMI units. Marked oscillations in weight should be avoided because this increases the risk for development of hypertension in obese, normotensive persons.[7] A randomized trial of the effectiveness of four popular diets on sustained weight loss and CV disease risk reduction concluded that a variety of diets can similarly reduce weight and BP, but only a minority of individuals can sustain high dietary adherence. High-protein, low-carbohydrate diets, advocated for weight loss by the media and lay public, are associated with an overall increase in CV events in women.[8]

Weight reduction should be accompanied by recommendations to increase physical activity unless it is contraindicated. Bariatric surgery and pharmacologic interventions for weight loss (e.g., orlistat) may be useful to achieve weight loss in some patients, but always as an adjunct rather than a substitute for lifestyle modification.

PHYSICAL ACTIVITY

Physical inactivity is associated with at least a 1.5- to 2-fold higher risk of hypertension and coronary heart disease.[9] Regular physical activity lowers all-cause morbidity and mortality and provides the basis for public health recommendations to exercise at least 30 minutes per day. A recent review reported that patients with high BP who participated in any level of physical activity had a reduced risk (by 16% to 67%) of CV mortality, whereas a greater than twofold increase in CV mortality risk was observed in nonactive individuals.[10] Regular physical activity in childhood was inversely correlated with diastolic BP, even in children as young as 5 years.[11]

Lifestyle Modifications for Prevention and Management of Hypertension

Modification	Recommendation	Average Systolic BP Reduction Range Achieved with Intervention*
Weight reduction	Maintain normal body weight (BMI = 18.5-24.9 kg/m^2)	5-20 mm Hg/ 10 kg
DASH eating plan	Adopt a diet rich in fruits, vegetables, and low-fat dairy products with reduced content of saturated and total fat	8-14 mm Hg
Dietary sodium restriction	Reduce dietary sodium intake to 100 mmol/day (2.4 g sodium or 6 g sodium chloride)	2-8 mm Hg
Aerobic physical activity	Regular aerobic physical activity (e.g., brisk walking) at least 30 min/day, most days of the week	4-9 mm Hg
Moderation of alcohol consumption	Men: limit to 2 drinks† per day; women and lighter-weight persons: limit to 1 drink per day	2-4 mm Hg

Table 35-1 Lifestyle modifications for prevention and management of hypertension (JNC 7). *BMI,* Body mass index; *BP,* blood pressure; *DASH,* Dietary Approaches to Stop Hypertension. *Effects are dose and time dependent. †One drink = ½ oz or 15 ml ethanol (e.g., 12 oz (360 ml) beer, 5 oz (150 ml) wine, 1.5 oz (45 ml) 80-proof whiskey). *(From reference 1.)*

Practical Guidelines for Exercise in Patients with Hypertension

All apparently healthy individuals should undergo pre-exercise screening to determine health risk status. The American College of Sports Medicine (ACSM) recognizes that two or more of the following risk factors increase the risk associated with exercise, and individuals should undergo pre-exercise graded exercise testing. Risk factors include male gender (older than age 45 years) or female gender (older than 55 years); serum cholesterol concentrations greater than 5.2 mmol/l; impaired glucose tolerance or diabetes mellitus; smoking; obesity (body mass index ≥30); inactivity; and family history of cardiovascular disease.

Patients with uncontrolled hypertension should embark on exercise training only after evaluation and initiation of therapy. Furthermore, patients should not participate in an exercise training session if resting systolic blood pressure is above 200 mm Hg or diastolic blood pressure is above 115 mm Hg.

Many patients with hypertension are overweight and should therefore be encouraged to follow a program that combines both exercise training and restricted calorie intake.[18]

Type of exercise: this should be predominantly endurance physical activity, including walking, jogging, cycling, swimming, or dancing. This should be supplemented by resistance exercise that can be prescribed according to the ACSM or American Heart Association guidelines.[19]

Frequency of exercise: most or preferably every day.

Intensity of exercise: moderate intensity at 40% to 60% of maximal oxygen consumption ($\dot{V}O_2$ peak).

Duration of exercise: more than 30 minutes of continuous or accumulated moderate physical activity daily.

Box 35-1 Practical guidelines for exercise in patients with hypertension. *(Modified from references 18 and 19.)*

Exercise Training Dose Response

In a meta-analysis of studies involving more than 1500 patients, exercise training in normotensive individuals has been shown to reduce systolic and diastolic BP by 3.0 ± 1 and 1.7 ± 1 mm Hg, respectively.[12] The rate of progression from prehypertension to hypertension in middle-aged and older male veterans was prevented when exercise capacity exceeded 8.5 peak metabolic equivalents (METs).[13] In hypertensive patients, the effect of exercise training is even more marked: a reduction of 7.8 ± 3.5 and 5.8 ± 2.0 mm Hg for systolic and diastolic BP, respectively. Studies in hypertensive patients have shown that the benefit of exercise on BP is maximal with 90 minutes of exercise per week, after which there was no further improvement.[14] Furthermore, only a modest amount of exercise was needed to reduce BP in patients with hypertension (>30 min/wk). Regular exercise prevents the development of left ventricular hypertrophy (LVH) that is independent of BP in young, stage 1 hypertensive patients.[15]

Fagard[12] found no benefit of increasing exercise intensity on BP reduction with exercise training, as long as intensity ranged between 40% and 70% of maximal, age-predicted heart rate. Exercise of higher intensity (75% maximum) was associated with a more marked and prolonged reduction in BP in the postexercise window compared with lower-intensity exercise (50% maximum).[16]

Mechanisms

In the acute postexercise period, the reduction in BP has been linked to a sympathetic inhibition and increased release of vasodilator substances.[17] The mechanisms by which chronic exercise lowers BP are less well understood but include reductions in systemic vascular resistance (SVR) secondary to neurohumoral and structural adaptations. Chronic exercise is also associated with a loss of weight and a reduction of serum uric acid levels, both of which could reduce BP.

Antihypertensive Medication and Guidelines for Exercise

Box 35-1 provides exercise guidelines for patients with hypertension.[18] β-Blockers decrease exercise tolerance. β-Blockers and diuretics may also alter thermoregulation in hot environments and provoke hypoglycemia. Patients using these medications should be educated about exercising in the heat, clothing, adequate hydration, and methods to prevent hypoglycemia.[19,20] Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and calcium channel blockers may be better suited for patients who exercise frequently or athletes with hypertension.

For patients undergoing supervised exercise training, the monitoring of postexercise BP may be helpful so that medications may be adjusted appropriately, considering the likelihood of postexercise hypotension. Particular care should be taken with patients planning to exercise in a hot environment.

DIET

Salt Intake

Epidemiologic studies have demonstrated that the prevalence of hypertension is directly related to the dietary salt intake in societies

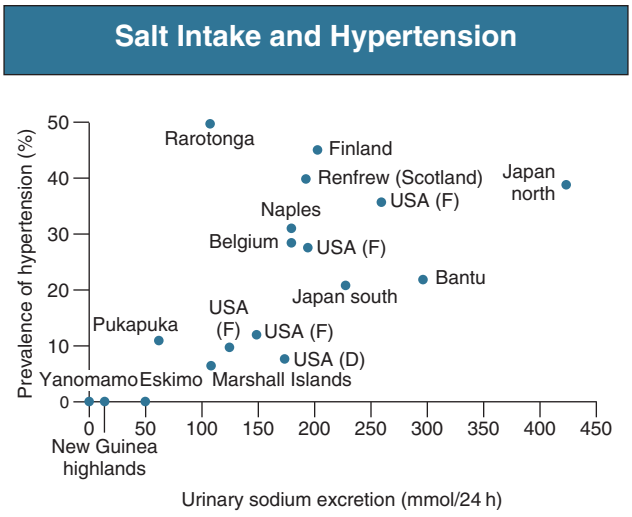

Figure 35-1 Relationship of salt intake with frequency of hypertension in different populations. *(D),* Data from Dahl; *(F),* data from Framingham study from different time periods. *(Modified from reference 21.)*

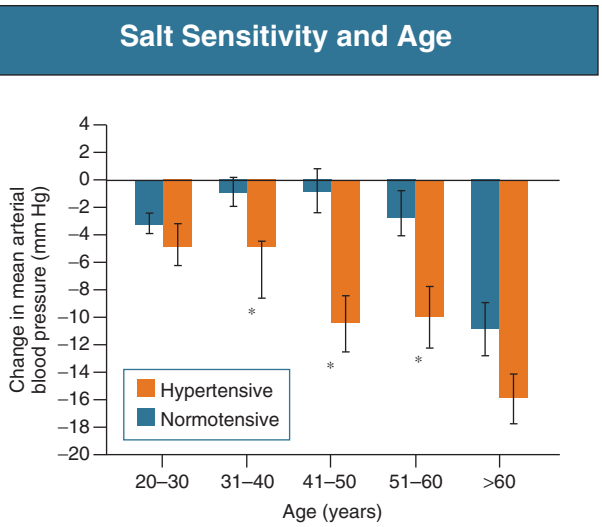

Figure 35-3 Increase in magnitude of salt sensitivity with increasing age. Salt sensitivity (determined by standardized test evaluating change in blood pressure from a volume-expanded to a contracted state) increases proportionately with age in both hypertensive and normotensive individuals (*bars* indicate standard error of the mean; **P* <.05). *(Modified from reference 23.)*

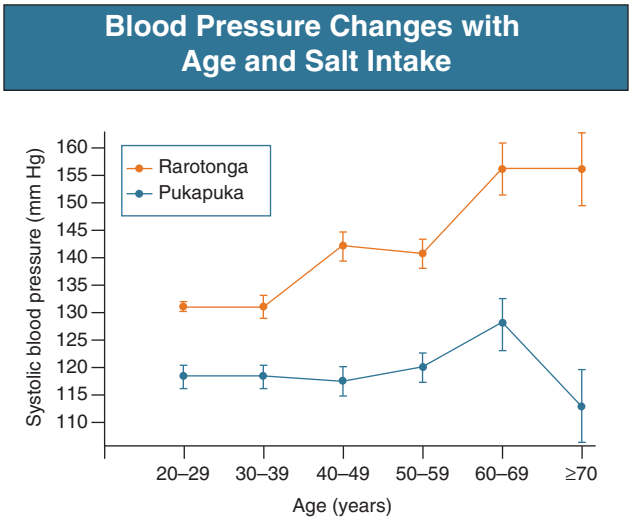

Figure 35-2 Blood pressure changes with age and salt intake. The increase in systolic blood pressure with age correlates with a higher salt intake in two Polynesian populations. In men of Rarotonga Island, where the sodium intake averages 130 mmol/day, systolic blood pressure increases with age. In contrast, it remains constant in men from Pukapuka Island, where the sodium intake averages 50 to 70 mmol/day. *(Modified from reference 22.)*

throughout the world in whom salt intake is above 50 to 100 mmol/day, or 3 to 6 g sodium chloride (NaCl)[21] (Fig. 35-1). Where daily intake is below that range, hypertension is rare. Salt intake also plays an important role in age-related increase in BP[22] (Fig. 35-2). Not all individuals respond similarly to high salt intake. "Salt sensitivity" describes a group of individuals who significantly decrease or increase their BP during periods of salt restriction or loading, respectively. Despite the definition remaining in the research rather than the clinical domain, the following groups of patients tend have increased susceptibility to salt sensitivity (salt-sensitive hypertension):

- People of African descent
- Elderly people
- Obese persons (not in all studies)
- Patients with type 1 or type 2 diabetes
- Patients treated with calcineurin inhibitors
- Patients with chronic kidney disease (CKD)

Salt sensitivity is observed in 75% of hypertensive African Americans compared with about 50% of hypertensive Caucasians[23] and increases with age in both normotensive and hypertensive populations[24] (Fig. 35-3). Response to salt restriction is predicted by polymorphisms in the G protein–coupled receptor kinase 4 (GRK-4) gene, which regulates Na^+ excretion in the proximal convoluted tubule.[25] Putative mechanisms for salt sensitivity are alterations in circulating levels of (or renal responses to) atrial natriuretic factor, kallikrein, prostaglandins, and nitric oxide (NO); increased levels of norepinephrine; abnormal suppression of both renin and aldosterone; genetic mechanisms; congenital reduction in nephron number; and acquired renal microvascular and tubular injury.[23]

The effects of salt restriction on BP have been demonstrated in several well-designed intervention studies.[26] In a randomized controlled trial (RCT) in British people age 60 to 78 who were not receiving antihypertensive medication, modest salt restriction from 10 g to 5 g per day resulted in a reduction in BP of 7.2/3.2 mm Hg during a 4-week period in both normotensive and hypertensive subjects.[27] A meta-analysis in children and adolescents demonstrated that sodium restriction for 4 weeks results in significant BP reductions.[28]

In the follow-up Dietary Approaches to Stop Hypertension (DASH)–Sodium Trial, the additional benefits of salt restriction over and above the DASH diet were investigated (Fig. 35-4).[29] Reduction of sodium intake from a high (150 mmol/day, or 9 g NaCl) to either an intermediate (100 mmol/day, or 6 g NaCl) or a low (65 mmol/day, or 4 g NaCl) intake resulted in a stepwise reduction in BP, which was approximately twice as great in participants receiving the control than receiving the DASH diet (Fig. 35-5). In those following the DASH diet, the addition of salt restriction resulted in a relatively small additional decrease in BP (3.0 and 1.6 mm Hg for systolic and diastolic BP, respectively). Thus, the greatest benefits of salt restriction are seen in those with typical Westernized high-fat, low-nutrient diet. Benefits of short-term salt restriction have been extended to children and adolescents.

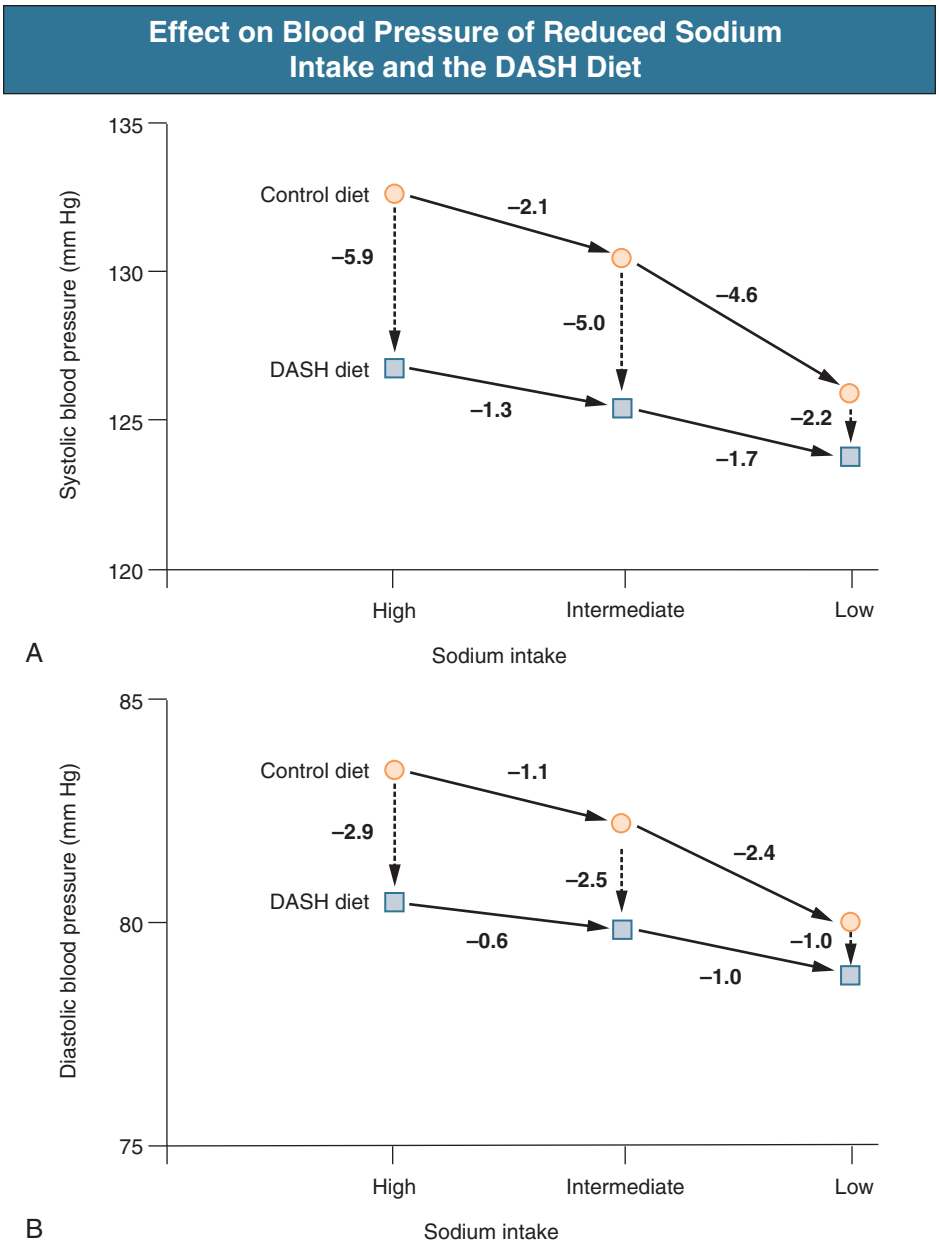

Figure 35-4 Reduced sodium intake and DASH diet. Effect on **A,** systolic blood pressure, and **B,** diastolic blood pressure. (***B*** *redrawn from reference 29.*)

The U.S. Department of Agriculture and U.S. Department of Health and Human Services Joint Dietary Guidelines for Americans calls for no more than 1500 mg/day of sodium (65 mmol/day, or ~4 g NaCl equivalent) in African Americans; people over age 51; and patients with hypertension, diabetes mellitus, or CKD; and no more than 2300 mg/day (100 mmol/day, or ~6 g NaCl) in all others.[30] The JNC 7 guidelines similarly recommend sodium intakes of less than 100 mmol/day.[1] The World Health Organization (WHO) and Food and Agriculture Organization (FAO) of the United Nations recommend less than 5 g NaCl daily (2000 mg, or 90 mmol/day Na) as a population goal, while ensuring that the salt is iodized.[31] The American Heart Association (AHA) Presidential Advisory in 2011 affirmed the recommendation of salt restriction based on evidence that this measure prevents and treats hypertension and reduces adverse cardiovascular disease (CVD) and cerebrovascular accident (stroke).[30]

Avoidance of added salt and salt-rich processed foods can reduce intake from 9 g/day to about 6 g/day. Further reduction in salt requires specialized dietary counseling. Despite these recommendations, long-term studies have reported only small reductions in BP associated with salt restriction (average of only 1.1/0.6 mm Hg).[28] These results undoubtedly reflect limited compliance, but this can be improved by regular contact with the patient, dietetic counseling, and educational sessions. Measurement of 24-hour urinary sodium is useful to check adherence with salt restriction (calculated as urine sodium [mmol/day] × 0.0585 = grams NaCl/day).

Recent reports of select observational studies and a meta-analysis have stirred controversy by suggesting potential harm from sodium restriction and spurred calls for an abandonment of reduction in salt intake. In a recent AHA Presidential Advisory, a detailed review of these studies documents substantial methodologic flaws that limit their usefulness in setting or reversing dietary recommendations. The evidence supporting population reduction in sodium intake remains robust and persuasive.[30] Furthermore, in a meta-analysis of prospective studies, higher salt intake was associated with greater

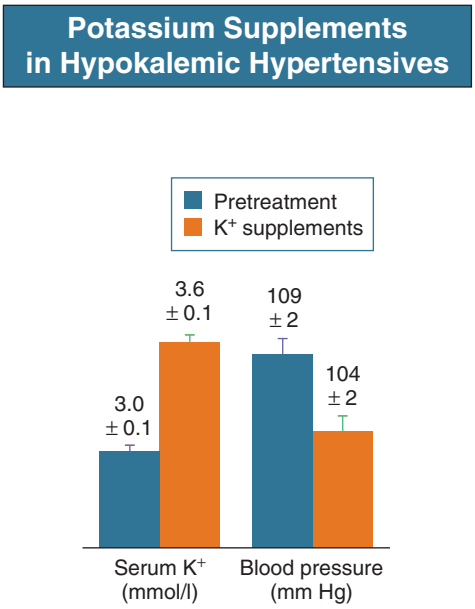

Figure 35-5 Potassium supplementation lowers blood pressure in hypokalemic hypertensive patients. Treatment with potassium chloride (60 mmol/day potassium for 6 weeks) resulted in an increase in serum potassium concentration and a decrease in mean arterial pressure in hypertensive patients taking thiazide diuretics. *(Redrawn from reference 37.)*

risk of stroke (pooled relative risk [RR] 1.23, $P = .007$) and CVD (RR 1.14, $P = .07$), with no significant evidence of publication bias. The associations observed were greater the larger the difference in sodium intake and the longer the follow-up.[32]

One of the most cost-effective ways to lower salt intake in the general population is to reduce salt in processed foods. This approach was effective in lowering the BP in drug-treated hypertensive patients in a low-income community in South Africa through the modification of the salt content of a small number of commonly consumed foods, including bread.[33] In Belgium, the reduction in the salt content of bread between the mid-1960s and the early 1980s was accompanied by marked reductions in 24-hour urinary sodium excretion. In recognition of the need for a concerted global effort to reduce population-wide salt intake, a WHO Forum and Technical meeting in 2006 recommended an integrated approach incorporating a commitment by the food industry to product reformulation, increased consumer awareness, and social marketing around salt and health issues.[34]

The United Kingdom was the first country to set voluntary sodium reduction targets for categories of foods, through its Food Standards Agency (2009), closely followed by Australia, the United States, and Canada. South Africa is the first country to adopt mandatory regulation for maximum sodium levels in food categories that are major contributors to salt intake in that population: bread, margarine and spreads, savory snacks, processed meats, soup powders, and stock cubes.[35] It is estimated that reducing the sodium content of bread by 50%, along with other proposed reductions in margarine, soups, and gravies, would decrease salt intake by 0.85 g/day, resulting in 7000 fewer deaths from CVD and 4000 less nonfatal strokes in the country per year, as well as save about $40 million (U.S.) each year in health care costs associated with nonfatal strokes alone. In the United States, as in most developed nations, a major challenge to sodium intake reduction efforts is the widespread use of sodium in the food supply, with more than 75% of total sodium intake from packaged and restaurant foods.[36]

Potassium Intake

One of the confounding factors of the relationship of salt and BP has been the inverse relationship between the intake of salt and that of potassium. Typically, diets with a high salt content are relatively deficient in potassium (and calcium); but in persons who consume little salt, the potassium (and calcium) intake is high.

In normotensive individuals with an average potassium intake above 1.95 g/day (50 mmol/day), potassium supplementation has no significant effect on BP. However, among hypertensive patients who are potassium deficient because of diuretic treatment or low potassium intake, potassium supplementation lowers BP[37] (see Fig. 35-5). The DASH diet lowers BP and is high in potassium because of the high fruit and vegetable content and inclusion of low-fat dairy products[38] (Table 35-2). However, the synergistic effect of the various food groups in the DASH diet makes it difficult to ascertain the contribution of the individual nutritional components. The mechanisms by which a low-potassium diet may contribute to hypertension are complex and poorly understood but may relate to stimulation of intrarenal angiotensin II (Ang II), oxidants, and endothelin; inhibition of intrarenal NO and prostaglandins; and induction of renal ischemia.

In the Trials of Hypertension Prevention (TOHP) I and II, a higher sodium-potassium excretion ratio (implying a high-salt and low-potassium intake) was more strongly associated with subsequent CV events than either urinary Na^+ or K^+ excretion alone.[39] Overall, it appears to be beneficial to optimize potassium intake in hypertensive patients to minimize hypokalemia, being careful to avoid the risk of hyperkalemia especially in those with renal impairment. If renal function is normal, optimal potassium intake is 80 to 120 mmol/day. For CVD prevention, WHO recommends a potassium intake that will keep the Na-K ratio close to 1 (i.e., 70 to 80 mmol/day if Na guidelines are met).

Calcium and Dairy Food Intake

Cross-sectional population surveys of self-reported nutrient intake suggest an inverse relationship between calcium intake and BP. The relationship is more convincing at low levels of calcium consumption (<300 to 600 mg/day). There may be a threshold of 700 to 800 mg/day, above which any further reduction in BP is attenuated. A meta-analysis of randomized calcium supplementation trials (mostly with 1 or 1.5 g calcium daily) demonstrated reductions in systolic BP (−0.9 to −1.7 mm Hg) that are of little clinical importance.[40] Although calcium in milk may contribute to BP lowering, dairy products may lower BP by other mechanisms. Biologically active peptides formed during the milk fermentation process, such as the casein-derived tripeptides isoleucine-proline-proline and valine-proline-proline, have ACE-inhibiting properties. These milk-derived tripeptides have been shown to reduce BP by 4.8 and 2.2 mm Hg for systolic and diastolic BP, respectively.[41] Vitamin D, which is often added to milk, may also help reduce BP by reducing renin expression. At present, AHA and JNC 7 do not recognize dairy consumption as a dietary approach to the prevention and management of hypertension.[1] Nevertheless, low-fat dairy products are recommended as an integral part of the DASH diet.

Magnesium Intake, Other Micronutrients and Bioactive Food Components

A weak inverse relationship has been reported between dietary intake of magnesium and BP, but in a meta-analysis of 20 RCTs,[42] magnesium supplementation had an insignificant effect on BP.

Dietary Approaches to Stop Hypertension (DASH) Diet*				
Food Group	**Daily Servings**	**Serving Sizes**	**Examples and Notes**	**Significance to the DASH Diet Pattern**
Grains and grain products	7-8	1 slice bread ½ cup dry cereal ½ cup cooked rice, pasta, or cereal	Whole-wheat bread, muffin, pita bread, bagel, cereals, oatmeal	Major sources of calories and fiber
Vegetables	4-5	1 cup raw, leafy vegetables ½ cup cooked vegetables 6 oz vegetable juice	Tomatoes, potatoes, carrots, peas, squash, broccoli, turnip greens, kale, spinach, artichokes, green beans, sweet potatoes	Rich sources of potassium, magnesium, and fiber
Fruits	4-5	1 medium fruit ¼ cup dried fruit 6 oz fruit juice ½ cup fresh, frozen, or canned fruit	Apricots, bananas, dates, oranges, orange juice, grapefruit, grapefruit juice, mangoes, melons, peaches, pineapples, prunes, raisins, strawberries, tangerines	Important sources of potassium, magnesium, and fiber
Low-fat or nonfat dairy foods	2-3	8 oz milk 1 cup yogurt 1.5 oz cheese	Skim or low-fat (2%) milk, skim or low-fat buttermilk, nonfat or low-fat yogurt, nonfat or low-fat cheeses	Major sources of calcium and protein
Meats, poultry, and fish	≤2	3 oz cooked meats, poultry, or fish	Select only lean meats; trim away visible fats; broil, roast, or boil instead of frying; remove skin from poultry.	Rich sources of protein and magnesium
Nuts, seeds, and legumes	4-5/wk	1.5 oz or ⅓ cup nuts ½ oz or 2 tbsp seeds ½ cup cooked legumes	Almonds, mixed nuts, peanuts, walnuts, sunflower seeds, kidney beans, lentils, split peas	Rich sources of calories, magnesium, potassium, protein, and fiber

Table 35-2 Dietary Approaches to Stop Hypertension (DASH) diet. *The DASH eating plan shown is based on 2000 kcal/day. Depending on energy needs, the number of daily servings in a food group may vary from those listed. *(Modified from the Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure.)*

In contrast, the inverse association between fruit/vegetable intake and BP and other CV risk factors is well established. Epidemiologic evidence suggests that polyphenol compounds found in fruit may explain in part the cardioprotective properties of fruits. Intervention trials have shown that fruits containing relatively high concentrations of flavonols, anthocyanins, and procyanidins, such as pomegranate, purple grapes, and berries, were effective at reducing CVD risk factors. Regular consumption of flavonol-rich foods, cocoa products, tea, and red wine may reduce BP.[43]

Dietary Fats and Sugars

High intake of fructose present in table sugar and high-fructose corn syrup has been correlated with the epidemics of obesity, hypertension, metabolic syndrome, and diabetes. In animals, the intake of fructose but not of glucose or starch can rapidly induce features of the metabolic syndrome. In an experimental study, an intake of 200 g fructose daily in healthy overweight adult men caused a significant increase in systolic and diastolic BP, a rise in plasma triglycerides, a fall in high-density lipoprotein (HDL) cholesterol, and an increase in relative insulin resistance. Other studies have shown that a diet rich in fructose can increase intra-abdominal fat and cause insulin resistance, particularly in those who are already overweight. The pathogenesis of the hypertension may be related to the unique ability of fructose as a sugar to cause intracellular adenosine triphosphate (ATP) depletion and uric acid generation. Allopurinol has been found to block the BP increase with fructose in both humans and rats.[44] These studies suggest that excessive sugar intake could have a role in the metabolic syndrome, and that reduction of sugar intake could be beneficial. Interestingly, whole fruits, which also contain fructose, do not appear to cause metabolic syndrome, probably because of the lower fructose content and the presence of numerous antioxidants (e.g., vitamin C) that block the effect of fructose to induce insulin resistance.

In epidemiologic studies, substantial red meat intake (mean 103 g/day) is associated with a rise in systolic BP of 1.25 mm Hg.[45] Red meat intake has also been associated with an increased risk for diabetes. The mechanisms are unknown but may be related to the production of oxidants, inflammatory cytokines, or uric acid. Supplementation with omega-3 fatty acids reduces the risk of myocardial infarction (MI) and sudden cardiac death,[46] but their effect on BP is small. In a recent meta-analysis, omega-3 supplementation significantly reduced diastolic BP by a mean of 1.8 mm Hg but had no effect on systolic BP, fibrinogen level, or heart rate.[47] About 10 portions of oily fish per week or 9 or 10 fish oil capsules per day are required (equivalent to ~3 g/day long-chain n-3 fatty acids), and this is not tolerated by most because of belching and fishy taste. Concerns about the cholesterol content as well as dioxin and polychlorinated biphenyl (PCB) content (environmental pollutants that have carcinogenic potential and, being fat soluble, can accumulate in the body) of some fish oil supplements also raise questions about the safety of very large doses. As a guideline for overall health, individuals with hypertension should aim to consume about 2 to 3 portions (200 to 400 g) of oily fish (e.g., herring, kippers, mackerel, pilchards, sardines, salmon, trout, fresh tuna, swordfish) per week.

Dietary Approaches to Stop Hypertension (DASH) Diet

The DASH RCT provided unequivocal evidence that nonpharmacologic methods can reduce BP.[38] Participants receiving a diet rich in fruit and vegetables for 8 weeks had a greater reduction in systolic and diastolic BP (2.8 and 1.1 mm Hg, respectively) than did those receiving a typical American control diet. Those randomized to the DASH diet, rich in fruit, vegetables, and low-fat dairy products and with a reduced sugar and saturated and total fat intake, had an even greater reduction in both systolic and diastolic BP (5.5 and 3.0 mm Hg). The effects of the 8-week DASH diet were greatest in hypertensive African Americans, in whom the BP reduction was 13.2/6.1 mm Hg. Increased efficacy of the DASH diet in African Americans may reflect a greater response to the higher potassium,

calcium, and magnesium content of the diet in persons who have habitually low intake of these nutrients.

SMOKING

Cigarette smoking is a well-established major risk factor for CVD, but its role in the development of hypertension is not well elucidated and not routinely included in recommendations for prevention and treatment of hypertension.[1] The relationship with hypertension may be confounded by changes in weight during and after the cessation of smoking. In a large epidemiologic study of middle-aged and older men from the United States, smoking was associated with a modest but important risk for development of hypertension; but in a study of Turkish adults, current smoking carried a borderline protective effect, whereas former smokers with abdominal obesity had a higher risk of incident hypertension.[48,49] Nevertheless, smoking increases overall non-CV and CV morbidity and mortality, and all smokers should be advised to quit.

ALCOHOL

A linear relationship exists among alcohol consumption, BP levels, and prevalence of hypertension in populations.[50] In Japan, alcohol intake above 300 g/wk (about 3 drinks daily) was associated with significantly greater increases of BP during a 7-year period, and baseline BP was higher in drinkers consuming 200 g/wk, with the effects more marked in men.[51,52] Heavy drinking is associated with increased risk of stroke, increase in BP after alcohol withdrawal, and attenuation of antihypertensive efficacy. Paradoxically, alcohol has a J-shaped relationship with coronary heart disease, with moderate consumption (1 to 2 drinks daily) having the lowest risk. In a large epidemiologic study, modest alcohol consumption was protective against first MI.[53] Alcohol may increase BP through activation of the SNS, whereas its protective effects include increasing HDL cholesterol, lowering fibrinogen, and inhibiting platelet activation. The JNC 7 guidelines recommend limiting alcohol consumption to no more than 2 drinks per day (24 oz beer, 10 oz wine, or 3 oz 80-proof whiskey) in most men and no more than 1 drink per day in women or lighter-weight men (see Table 35-1).

CAFFEINE

Caffeine is the most widely used psychoactive substance worldwide. Caffeine stimulates the cardiovascular system through the blockade of vascular adenosine receptors.[54] In a meta-analysis of RCTs of coffee ingestion, there was no effect on BP or risk of hypertension, although the quality of the evidence was low.[55] Caffeine tablets may have a greater effect on BP.[56] Coffee may also increase CV risk in smokers,[57] whereas paradoxically, it may reduce the risk for metabolic syndrome and diabetes. The JNC 7 guidelines do not address the issue of caffeine, but it seems reasonable to propose that coffee consumption is safe, at least in nonsmokers, but that pharmacologic ingestion of caffeine and the use of "smart drinks" supplemented with caffeine should be avoided.

PSYCHOLOGICAL STRESS

Chronic psychological stress is an important contributor to the development and maintenance of hypertension. Men exposed to job strain had a 10.7 mm Hg and 15.4 mm Hg higher work and home ambulatory systolic BP than did controls, respectively.[58] The INTERHEART study showed that psychosocial stress was associated with a twofold increase in the risk of the first MI.[53] Nevertheless, stress reduction approaches have shown either negative or heterogeneous effects on BP.[59] As a result, JNC 7 offers no recommendations on stress reduction techniques for the management of hypertension.[1]

ADOPTING LIFESTYLE MODIFICATIONS

Compliance with lifestyle changes has always been a concern. The Prevention of Myocardial Infarction Early Remodeling (PREMIER) trial evaluated the effects of implementing JNC 7 lifestyle recommendations and the DASH diet.[60] Adults with prehypertension or untreated stage 1 hypertension were randomly assigned to one of three groups for 6 months: advice only, JNC recommendations, and JNC recommendations plus DASH diet. At 6 months, the JNC and JNC plus DASH groups had significantly reduced BP compared with the advice-only group, but there was little additional benefit of adding the DASH diet to JNC recommendations. However, participants purchased their own foods in the PREMIER study, instead of being provided with foods as in the DASH[38] and DASH low-salt diet[28] studies. Similarly, in the DASH low-salt diet study, the BP-lowering effect attributable to salt reduction was −6.7/−3.5 mm Hg; whereas in meta-analyses of 40 salt restriction trials in which participants prepared their own low-salt meals, this effect was only −2.54/−1.96 mm Hg.[61] Thus, in the outpatient setting, even highly motivated individuals usually cannot meet DASH dietary goals unless their meals are provided.

The TOHP II study demonstrated the problems of sustainability of dietary intervention and the need for regular counseling.[62] The effect of adding salt restriction to weight loss appeared to offer no further decrease in BP. Assessed by urinary sodium excretion, adherence to lower dietary sodium was poor in the long term. At 36 months of follow-up, mean urinary sodium was 40 mmol/24 hours lower than baseline in the sodium-restricted group, and only 21% achieved the target of less than 80 mmol/24 hours. A higher attendance at counseling sessions was associated with a greater reduction in urinary sodium. At 36 months, a decrease of 84 mmol/day of sodium from baseline levels could be achieved only in those who attended more than 80% of the counseling sessions. In summary, the sustainability of long-term lifestyle interventions remains problematic, but it appears that regular and long-term counseling can improve adherence.

CHAPTER 36

Pharmacologic Treatment of Hypertension

Bryan Williams

Successful lifestyle interventions can delay the development of hypertension (see Chapter 35), but the majority of patients with confirmed hypertension require lifelong drug treatment, usually with more than one drug. This has resulted in a multibillion-dollar industry, in which numerous pharmacologic agents have been introduced (Table 36-1). In turn, this creates complexity for clinicians in trying to decide which drugs would be the most effective option for specific patient groups. The following sections review who should receive pharmacologic treatment, what target blood pressures to attain, and how to decide on what pharmacologic agent to use.

DEFINING WHO SHOULD RECEIVE PHARMACOLOGIC TREATMENT

Blood pressure (BP) is distributed normally within populations, and thus "hypertension" is an arbitrarily defined, moving target with diagnostic thresholds subject to change as new evidence from clinical trials emerges. From a practical perspective, hypertension is best defined as *that level of blood pressure at which treatment to lower blood pressure results in significant clinical benefit*. This statement highlights the conundrum in defining hypertension because the risk associated with BP is a continuum, and the BP level at which treatment results in "significant clinical benefit" for any individual will depend on the absolute cardiovascular (CV) risk.[1-3] This varies because some people will be more vulnerable than others to end-organ damage at a given level of pressure. Defining that vulnerability case by case remains impractical, and thus differential BP targets and thresholds have emerged that group patients into categories defining their threshold BP for therapeutic intervention and optimal BP goals. In addition, specific drug classes have been given "compelling indications" and "compelling contraindications" for specific groups of patients. This has been useful in tailoring therapy from a wide range of drug classes but has sometimes been misinterpreted as indicating that the specific drug is more important than the achieved BP, which is not the case. The primary objective of therapy must always be to lower BP as effectively as possible.[4-6]

Blood Pressure Thresholds for Intervention (Office Blood Pressure)

There is substantial evidence that treating a seated "office" BP above a systolic pressure of 160 mm Hg and/or a diastolic pressure above 100 mm Hg reduces cerebrovascular accidents (strokes), myocardial infarction (MI), heart failure, and mortality.[4-10] There is also evidence that treating pressures above 140/90 mm Hg, especially in high-risk patients, is beneficial. Consequently, most recent guidelines define hypertension as an office BP of 140/90 mm Hg or higher.[7,8] The exception is the recent United States guideline (JNC VIII), which has adopted a treatment threshold of 140/90 mm Hg for adults aged younger than 60 years but recommends a more relaxed threshold for the diagnosis of hypertension (i.e., 150/90 mm Hg in those aged 60 years and older).[9] Various grades of hypertension have also been specified (Table 36-2). Previous guidelines from the United States (JNC VII) included a category of prehypertension to highlight those with borderline hypertension.[10] This was designed to encourage lifestyle change because the risk of progression from prehypertension to overt hypertension is very high. Furthermore, data from the Framingham heart study have shown that people with a "high normal" BP experience a doubling in risk of CV complications (Fig. 36-1).[11] Thus, prehypertension is not benign, and these people are almost certain to develop more severe hypertension without successful lifestyle intervention or drug therapy.

Clinical Dilemma of End-Organ Damage and "Normal" Blood Pressure

There is debate about treatment for people with prehypertension who already have evidence of end-organ damage, such as left ventricular hypertrophy (LVH), or microalbuminuria. This could be an example of the insensitivity of the defined thresholds for diagnosis of hypertension. Clearly, such a patient who has developed hypertensive LVH or microalbuminuria has a BP that is causing damage, but considered below the usual threshold for intervention. Thus, clinical understanding of the disease process is critical to enable the optimal use of guidelines for treatment decisions. There remains considerable uncertainty in the evidence base, and clinical judgment should not, and indeed cannot, be replaced by guidelines.

Blood Pressure Thresholds for Intervention (Ambulatory and Home Blood Pressure Monitoring)

Diagnostic thresholds for hypertension vary according to the method of measurement. Ambulatory blood pressure monitoring (ABPM) and home BP monitoring are increasingly advocated and used. When used to classify hypertension, the diagnostic thresholds are lower. The recent National Institute for Health and Clinical Excellence (NICE) guideline[8] in the United Kingdom has recommended the routine use of ABPM to confirm the diagnosis of hypertension because of high rates of white coat and masked hypertension (http://guidance.nice.org.uk/CG127). Table 36-3 summarizes the diagnostic thresholds for hypertension according to different methods of measurement (see also Chapter 33).

WHAT ARE THE BLOOD PRESSURE TREATMENT GOALS?

An area of great uncertainty has been the definition of the optimal BP treatment goals. As previously discussed, the ideal BP treatment goal is likely to be patient specific, but guidelines must be generalizable to populations. Thus, guidelines should be conservative and pragmatic, should curb the zeal of specialists to advocate ever lower BP goals, and should confine their recommendations to those supported by solid evidence. Until recently, there was international

consensus that two BP goals were appropriate: less than 140/90 mm Hg for those with "uncomplicated hypertension" and a lower goal of <130/80 mm Hg for those at higher risk, that is, patients with diabetes, established CV or cerebrovascular disease, or chronic kidney disease (CKD). To define such goals, ideally there should be randomized controlled trials (RCTs) with different groups of patients randomized to different BP treatment targets (i.e., "more versus less" BP control) to determine whether the more aggressive BP target is appropriate and safe. Despite the firm consensus on BP targets previously outlined, no large-scale RCTs have targeted more versus less systolic BP lowering, and only a small number have targeted more versus less diastolic BP lowering.[12,13] The guidelines were ahead of the evidence (Fig. 36-2).

In an attempt to obtain more data with regard to systolic BP lowering, the Cardio-Sis study showed that targeting treatment to a systolic BP of less than 130 mm Hg versus less than 140 mm Hg was more effective at preventing the development of electrocardiographically defined LVH and a composite CV outcome.[14] However, this is a single, relatively small study ($n = 1111$), and insufficient to justify a widespread application of a lower BP target of <130/80 mm Hg. An analysis of the baseline and in-treatment BP levels of patients at

Development of Therapeutic Strategies for Hypertension

Year	Nondrug Therapy
1920s	Strict low-sodium diet
1929	Lumbar sympathectomy
1944	Kempner rice diet
Year	**Drug Therapy**
1930s	Veratrum alkaloids
1940s	Thiocyanates
1948	Reserpine, phenoxybenzamine
1950	Ganglion blockers
1951	Monoamine oxidase inhibitors
1958	Thiazide diuretics (chlorothiazide)
1960s	Central α_2-receptor agonists, nondihydropyridine calcium channel blockers, and β-blockers
1970s	Angiotensin-converting enzyme (ACE) inhibitors, α_1-receptor blockers
1980s	Dihydropyridine calcium channel blockers
1990s	Angiotensin receptor blockers (ARBs)
2000s	Renin inhibitors, angiotensin receptor neprilysin inhibitor (ARNI)

Table 36-1 The development of therapeutic strategies for hypertension.

Diagnostic Thresholds for Hypertension

	Blood Pressure (mm Hg)	
Place/Time of Measurement*	***Systolic***	***Diastolic***
Office or clinic	140	90
24-hour	125-130	80
Day	130-135	85
Night	120	70
Home	130-135	85

Table 36-3 Diagnostic thresholds for hypertension according to different methods of measurement. **24-hour, day,* and *night* refer to average blood pressure (BP) measurements in those time periods recorded using ambulatory BP monitoring. *Home* refers to an average of at least 4 days of seated BP monitoring at home, usually twice daily (i.e., average of ~14 readings).

Classification of Hypertension According to Current Hypertension Guidelines

ESH/ESC Classification of Hypertension (2013)

Category	Systolic (mm Hg)		Diastolic (mm Hg)
Optimal	<120	and	<80
Normal	120-129	and/or	80-84
High-normal	130-139	and/or	85-89
Grade 1 hypertension	140-159	and/or	90-99
Grade 2 hypertension	160-179	and/or	100-109
Grade 3 hypertension	≥180	and/or	≥110
Isolated systolic hypertension	≥140	And	<90

Guideline	BP Threshold (mm Hg)	BP Goal (mm Hg)	Initial Therapy
U.S. JNC VIII Committee 2014	Age < 60 yr = 140/90 Age ≥ 60 yr = 150/90	<140/90 <150/90	Non-Black: Thiazide type diuretic, ACEi, ARB, CCB Black: Thiazide-type diuretic, CCB
ESC/ESH 2013	Age < 80 yr = 140/90 Age ≥ 80 yr = 150/90	<140/90 <150/90	Thiazide-type diuretic, β-blocker, ACEi, ARB, CCB
NICE U.K. 2013	Age < 80 yr = 140/90 Age ≥ 80 yr = 150/90	<140/90 <150/90	Non-Black Age < 55 yr: ACEi/AGB Non-Black ≥ 55 yr: CCB Black any age: CCB

Table 36-2 Blood pressure treatment thresholds, goals, and initial therapy choices according to most recent major international guidelines. Hypertension grades or stages replace the older terminology of mild, moderate, and severe. *ESH/ESC,* European Society of Hypertension/European Society of Cardiology; *ACE,* angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *BB,* β-blocker; *CCB,* calcium channel blocker; *DBP,* diastolic blood pressure; *SBP,* systolic blood pressure. *Treatment determined by highest blood pressure (BP) category. †Initial combined therapy should be used cautiously in those at risk for orthostatic hypotension. ‡Treat patients with chronic kidney disease (CKD) or diabetes to BP goal of less than 130/80 mm Hg.

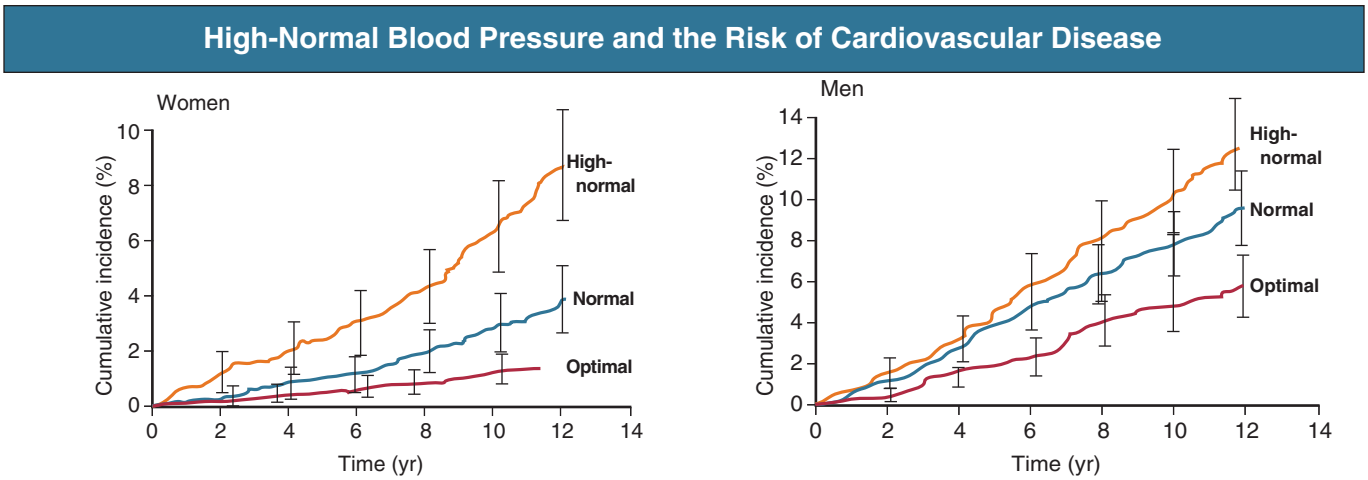

Figure 36-1 "High-normal" blood pressure (BP) and risk of cardiovascular disease. Cumulative incidence of cardiovascular events in women *(left)* and men *(right)* without hypertension, according to BP category at the baseline examination, showing 95% confidence intervals. For this analysis, "optimal" BP was defined as systolic pressure of less than 120 mm Hg and diastolic pressure less than 80 mm Hg; "normal" BP as systolic 120 to 129 or diastolic 80 to 84 mm Hg; and "high-normal" BP as systolic 130 to 139 or diastolic 85 to 89 mm Hg. *(Modified from reference 11.)*

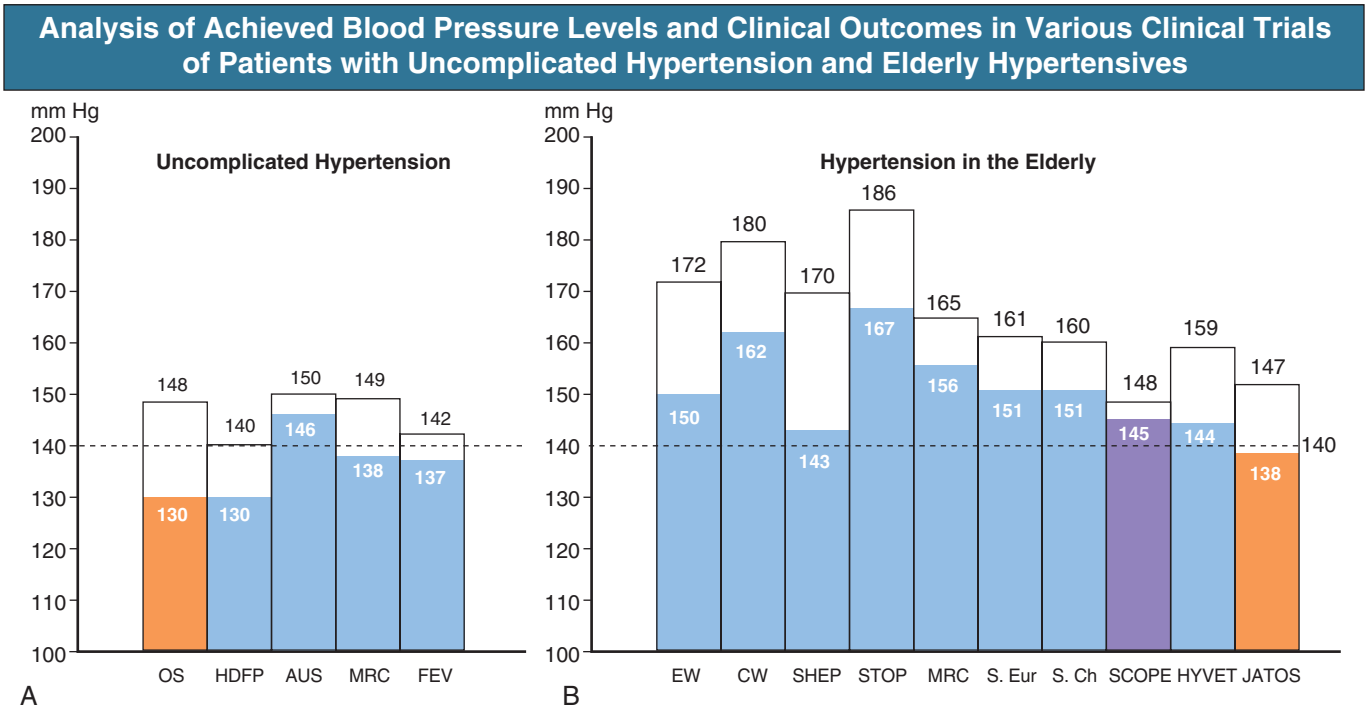

Figure 36-2 Analysis of achieved blood pressure (BP) levels and clinical outcomes in various clinical trials of hypertensive patients. A, Patients with uncomplicated hypertension. **B,** Elderly patients with hypertension. The abbreviations on the base axis refer to the trials for the source data. *Open rectangles* show less active BP lowering; *solid rectangles* show more active BP lowering. The achieved systolic BP values are shown; *orange rectangles*, no significant benefit of more active treatment; *blue*, significant benefit of more active treatment on major cardiovascular outcomes; *purple bar*, significant benefit limited to some secondary outcomes. Numbers refer to achieved mean systolic BP for less active versus more active treatment for each study. The *dotted line* shows the currently recommended systolic BP treatment target. *(Modified from reference 13.)*

high CVD risk in the ONTARGET trial suggests that for people with hypertension at baseline (i.e., systolic BP ≥140 mm Hg), the risk of major CV events and of stroke in particular was reduced with progressive BP lowering.[15] However, for those with a systolic BP of 130 mm Hg or less at baseline, there was much less evidence of benefit with further BP lowering and a signal of possible harm. The ACCORD trial tested the more (<120 mm Hg) versus less (<140 mm Hg) systolic BP lowering hypothesis in a high-risk population with type 2 diabetes.[16] The study failed to provide conclusive evidence that the more intensive BP treatment strategy reduced a composite of major CV events, although stroke rates were significantly reduced. This study appeared underpowered to test this hypothesis definitively.

Thus, although previous guidelines have advocated the more aggressive target of less than 130/80 mm Hg for all higher-risk patients, the evidence has always been weak, and more recent studies and analyses have generated concern about a "lower is better for all" approach. As a consequence, recent guidelines have retreated from

the "lower is always better" philosophy for BP goals. The European and U.K. NICE guidelines have adopted a single BP goal for most people with treated hypertension (uncomplicated or high risk) of less than 140/90 mm Hg, with a more conservative BP goal of less than 150/90 mm Hg for patients aged 80 years and older, based on the data from the HYVET study.[7,8,17] The recent U.S. JNC VIII guideline has adopted a much more conservative approach, consistent with their more conservative aforementioned BP thresholds for intervention. The JNC VIII guideline has recommended a BP goal of <140/90 mm Hg, similar to other guidelines, for those aged younger than 60 years but a BP goal of less than 150/90 mm Hg for those aged 60 years and older, with the caveat being those with diabetes and/or CKD, where a BP goal of <140/90 mm Hg is recommended.[9] Thus, the European and NICE BP goals for those aged 60 to 80 years are lower than those recommended for Americans in the same age group, a notable reversal of usual trends. All guidelines acknowledge that lower BP targets may be appropriate for higher risk patients, on a case-by-case basis, depending on the patient's ability to tolerate lower BP goals, with the caveat that the evidence supporting such a strategy is limited.

GUIDE TO SELECTION OF ANTIHYPERTENSIVE AGENTS

Key Principles from Clinical Trials

Aside from the limitations of the evidence defining optimal BP treatment targets, the pharmacologic treatment of hypertension has the most impressive evidence base in medicine to guide treatment decisions. BP lowering undoubtedly reduces morbidity and mortality, but nephrologists do not know "how low to go." Many large RCTs have compared different classes of active treatments with placebo and different treatment strategies with each other (see references 4 to 6 for overviews). Table 36-4 summarizes a detailed systematic review and analysis conducted for the UK NICE hypertension guideline development group in 2006 (http://www.nice.org.uk/CG034guidance), which compared and ranked the effectiveness of different classes of BP-lowering medication with regard to major CV events. The differences between the various drug classes on clinical outcomes are primarily driven by differences in the quality of BP control. Analysis of these trials has provided some important guiding principles with regard to treatment strategies for hypertension, as follows:

1. Effective BP lowering is overwhelmingly important in reducing the risk of major CV events in people with hypertension. Thus, the first priority in treatment is to control BP.
2. Early studies focused primarily on diastolic BP as the treatment target, but systolic BP is invariably more difficult to control and more closely linked to CV outcomes and should now be the primary but not the sole focus of treatment.
3. Monotherapy is rarely sufficient to control BP, and many patients will require more than one drug as part of their treatment strategy.
4. The response to any class of BP-lowering medication is heterogeneous; that is, some patients will respond better than others.
5. Some trials have indicated that certain comorbidities (e.g., diabetes) and target organ damage (e.g., LVH, CKD) provide compelling indications for inclusion of specific classes of drug therapy in the treatment regimen, but this consideration should not override the importance of BP control.
6. There are inadequate clinical outcome data for treatment studies of younger patients. Most studies, especially the more recent, have been conducted in patients older than 55 and typically with a mean age older than 65.
7. On average, lowering of BP by 20/10 mm Hg in hypertensive patients will reduce the risk of major CV events by half.
8. The reduction in stroke risk appears to follow the predicted reduction in risk based on the epidemiologic association between stroke and BP.
9. There appears to be a shortfall in the reduction in risk of coronary heart disease with BP lowering compared with epidemiologic predictions, which is best addressed by attention to concomitant risk factors.
10. The risk reduction associated with BP lowering appears to be continuous across a wide range of BPs; thus the absolute benefit from treatment is greatest in those with the highest absolute CVD risk. This provides the rationale for advocating the use of complementary strategies to reduce CVD risk (e.g., statins and antiplatelet therapy in those with established vascular disease, with target organ damage, or at high calculated CVD risk, i.e., ≥20% during 10 years).

Selection of Drug Therapy

The major classes of BP-lowering therapies are summarized here. International guidelines recommend certain indications and contraindications for the use of specific classes of BP-lowering therapy in specific clinical situations (Box 36-1 and Table 36-5). These lists are not comprehensive and are subject to change as new evidence emerges. Table 36-6 outlines the more common adverse effects associated with the major classes of BP-lowering drug therapies.

Relative Risk and Benefit of Antihypertensive Drug Classes

Outcome	Thiazide-Type Diuretics (D)	Calcium Channel Blockers (C)	β-Blockers (B)	ACE/ARBs* (A)
Unstable angina	0.89	0.88	0.98	0.97
Myocardial infarction	0.78	0.79	0.85	0.81
Diabetes	0.98	0.80	1.13	0.72
Stroke	0.69	0.65	0.85	0.73
Heart failure	0.53	0.73	0.76	0.64
Death	0.91	0.88	0.93	0.90

Table 36-4 Relative risk and benefit of drugs used to treat hypertension. Table shows effectiveness of drugs where 1.0 = no benefit/harm, <1.0 = benefit, and >1 = potential harmful effect, from a meta-analysis of major blood pressure–lowering trials conducted for the UK National Institute for Health and Clinical Excellence (NICE) Hypertension Guideline Development Group, 2006. *Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) were grouped as a single class for the purposes of this analysis. *(Modified from data in http://www.nice.org.uk/CG034guidance.)*

Clinical Indications Favoring Use of Specific Antihypertensive Medications

ACE Inhibitors
Heart failure
LV dysfunction
Post–myocardial infarction
Diabetic nephropathy
Nondiabetic nephropathy
LV hypertrophy
Carotid atherosclerosis
Proteinuria/microalbuminuria
Atrial fibrillation
Metabolic syndrome

Angiotensin Receptor Blockers
Heart failure
Post–myocardial infarction
Diabetic nephropathy
Proteinuria/microalbuminuria
LV hypertrophy
Atrial fibrillation
Metabolic syndrome
ACE inhibitor–induced cough

β-Blockers
Angina pectoris
Post–myocardial infarction
Heart failure
Tachyarrhythmias
Glaucoma
Pregnancy

Calcium Antagonists (Verapamil, Diltiazem)
Angina pectoris
Carotid atherosclerosis
Supraventricular tachycardia

Calcium Antagonists (Dihydropyridines)
Isolated systolic hypertension (elderly)
Angina pectoris
LV hypertrophy
Carotid/coronary atherosclerosis
Pregnancy
Hypertension in blacks

Thiazide Diuretics
Isolated systolic hypertension (elderly)
Heart failure
Hypertension (blacks)

Diuretics (Antialdosterone)
Heart failure
Post–myocardial infarction

Loop Diuretics
End-stage renal disease
Heart failure

Box 36-1 Clinical indications favoring the use of specific classes of BP-lowering medications in hypertensive patients. *ACE,* Angiotensin-converting enzyme; *LV,* left ventricular.

Contraindications to Specific Blood Pressure–Lowering Therapies

Pharmacologic Therapy	Contraindications	
	Compelling	***Possible***
Thiazide diuretics	Gout	Metabolic syndrome Glucose intolerance Pregnancy
β-Blockers	Asthma A-V block (grade 2 or 3)	Peripheral artery disease Metabolic syndrome Glucose intolerance Athletes, physically active patients COPD Asthma (use cardioselective β-blocker)
Calcium antagonists (dihydropyridines)		Tachyarrhythmias Heart failure
Calcium antagonists (verapamil, diltiazem)	A-V block (grade 2 or 3) Heart failure β-blocker therapy	
Angiotensin-converting enzyme inhibitors	Pregnancy Angioneurotic edema Hyperkalemia Bilateral renal artery stenosis	
Angiotensin receptor blockers	Pregnancy Hyperkalemia Bilateral renal artery stenosis	
Diuretics (antialdosterone)	CKD stages 4 and 5 Hyperkalemia	
Direct renin inhibitors	Pregnancy Hyperkalemia Bilateral renal artery stenosis	

Table 36-5 Compelling and possible contraindications to specific classes of BP-lowering therapies. *A-V,* Atrioventricular; *COPD,* chronic obstructive pulmonary disease.

Figure 36-3 shows the sites of mechanism of action of the various classes of BP-lowering drugs discussed.

Thiazide and Thiazide-like Diuretics

Thiazide diuretics were the first major class of drug used to treat hypertension. The class includes the traditional thiazide diuretics such as hydrochlorothiazide and bendroflumethiazide, as well as thiazide-like diuretics such as chlorthalidone and indapamide. The latter are termed *thiazide-like* because like the thiazide diuretics, these agents act primarily by inhibiting the Na^+-Cl^- cotransporter in the distal tubule of the kidney, promoting sodium excretion, which is integral to their antihypertensive effect. However, the thiazide-like diuretics have different structure to the classic thiazides and differing actions on other aspects of renal tubular function, such as carbonic anhydrase inhibition in the proximal tubule. The importance of the differentiation of the thiazide and thiazide-like diuretics will become apparent in this discussion.

Thiazide and thiazide-like diuretics remain an important therapeutic option for the treatment of hypertension. The early changes in salt and water balance induced by these diuretics are usually accompanied by counteractivation of several vasoconstrictor mechanisms, including the renin-angiotensin-aldosterone system (RAAS), which may transiently raise peripheral vascular resistance (PVR) and attenuate BP lowering. Subsequently, a gradual reduction in PVR and a new steady state of reduced total body sodium and BP are established, usually after about 2 months of treatment.

The sustained actions of thiazide-type diuretics on the kidney make them preferable to loop diuretics for the control of BP. Although loop diuretics are more potent with regard to promoting acute sodium and water loss, their shorter duration of action can result in compensatory sodium retention during the latter part of the dosing interval, thereby reducing their BP-lowering efficacy. Loop diuretics have no place in the routine management of primary hypertension in patients with a well-preserved glomerular filtration rate (GFR). However, thiazide-type diuretics lose efficacy in patients with a GFR below 30 ml/min. In such patients, loop diuretics are often required for effective BP lowering, especially when there is clinical evidence of sodium and water retention.

The main adverse effects of thiazide/thiazide-like diuretics are hypokalemia, hyponatremia (less frequently), impaired glucose tolerance, and small increments in blood levels of low-density lipoprotein (LDL) cholesterol and triglycerides. Thiazide-type diuretics also elevate serum uric acid levels and should be avoided in patients predisposed to gout, as well as in those receiving lithium because of a high risk of lithium toxicity. Lithium is reabsorbed similar to

Common Side Effects Associated with Various Classes of Antihypertensive Drugs

Drug Class	Side Effects
ACE inhibitors	Cough, hyperkalemia
ARBs	Much less frequent hyperkalemia compared to ACE inhibitors
CCBs	
DHP CCBs	Pedal edema, headache
Non-DHP CCBs	Constipation (verapamil), headache (diltiazem)
Diuretics	Frequent urination, hyperglycemia, hyperlipidemia, hyperuricemia, sexual dysfunction
Central α-agonists	Sedation, dry mouth, rebound hypertension, sexual dysfunction
α-Blockers	Pedal edema, orthostatic hypotension, dizziness
β-Blockers	Fatigue, bronchospasm, hyperglycemia, sexual dysfunction
Potassium [K^+] channel openers	Hypertrichosis (minoxidil); lupus-like reactions, pedal edema (hydralazine)

Table 36-6 Common side effects associated with various classes of antihypertensive drugs. *ACE,* Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *CCBs,* calcium channel blockers; *DHP CCBs,* dihydropyridine calcium channel blockers; *non-DHP CCBs,* nondihydropyridine calcium channel blockers.

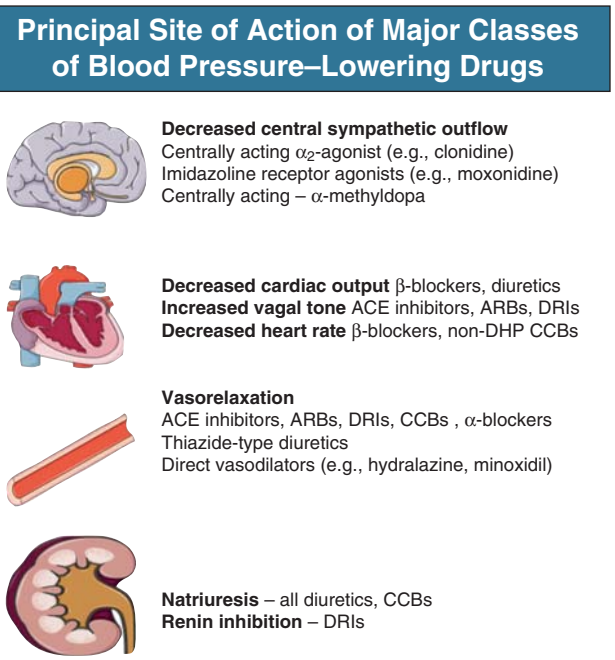

Figure 36-3 Principal site of action of major classes of blood pressure (BP)–lowering drugs. *ACE,* Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *CCBs,* calcium channel blockers; *DRIs,* direct renin inhibitors; *non-DHP CCBs,* nondihydropyridine calcium channel blockers.

sodium through the proximal tubule, and thus distal sodium loss caused by thiazides can promote proximal reabsorption of sodium and lithium; because lithium has a narrow therapeutic window, this can lead to lithium toxicity. An incidental advantage of thiazide-type diuretics may be reduction in osteoporosis as a result of calcium retention.

There has been a trend during recent years to reduce the recommended dose of thiazide-type diuretics to minimize their adverse metabolic effects. The dose-response to thiazide-type diuretics is flat (unlike the adverse effect profile), and this has been used to justify the low-dose strategy. However, some patients respond well to higher doses of thiazide-type diuretics, which they tolerate. Moreover, when thiazides are combined with drugs that block the renin-angiotensin system (RAS), such as angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), the dose-response curve is steeper, and higher doses (e.g., hydrochlorothiazide 25 to 50 mg or chlorthalidone 25 mg) may be especially effective in patients with more resistant hypertension. The recent NICE hypertension guideline reviewed the evidence for clinical outcome benefits with low dose thiazide and thiazide-like diuretics and has recommended the preferred use of thiazide-like diuretics such as chlorthalidone and indapamide, rather than traditional thiazides such as hydrochlorothiazide because there is limited outcome data with the latter when used at low dose.[10]

Potassium-Retaining Diuretics (e.g., Spironolactone, Amiloride, Eplerenone) Spironolactone is an aldosterone receptor antagonist that acts in the renal distal tubule and collecting ducts, decreasing the reabsorption of sodium and water and decreasing the excretion of potassium. The main action of spironolactone is to decrease the tubular expression of epithelial sodium channel (ENaC) and renal outer medullary potassium (ROMK) channels, and thus it has a relatively slow onset and offset of action. Because its main site of action is on sodium and water handling in distal tubule and collecting ducts, spironolactone is a relatively weak diuretic. Nevertheless, it is effective as a BP-lowering agent but currently rarely used for the initial routine treatment of hypertension. Spironolactone has the advantage over thiazide-type diuretics that it does not cause hypokalemia or hyperuricemia, and it does not impair glucose tolerance. However, spironolactone has antiandrogen activity by binding to the androgen receptor and preventing it from interacting with dihydrotestosterone. Consequently, it can cause nipple tenderness and gynecomastia in some male patients (~6%), which is dose dependent and can limit its use. Another concern with potassium-sparing diuretics in general is the risk of hyperkalemia in people with substantially reduced GFR (see later discussion).

Eplerenone is more selective for the aldosterone receptor than spironolactone and thus avoids its antiandrogen effects. There is very limited experience with use of eplerenone for the routine management of hypertension. Empirically, milligram per milligram, eplerenone is less potent than spironolactone and less effective at lowering BP.

Amiloride is an antagonist of the ENaC in the distal convoluted tubules and collecting ducts of the kidney, decreasing sodium and water reabsorption and promoting potassium excretion. Previously, amiloride was a popular treatment of primary hypertension, when, like spironolactone, it was often used in combination with thiazide-type diuretics. Amiloride is less used now even though it shares the advantage of spironolactone over thiazide-type diuretics of not causing hypokalemia, hyperuricemia, or impaired glucose tolerance. Amiloride is the treatment of choice in patients with Liddle syndrome who have hypertension caused by a gain-of-function mutation of ENaC.

The reason for the decline in popularity of potassium-sparing diuretics for the initial treatment of primary hypertension is not clear; it may reflect the emergence of ACE inhibitors or ARBs. These RAAS blockers are increasingly used for the routine management of hypertension, and there is an increased risk of hyperkalemia when these are combined with spironolactone or amiloride, especially in patients with renal impairment. Spironolactone and amiloride are,

however, increasingly used as additional diuretic therapy as part of a multidrug strategy for the treatment of patients with resistant hypertension, for whom these drugs can be very effective.[18-20]

β-Adrenoceptor Blocking Drugs

β-Blockers reduce BP and CV events in patients with hypertension. Most β-blockers, with the exception of those with strong intrinsic sympathomimetic activity, reduce cardiac output by their negative chronotropic and inotropic effects. As with diuretics, short-term hemodynamic responses can be offset by counteractivation of vasoconstrictor mechanisms, which may limit initial BP lowering. Longer-term reduction in arterial pressure occurs because of restoration of PVR to pretreatment levels. Partial blockade of renin release from the kidney may contribute to the later hemodynamic response.

The β-blockers differ in their duration of action, selectivity for β_1 receptors, lipophilicity, and partial agonist activity. Side effects include lethargy, aches in the limbs on exercise, impaired concentration and memory, aggravation of depression and psoriasis, erectile dysfunction, vivid dreams, and exacerbation of symptoms of peripheral vascular disease and Raynaud syndrome. Nonselective β-blockers are contraindicated in asthma patients and can cause adverse metabolic effects, including impaired glucose tolerance and worsening of dyslipidemia, notably reduced high-density lipoprotein (HDL) cholesterol and raised triglyceride levels. There is accumulating evidence that β-blockers increase the likelihood of new-onset diabetes, particularly in combination with thiazide-type diuretics.[21,22] Moreover, recent meta-analyses suggest that there is a shortfall in CV protection with β-blocker–based treatment of hypertension (especially in stroke reduction) compared with treatment with other major drug classes[10,23,24] (see Table 36-4). As a consequence, the UK guidelines have suggested since 2006 that β-blockers are no longer preferred as an initial therapy for routine hypertension and should be used only when there is a compelling indication other than BP control (e.g., in patients with hypertension and angina or chronic heart failure).[10]

One caveat is in younger women of childbearing potential, in whom β-blockers are often effective at lowering BP and are safer than ACE inhibitors or ARBs in women anticipating pregnancy. The generally good BP-lowering efficacy in younger people most likely reflects the higher renin levels in younger than in older people, and the BP-lowering action of β-blockers, at least in part, relates to suppression of renin release. Newer β-blockers have associated α-blocking activity, such as carvedilol and nebivolol. However, no clinical outcome trial data exist for the treatment of hypertension with these agents. The recent ESC/ESH guideline did not come out quite so strongly against β-blockers but did not specifically endorse these agents as a preferred initial treatment, or as an ideal drug in combination with other treatments, compared with other options for combination therapy.[8] The U.S. JNC VIII committee guidelines, like the U.K. NICE guidance, no longer cite β-blockers as a preferred initial therapy for hypertension unless there are specific indications for their use, other than the routine lowering of BP.[9]

Calcium Channel Blockers

Calcium channel blockers (CCBs) are effective at reducing BP and have an extensive evidence base supporting their use for the treatment of hypertension.[4,6] In addition to their BP-lowering properties, CCBs are also effective antianginal agents. They appear to be metabolically neutral with regard to glucose tolerance and lipid parameters. More recent data have highlighted that CCBs are especially effective at smoothing BP variability. Increased BP variability is an independent risk factor for stroke, which may explain why systematic reviews have shown CCBs (particularly amlodipine) to be the most cost-effective treatment option for hypertension, mainly because they are the most effective agent at preventing stroke.[10] An interesting aspect of the BP response to CCBs is that it is largely determined by the magnitude of BP elevation, perhaps more so than with other drugs. Thus, patients with higher baseline BP levels experience greater BP lowering with CCBs, whereas those with only modest elevations of BP experience much smaller decreases in BP. This property may also explain the "smoothing" effect of CCBs on BP variability.

There are two main groups of CCBs, the *dihydropyridines* (e.g., amlodipine, nifedipine) and the *nondihydropyridines* (e.g., diltiazem, verapamil). The dihydropyridine (DHP) CCBs act mainly by inducing relaxation of arterial smooth muscle by blocking L-type calcium channels, thereby inducing peripheral vascular relaxation with a fall in PVR and arterial pressure. Nondihydropyridine (non-DHP) CCBs block calcium channels in cardiac muscle and reduce cardiac output. Verapamil has an additional antiarrhythmic action through its effects on the atrioventricular node. Physicians have occasionally combined DHP and non-DHP CCBs, but no robust data are available on the BP-lowering efficacy of this approach or on clinical outcomes, and it is not a recommended combination therapy in international guidelines.

Earlier formulations of some DHP CCBs, such as capsular nifedipine, had a rapid onset and a short duration of action, with unpredictable effects on BP. These responses were often accompanied by reflex sympathetic stimulation and tachycardia. The shorter-acting oral preparations of CCBs have no place in the routine management of hypertension. More modern, longer-acting formulations of DHP CCBs produce more sustained and predictable responses.

Side effects of DHP CCBs include dose-dependent peripheral edema, which is not caused by fluid retention but by transudation of fluid from the vascular compartments into the dependent tissues as a result of precapillary arteriolar dilation. This edema does not respond to diuretic therapy but is alleviated by limb elevation. There is emerging evidence that this edema may also be reduced by coadministration of an ACE inhibitor or ARB because of its effects on venous capacitance. Gum hypertrophy can occur with DHP CCBs but is rarely seen with non-DHP CCBs. Nondihydropyridine CCBs cause less peripheral edema but are negatively inotropic and negatively chronotropic and should therefore be avoided in patients with compromised left ventricular function and in combination with β-blockers. Verapamil use is commonly accompanied by constipation.

Blockade of Renin-Angiotensin System

The RAS has become a popular target for drug development to treat hypertension. Inhibition of RAS is predictably effective at lowering BP by inhibiting the various central and peripheral pressor effects of angiotensin II (Ang II). Blockade of RAS may also lower BP by other mechanisms involving improvements in endothelial function, vagal tone, and baroreceptor function and through inhibition of the renal tubular reabsorption of sodium. In addition, inhibition of RAS has been popularized by clinical trial evidence showing reduced morbidity and mortality in patients with heart failure, delayed progression of renal disease, and reduced CV events in those at high CV risk with treatment strategies that involve inhibition of RAS.[6] Three classes of drugs are now available that directly target the RAS (Fig. 36-4): ACE inhibitors, ARBs, and a new class, the direct renin inhibitors (DRIs).[25]

Angiotensin-Converting Enzyme Inhibitors ACE inhibitors were the first effective strategy to inhibit RAS and have been used to

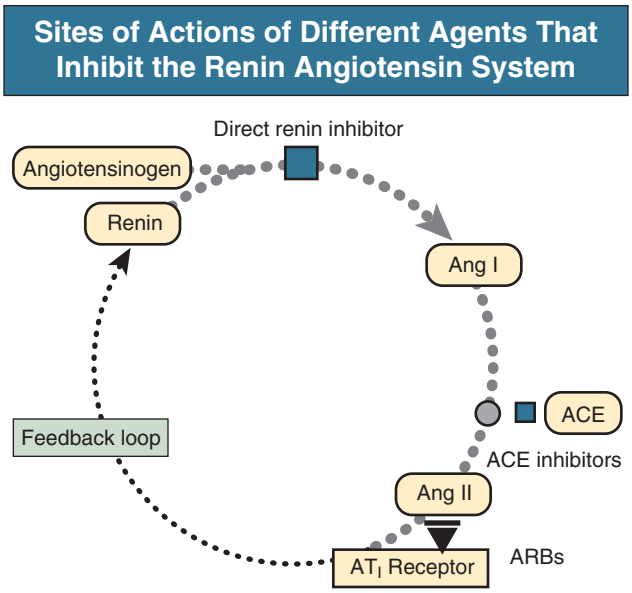

Figure 36-4 Sites of actions of different agents that inhibit the renin-angiotensin system. The resulting neurohumoral profile is also shown. *ACE,* Angiotensin-converting enzyme; *Ang,* angiotensin; *ARB,* angiotensin receptor blocker; *DRI,* direct renin inhibitor.

treat hypertension since the late 1970s. ACE inhibitors block the conversion of Ang I to Ang II by inhibiting ACE. The resulting reduction in levels of Ang II leads to vasodilation and a fall in BP. Ang II has many additional actions that are potentially harmful to the CV system and has been implicated in the pathogenesis of structural changes in the heart, blood vessels, and kidneys in hypertension. Sharp falls in BP after the introduction of ACE inhibitors may occur when the RAS is activated, for example, in patients who are dehydrated, in heart failure, or with accelerated hypertension. This is rarely a problem when therapy is initiated in uncomplicated hypertensive patients.

Side effects of ACE inhibitors include the development of a persistent dry cough in about 20% of users. This is more common in women and in people from the Far East and Pacific Rim. The cough disappears only after discontinuation of the drug. Another rare but important complication is angioedema, which occurs in about 1% and is much more common in the black population (~4%). ACE inhibitors should be avoided in women of childbearing potential because of the danger of fetal malformation, especially from exposure in the first trimester, when women may be unaware they are pregnant. ACE inhibitors should not be used in patients with significant bilateral renal artery disease because they may precipitate deterioration in renal function and renal failure. Careful monitoring of renal function and serum potassium concentration is also required in patients with more advanced renal impairment of any cause, because of the risk of hyperkalemia.

Angiotensin Receptor Blockers In the 1990s, ARBs emerged as an alternative to ACE inhibition. ARBs are highly selective inhibitors of the Ang II type 1 receptor (AT_1). In common with ACE inhibitors, ARBs inhibit the actions of Ang II on the CV system and kidney. ARBs reduce BP as effectively as ACE inhibitors but generally have a longer duration of action than ACE inhibitors. When ACE inhibitors and ARBs have been compared, they appear to be equally effective in reducing albuminuria and preserving GFR,[26] as well as similar in efficacy for preventing major CV events in patients with established CVD.[27] Because of their selectivity and specificity for the AT_1 receptor, the ARBs are well tolerated by patients, with a placebo-like adverse effect profile. Moreover, cough and angioedema are much less likely to occur with ARBs than with ACE inhibitors, and most guidelines recommend switching patients to an ARB when an ACE-induced cough occurs. Cautions and contraindications are similar to those outlined for ACE inhibitors.

Direct Renin Inhibitor A third strategy recently emerged to inhibit RAS for the treatment of hypertension: the first nonpeptide, orally active direct renin inhibitor (DRI), aliskiren.[25] Aliskiren has high specificity for renin and is a potent inhibitor of plasma renin activity with a long half-life (~24 hours). Aliskiren inhibits the rate-limiting step in angiotensin production, notably the renin-dependent conversion of angiotensinogen to Ang I. The DRI appears to have BP-lowering efficacy similar to that of other means of inhibiting the renin system (i.e., ACE inhibitors, ARBs) but with less side effects than ACE inhibitors.[26] The contraindications to use are similar to those for ACE inhibitors and ARBs. The main factor differentiating the DRI from ACE inhibitors or ARBs is that ACE inhibitors or ARBs activate plasma renin activity, whereas the DRI inhibits plasma renin activity. Aliskiren also has a much longer duration of action than the other forms of RAAS blockade. The ALTITUDE trial tested the efficacy of aliskiren at reducing CV and renal events when added to preexisting RAS blockade in patients with type 2 diabetes and high CVD risk.[28] The study was discontinued for futility and a signal of potential increased risk of harm when aliskiren was combined with another RAS blocker in this high-risk group of patients. Thus, aliskiren remains as a strategy for RAS blockade to treat hypertension, but the DRI should not be used in combination with either an ACE inhibitor or ARB in patients with diabetes or renal impairment. Further studies are ongoing.

α-Adrenergic Blocking Drugs

The original members of the α-adrenergic blocking class (e.g., prazosin) were short-acting drugs that blocked the activation of α_1-adrenoceptors in the vasculature, leading to vasodilation. Initially, the recommended dosage was too high, and postural hypotension and syncope proved serious problems that hindered the acceptance of this class of drugs, although the use of lower doses and the development of longer-acting agents (e.g., doxazosin) have largely overcome this problem. Blockade of sphincteric receptors improves symptoms in patients with benign prostatic hypertrophy. On occasion, these same sphincteric effects can worsen symptoms of stress incontinence in women. Uniquely among antihypertensive drugs, the α_1-antagonists produce modest favorable changes in plasma lipids, with a reduction in total and LDL cholesterol and triglyceride levels and an increase in HDL cholesterol.

Centrally Acting Sympatholytic Drugs

Some of the earliest drugs developed to treat hypertension targeted the activation of the sympathetic nervous system (SNS) at various levels, including the CV regulatory nuclei in the brainstem, the peripheral autonomic ganglia, and the postganglionic sympathetic neuron. Few of these agents have any residual role to play in the modern treatment of hypertension because side effects are common, and their use has been superseded by classes of drugs with a more tailored mechanism of action.

Methyldopa reduces sympathetic outflow from the brainstem. Originally developed in the late 1950s, methyldopa was a mainstay of antihypertensive therapy for many years. However, it frequently causes sedation, impaired psychomotor performance, dry mouth, and erectile dysfunction. Its unfavorable impact on quality of life resulted in methyldopa being gradually replaced by more effective drugs, although it is still extensively used in the management of hypertension of pregnancy, which is now its main indication.

Clonidine is now rarely used because of its short duration of action and risks of a withdrawal syndrome, which occurs when sudden discontinuation results in a rebound rise in catecholamines with features that may resemble pheochromocytoma, such as severe hypertension, tachycardia, and sweating. This is exacerbated when patients are also receiving nonselective β-blockers such as propranolol. The syndrome is treated by readministration of the drug and then gradual discontinuation or the intravenous infusion of labetalol in an emergency. Clonidine is still used and can be effective in some patients with drug-resistant hypertension. Longer-acting preparations of clonidine are being developed and may find a place in the management of resistant hypertension.

A newer centrally acting agent, *moxonidine* is an imidazoline receptor agonist that reduces sympathetic outflow and BP. It has a lower incidence of side effects and is better tolerated than other centrally acting agents. Moxonidine has no clinical trial evidence to support its use as a preferred first-line agent but is used in patients with more resistant hypertension.

Direct Vasodilators

Hydralazine was previously extensively used as part of the original "stepped care" treatment regimens for hypertension. The main disadvantages were sympathetic activation and the development of a lupus-like syndrome, particularly in patients with the slow acetylator genotype. Also, multiple daily dosage was required. Hydralazine is no longer recommended as a first-line agent for hypertension management. It is still occasionally used in severe hypertension and hypertension associated with pregnancy.

Minoxidil is a potent vasodilator, and its use is largely confined to specialist centers for the treatment of severe and resistant hypertension. This is because of its side effect profile, which includes stimulation of body hair growth; tachycardia and severe fluid retention reflect its potent vasodilator action and concomitant reflex SNS activation. For this reason, minoxidil is usually combined with a potent loop diuretic and a β-blocker as part of a triple-therapy approach to severe hypertension. Long-term use can be associated with insidious development of peritoneal and pericardial effusions (especially in patients with impaired renal function). These necessitate and respond to treatment withdrawal.

Treatment Strategies

Given the multiple drug classes for the treatment of hypertension, there is a need for a treatment strategy that identifies the preferred drugs for initial therapy and preferred combinations for patients requiring more than monotherapy to control their BP. The use of drug therapy to lower BP should usually follow a period of observation and repeated measures of BP to ensure that there is a sustained elevation of BP that merits treatment. The duration of the observation period is inversely related to the severity of hypertension. This ranges from immediate treatment to repeated measurement over days or months.

Lifestyle interventions should be initiated during this period of observation and continued even if treatment with drug therapy is initiated (see Chapter 35). This is important because the actions of drug therapy can often be potentiated by concomitant lifestyle changes, especially body weight reduction and reduction in dietary sodium intake.[29] Furthermore, lifestyle changes are also important to improve the overall health and CV risk profile of the patient, beyond the impact on BP. Another key aspect of the initial assessment of patients is to identify concomitant risk factors, comorbidities, and target organ damage, all of which might influence the selection of drug therapies to improve BP control.

Initial Drug Therapy

Current practice is to initiate treatment with a single drug. Depending on the BP level at baseline, monotherapy will on average reduce systolic pressure by 7 to 13 mm Hg and diastolic pressure by 4 to 8 mm Hg; the greater reductions will generally be observed in those with the highest baseline BP.[30] It is emphasized that these are "average BP responses," and there can be marked heterogeneity in response among individual patients and with different classes of drugs in individual patients. Treatment should normally commence with a low dose of the drug selected. If this is inadequate, there is the following range of options:

1. If BP responds to low-dose monotherapy and is not yet controlled but is likely to be controlled with monotherapy (i.e., BP within ~10/5 mm Hg of BP goal), the dose of the initial drug should be titrated upward.
2. If the BP response to the initial low dose is inadequate and the patient's BP remains well short of the target BP, a more appropriate action is to add a second drug, either separately or as a combination tablet, because the majority of patients will require two or more drugs to control their BP.
3. If the initial drug produced a weak response or no response at all and the patient could conceivably achieve the BP goal with monotherapy, the first drug could be discontinued and replaced with another class of antihypertensive agent.

Choice of Initial Therapy There was previously wide variation in international guidelines with regard to the preferred initial therapy for primary hypertension. The previous U.S. JNC VII report recommended low-dose thiazide diuretic therapy as initial therapy for all, unless contraindicated. The recent report from the U.S. JNC VIII committee has changed that stance and has recommended initial therapy with an ACE-inhibitor, ARB, a low-dose thiazide-type diuretic, or a CCB for non-black patients. The recommendation for initial therapy for black patients is either a thiazide-type diuretic or CCB.[9]

The most recent European guideline recommends that five major classes of BP lowering drugs—ACE-inhibitor, ARB, low-dose thiazide-type diuretics, CCBs, or β-blockers—are suitable as initial therapy, guided by the specific indications shown in Box 36-1 and Table 36-5.[7] The U.K. NICE guideline adopts a different approach and suggests that both age and ethnicity are important determinants of the BP response to initial therapy,[8] the latter now also adopted by the U.S. JNC VIII guideline. The rational for this approach is that the renin-angiotensin system is usually more active in younger people and less so in older people and black people at any age. Thus, the U.K. NICE guideline recommends initial therapy with and ACE-inhibitor or ARB in non-black patients aged younger than 55 years and a CCB as the preferred initial therapy for most patients aged 55 years and older. For black patients at any age, the U.K. NICE guidence recommends a CCB as the preferred initial therapy. The caveats to these recommendations are (1) that a thiazide-type diuretic may be preferred to a CCB where a CCB is not tolerated or in those with signs of heart failure or at high risk of heart failure (e.g., the very elderly) and (2) that an ACE-inhibitor or ARB should not be used in women of child-bearing potential, when instead a β-blocker may be preferred. Thus, the U.S. JNC VIII has moved much closer to the U.K. (see Fig. 36-7). NICE and European guidelines with regards to initial therapy choices. Moreover, like the U.K. NICE guidelines, the U.S. JNC VIII committee have recommended against the preferred use of β-blockers as initial therapy for hypertension, unless there is a specific indication for their use (e.g., in patients with chronic heart failure, symptomatic angina, or post-myocardial infarction). The reason for this is that the JNC VIII committee agreed with the assessment of the U.K. NICE conclusions

that β-blockers (1) appear less effective than alternative drugs at reducing the risk of stroke, (2) were no more effective than other drugs at preventing incident ischemic heart disease, (3) were more likely to increase the risk of developing type 2 diabetes, especially when combined with diuretic therapy, and (4) were as a consequence, the least cost-effective option for the initial treatment of primary hypertension.[8,24]

Combination Therapy for Controlling Blood Pressure

The U.S. JNC VIII committee has recommended ACE-inhibitor or ARB with CCB and/or thiazide-type diuretic, for the preferred dual and triple therapy combinations. This is now very similar to the prior U.K. NICE recommendations, with the caveat that U.K. NICE guidance was the first to give explicit guidance for the use of ACE-inhibitor or ARB with a CCB (A+C) as the preferred two-drug combination for most people, while accepting that an ACE-inhibitor or ARB with a low-dose thiazide-type diuretic is a suitable alternative when a diuretic has been used as initial therapy (see Fig. 36-5). The recommendation for the preferred use of A+C by the U.K. NICE guideline was supported by the ACCOMPLISH trial, which specifically evaluated whether the type of two-drug combination was important in influencing clinical outcomes by comparing two different single pill combinations, an ACE-inhibitor with a CCB versus the same ACE-inhibitor combined with a low-thiazide diuretic, in a high-risk group of patients.[31] There was a significant (~20%) reduction in the primary end point in favor of the ACE-inhibitor-CCB combination, and all components of the primary composite en-point showed this trend. Moreover this outcome was not determined by any obvious difference in BP control between the two treatment groups. These data from ACCOMPLISH, alongside the wealth of data from ACE-inhibitor or ARBs in combination with low-dose thiazide diuretic therapy, provide two excellent evidence-based options to combine with either an ACE-inhibitor or ARB as a two-drug combination therapy (i.e., A+C or A+D, with the use of A+C+D when a three-drug combination is required in more resistant hypertension). Thus, there is strong alignment between the U.K. NICE and JNC VIII committee guidance on preferred combination therapy for most patients at steps 2 and 3 of the treatment algorithm. In fact, distilling the down European guideline to only the solid green lines (see Fig. 36-6) (i.e., the preferred combinations), the preferred combinations are also similar to the U.S and U.K. guidance (i.e., A+C or A+D, and A+C+D when required). The only difference is that the European guideline also endorses another step 2 combination, that is, a CCB + thiazide-type diuretic, which has been effective in some trials but is rarely used because it eliminates RAS blockade, which many would consider complementary to either a CCB or thiazide-type diuretic to both lower BP and prevent reflex activation of the RAS system, which would otherwise occur with a C+D combination. What is clear is that all guidelines have converged and are closer than they have ever been with regard to preferred initial and combination therapies.

Initial Therapy with a Two-Drug Combination "Low-dose" two-drug combination therapy has been recommended in the European and American hypertension guidelines for the treatment of patients whose BP is more than 20/10 mm Hg above their goal BP

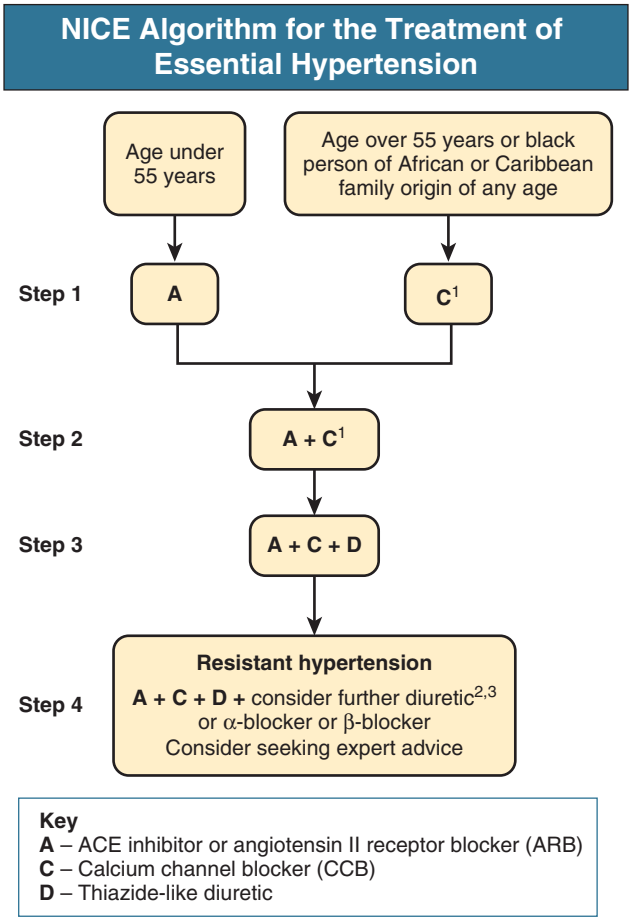

Figure 36-5 Algorithm for treatment of essential hypertension. UK National Institute for Health and Clinical Excellence (NICE) guidelines: [1]CCB is preferred, but consider a thiazide-like diuretic (chlorthalidone or indapamide) if a CCB is not tolerated or the patient has edema, heart failure or is at high risk of developing heart failure; [2]consider low-dose spironolactone; [3]higher doses of the thiazide-like diuretic. *(Modified from reference 8.)*

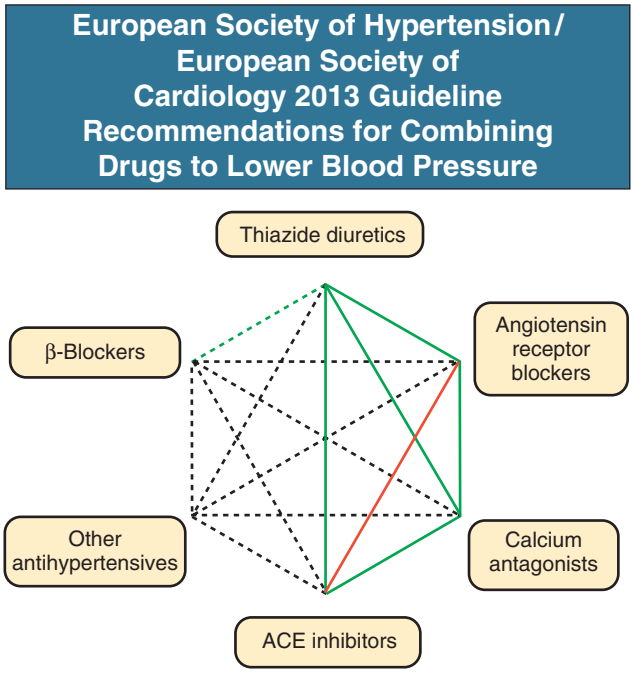

Figure 36-6 ESH/ESC recommendations for combining drugs to lower blood pressure. *Green continuous lines* are the preferred combinations, *green dashed line* is considered a useful combination but with some limitations, *black dashed line* are possible but less well tested combinations; and the *red line* is not recommended as a combination treatment for hypertension; *ACE,* angiotensin-converting enzyme. *(From reference 7.)*

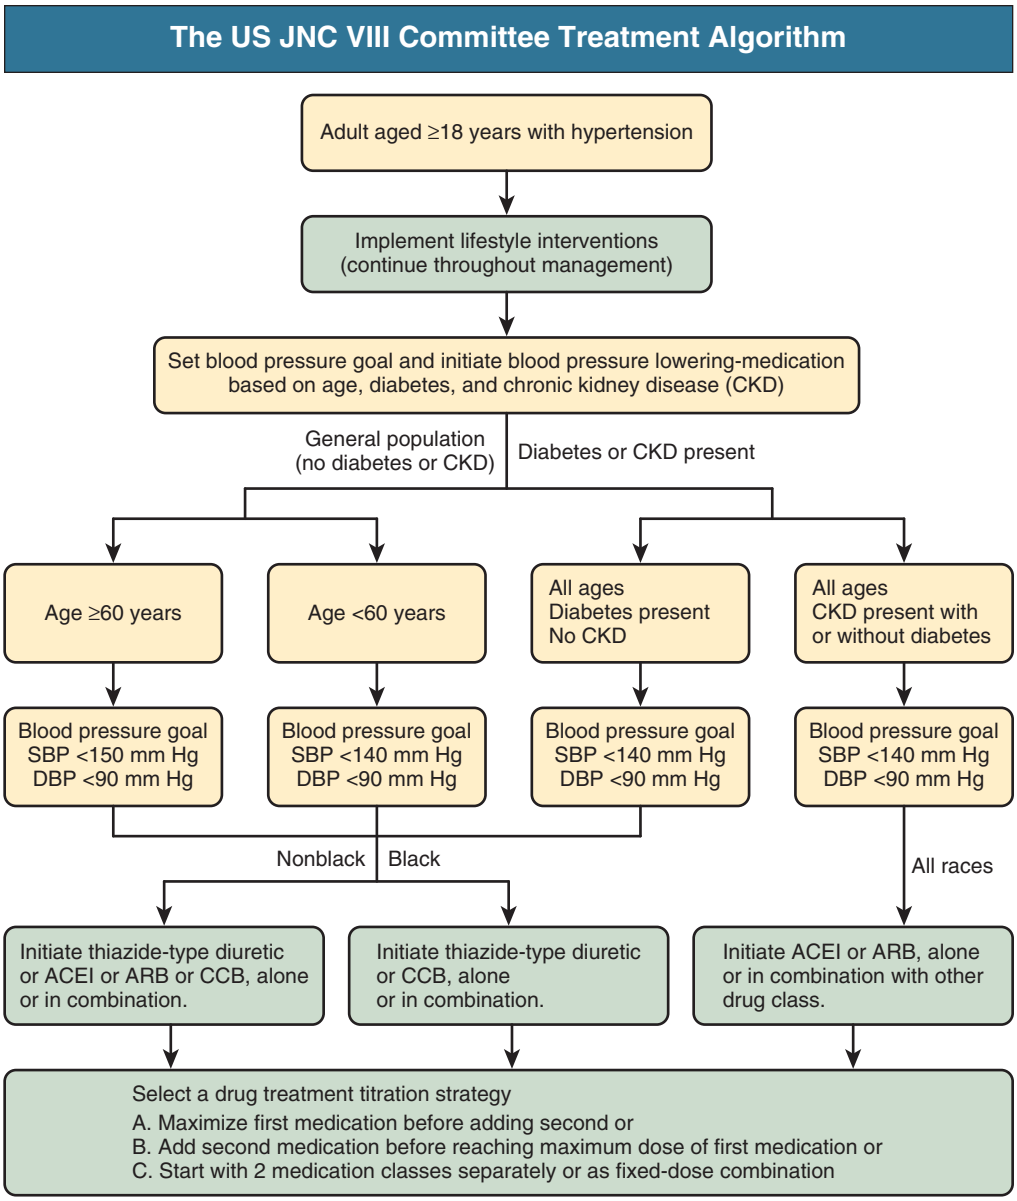

Figure 36-7 **The U.S. JNC VIII Committee treatment algorithm.**

and therefore unlikely to be controlled with monotherapy. The concept of initial therapy with a two-drug combination has in part been driven by concern that the upward titration of treatment in people at high risk may be too slow and leave them at risk for too long. A two-drug combination is also logical because the response to a single drug is often limited by counteractivation of pressor systems that limit the effectiveness of monotherapy. This also explains why many BP-lowering drugs in monotherapy have a relatively flat dose-response curve. For example, sodium and water loss caused by diuretics or vasodilation with CCBs will activate RAAS, which limits the BP lowering. Thus, low-dose two-drug combination therapy is likely (1) to produce much greater BP lowering, (2) to reduce heterogeneity in the BP-lowering response, and (3) to have a more effective dose-response to upward titration of either component. The main concern has been safety and tolerability with regard to potentially large initial BP falls in treatment-naive patients. It seems inevitable that low-dose combinations will become more popular as an initial therapy option for a greater proportion of patients, with the preferred combinations likely to be RAAS blockade plus diuretic and RAAS blockade plus CCB.

Combining Renin-Angiotensin-Aldosterone System Blockade?

The popular view that RAAS blockade is an important way of preventing or regressing hypertension-mediated structural and functional damage led to suggestions that different strategies to block RAAS should be combined to deliver more effective RAAS blockade. Data from the ONTARGET and ALTITUDE trials demonstrated that dual RAAS blockade in high-risk patients with an ACE inhibitor plus ARB combination in ONTARGET,[27] or an ACE inhibitor or ARB plus a DRI in ALTITUDE,[28] was no more effective than RAAS monotherapy alone at preventing major CV events in a high-risk population of patients, including those with diabetes.[28] Moreover, in both studies, the risk of adverse events, especially renal impairment, was greater with the dual RAAS blockade strategy. These findings suggest that dual RAAS blockade should not be routinely used for the management of patients with primary hypertension and especially those with diabetes or renal impairment. All guidelines now concur specifically that two different classes of RAAS blockers, ACE-inhibitors, or ARBs or Direct Renin Inhibitors, should not be combined for the treatment of hypertension.

Considerations in the Patient with Resistant Hypertension

Patient Factors	Secondary Causes of Resistant Hypertension	Concomitant Medications that May Raise BP	Causes of "Pseudoresistant Hypertension"
Demographics	***Common Causes***	***Prescription***	***Poor Patient Adherence to Medications***
Older age, especially over 75 Obesity Women > men More common in blacks Excess dietary sodium High baseline BP and chronicity of uncontrolled hypertension	Primary hyperaldosteronism (Conn adenoma) Atherosclerotic renovascular disease Sleep apnea CKD	Oral contraceptives NSAIDs Sympathomimetics (e.g., decongestants in cold remedies) Cyclosporine Erythropoietin Corticosteroids (e.g., prednisone, hydrocortisone)	Check BP response to directly observed medication.
Concomitant Disease	***Uncommon Causes***	***Nonprescription***	***Errors in BP Measurement***
Target organ damage: LVH or CKD Diabetes Atherosclerotic vascular disease Aortic stiffening	Pheochromocytoma Aortic coarctation Cushing disease Hyperparathyroidism	Drug abuse (e.g., cocaine, amphetamines) Excess licorice ingestion Herbal remedies (e.g., ephedra, also known as ma huang)	Including BP cuff too small for arm circumference
			White Coat Hypertension
			Check BP with ABPM or home BP measurements.

Table 36-7 Considerations in diagnosis and treatment of patient with resistant hypertension. *BP,* Blood pressure; *ABPM,* ambulatory blood pressure monitoring; *CKD,* chronic kidney disease; *LVH,* left ventricular hypertrophy; *NSAIDs,* nonsteroidal anti-inflammatory drugs. *(Modified from reference 18.)*

Resistant Hypertension

Resistant hypertension has been defined as BP that remains above goal despite the concurrent use of three antihypertensive agents of different classes, which would usually include a thiazide-like diuretic. Indeed, the U.S., European, and UK guidance all suggest that one of the three agents should be a thiazide-like diuretic and that all agents should be prescribed at optimal doses.[8,10,19] The definition could have been even more prescriptive, as in the NICE guidelines,[10] by suggesting that the three drugs would usually comprise A + C + D in best tolerated doses. Most of these people will be older, often obese, and invariably with evidence of target organ damage. In the absence of evidence of target organ damage, white coat hypertension should be excluded by 24-hour ambulatory monitoring. Other causes of resistant hypertension should also be considered (Table 36-7).[18]

The evidence base from which to define the optimal treatment of resistant hypertension is limited. Most patients with drug-resistant hypertension are likely to be retaining sodium and will respond to further diuretic therapy. This can be achieved by further increasing the dose of the thiazide/thiazide-like diuretic or using low-dose spironolactone (e.g., 25 mg/day) or amiloride (10 to 20 mg/day), with careful monitoring of electrolytes.[18] For some patients with severe drug-resistant hypertension, it may be necessary to use a combination of minoxidil, loop diuretic, and β-blocker to improve BP control.

Medication to Reduce Cardiovascular Risk

Blood pressure should not be treated in isolation, and treatment should be considered part of a more comprehensive strategy to reduce CVD risk. Patients at high risk, that is, those with established CVD, target organ damage, or diabetes, and those with a calculated CVD risk that is elevated (e.g., ≥20% over 10 years) should be considered for additional interventions to reduce risk.[34] These include reinforcement of lifestyle advice, especially smoking cessation, and treatment with statin therapy to further reduce the risk of stroke and coronary disease. In studies, routine use of statins to reduce total cholesterol values by 40 mg/dl (~1 mmol/l) has been associated with a reduction in the risk of ischemic heart disease events by about one third and of stroke by about one fifth, over and above the benefit already accrued from BP lowering.[34,35] Moreover, the relative risk reduction associated with statin therapy in higher-risk hypertensive patients was not dependent on a high baseline cholesterol value. Higher-risk hypertensive patients should also be considered for treatment with antiplatelet drugs once BP has been controlled.

Follow-up

In the early stages of treatment, the frequency of monitoring will be determined by the patient's response to therapy, the comorbidities, and the complexity of the treatment regimen required to control the BP. Once BP is controlled, patients should be reevaluated at least annually for a formal review, and most will be reevaluated every 6 months. Patients are increasingly monitoring their own BP in the intervening periods, and this trend is likely to increase.

Withdrawal of Therapy

Most patients with hypertension require lifelong therapy. Some with grade 1 hypertension who make major adjustments to their lifestyle may obtain sufficient fall in their BP to warrant safe withdrawal of monotherapy. However, patients with target organ damage or those at high CVD risk should not usually have their therapy withdrawn unless there is a compelling clinical reason to do so.[7-9] In patients with previously severe hypertension that has subsequently been well controlled, treatment withdrawal may not always result in an immediate increase in BP. After treatment withdrawal, BP can sometimes take many months to rise progressively back to dangerously high pretreatment values. Any patient who discontinues therapy must remain under review with regular BP monitoring. All but a very few will require treatment again.

Indications for Specialist Referral

Referral to a specialist center is sometimes indicated for the patient in management of hypertension. Indications include uncertainty about the decision to treat, investigations to exclude secondary hypertension, severe and complicated hypertension, and resistant hypertension (Box 36-2).

Hypertension in People of Black African Origin

Hypertension is more prevalent in blacks, is associated with more target organ damage, and consequently carries a worse prognosis,

Indications for Specialist Referral for Patients with Hypertension

Urgent Treatment Needed

Accelerated hypertension (severe hypertension with grade III or IV retinopathy)

Particularly severe hypertension (>220/120 mm Hg)

Impending complications (e.g., transient ischemic attack, left ventricular failure)

Possible Underlying Cause

Any clue in history or examination of a secondary cause (e.g., hypokalemia with increased or high-normal plasma sodium [Conn syndrome])

Elevated serum creatinine

Proteinuria or hematuria

Sudden onset or worsening of hypertension

Resistance to multidrug regimen (i.e., ≥3 drugs)

Young age (any hypertension <20 years; needing treatment <30 years)

Therapeutic Problems

Multiple drug intolerance

Multiple drug contraindications

Persistent nonadherence or noncompliance

Special Situations

Unusual blood pressure variability

Possible white coat hypertension

Hypertension in pregnancy

Box 36-2 Indications for specialist referral for patients with hypertension.

with a particularly high risk of stroke.[37] Black patients as a group tend to respond better to diuretics, CCBs, and dietary salt restriction than Caucasian patients. ACE inhibitors, ARBs, and β-blockers are generally less effective as initial therapy in black patients but become more effective in combination with diuretics or CCBs.

Hypertension in Older People

If a BP of 140/90 mm Hg or higher is used to define hypertension, more than 70% of people older than 60 years will be hypertensive, the majority of these patients having isolated systolic hypertension.[38] Surveys suggest that physicians consistently underestimate the risks and undertreat hypertension in older people. However, important considerations in treating older people include the following.

1. The arterial wall stiffening that gives rise to systolic hypertension and increased pulse pressure (isolated systolic hypertension) is also associated with impaired baroreflex sensitivity with increased risk of orthostatic hypotension. Thus, it is important to record lying and standing BP readings in elderly patients.
2. Estimated GFR declines with age, with impaired renal conservation of sodium and fluid in the face of depletion. Elderly patients are therefore more subject to volume depletion as a result of diuretic therapy.
3. Clearance of drugs and their active metabolites is decreased as a result of declining hepatic and renal function.
4. Cardiac function and reserve are often reduced, and patients are therefore much more likely to develop cardiac failure. This explains why end point trials of hypertension treatment have consistently shown reductions in morbidity and mortality from cardiac failure.
5. Comorbidity is much more common in elderly patients.
6. Communication and adherence with therapy may be more difficult with decline in cognitive function. Some evidence from clinical trials suggests that this decline may be slowed by antihypertensive treatment.

Despite these considerations, elderly patients tolerate BP-lowering medications well, and the benefits of BP reduction are impressive with regard to reductions in morbidity and mortality from stroke, ischemic heart disease, and heart failure. As a general rule, drug regimens should be as simple as possible and dosages increased more gradually. The greatest danger results from lowering of blood pressure too rapidly. Until recently, there was uncertainty about the risks and benefits of treating hypertension in the very elderly population, that is, those older than 80 years. The HYVET study in this age group confirmed that treatment is well tolerated and associated with impressive reductions in the risk of stroke, heart failure, and mortality.[17] Thus, there is no reason to manage very elderly patients any differently from those who are not as old. Biologic rather than chronologic age should be the deciding factor in initiating antihypertensive treatment.

CHAPTER 37

Evaluation and Treatment of Hypertensive Urgencies and Emergencies

Pantelis A. Sarafidis and George L. Bakris

The term *malignant hypertension* first appeared in 1928 and described patients with extremely high blood pressure (BP) values, to emphasize that because of rapid target organ damage, their average prognosis was similar to that of most cancer patients.[1] Subsequently, malignant (or accelerated) hypertension was used to describe patients with greatly elevated BP and vascular damage that could manifest as retinal hemorrhage/exudate and papilledema, usually associated with encephalopathy, acute kidney injury, and microangiopathic hemolytic anemia.[2,3] However, dramatic advances in both in-hospital and outpatient treatment of hypertensive emergencies have led to an improved prognosis, that is, a decrease in 1-year mortality from 80% in 1928 to 50% in 1955 and to less than 10% after 1990.[4,5] Thus, terms such as malignant and accelerated hypertension have been replaced by hypertensive emergency and hypertensive urgency.

Marked elevations in systolic and diastolic BP, usually above 180/120 mm Hg, can be classified as either emergencies or urgencies. A *hypertensive emergency* is defined as a marked elevation in BP complicated by evidence of acute target organ damage, such as coronary ischemia, dissecting aortic aneurysm, pulmonary edema, hypertensive encephalopathy, cerebral hemorrhage, and eclampsia. In hypertensive emergency, BP should be reduced by at least 20 to 40 mm Hg within 10 to 30 minutes using parenteral drug therapy in an intensive care unit (ICU) to limit end-organ damage. *Hypertensive urgency* is a clinical setting of significant BP elevation without acute target organ dysfunction. The approach to hypertensive urgency is a gradual BP reduction within hours, usually with oral medications.[4,6-8]

ETIOLOGY AND PATHOGENESIS

Hypertensive emergencies and urgencies can develop *de novo* in normotensive individuals or can complicate underlying primary or secondary hypertension.[4,8] Box 37-1 shows the most common etiologies of hypertensive crises. In some hypertensive emergencies, an underlying condition is the clear cause of acute BP elevation. In acute glomerulonephritis, renal crisis (in patients with scleroderma), or renal artery stenosis, severe BP elevations are evoked through increased activity of the renin-angiotensin system (RAS). In pheochromocytoma, cocaine intoxication, or spinal cord injury, acutely elevated BP is the result of excess catecholamine release. In other patients, acute sustained elevations in BP itself are the etiologic factor resulting in conditions such as hypertensive encephalopathy or acute left ventricular failure and pulmonary edema. In some cases, however, it may be difficult to differentiate whether BP elevation is the cause or the result of a hypertensive emergency. Thus, a careful diagnostic evaluation of hypertensive emergencies and urgencies is essential to guide proper treatment.

A hypertensive emergency can occur in various clinical settings, but the most common is chronic, often untreated or poorly controlled hypertension in a patient whose usual BP is above 180/120 mm Hg. In many of these patients, chronically elevated BP does not affect target organ perfusion because of autoregulation. *Autoregulation* is the ability of blood vessels to dilate or to constrict in response to changes in perfusion pressure and thereby maintain normal organ perfusion. This mechanism is present in the brain and kidneys and involves L-type calcium channels.[9] Arteries from normotensive individuals can maintain flow over a wide range of mean arterial pressures, 80 to 150 mm Hg, associated with systolic BP of around 90 to 180 mm Hg. Chronic BP elevations cause compensatory functional and structural changes in the arteriolar circulation and shift the autoregulatory curve to the right, which allows hypertensive patients to maintain normal perfusion and avoid excessive blood flow at higher BP levels.[3,10] Over time, the structural and functional changes in cerebral and renal arterioles may lead to a progressive inability of the arterioles to autoregulate properly[8,9] (Fig. 37-1).

Target organ damage associated with hypertensive emergency results from the inability of autoregulatory mechanisms to maintain normal perfusion pressures in certain vascular beds (especially of brain and kidney) when BP rises above the autoregulatory range.[10] The resultant endothelial injury causes a loss of endothelial antithrombotic properties, with activation of platelets and the coagulation cascade, increased vascular wall permeability, and vascular smooth muscle cell proliferation culminating in an increase of tissue ischemia and ultimately fibrinoid necrosis. This is coupled with activation of hormonal systems and release of vasoactive substances (RAS, catecholamines, endothelin, vasopressin) that maintain a vicious cycle of elevated BP and vascular injury.[3,8]

The typical structural changes associated with hypertensive emergencies are fibrinoid necrosis of small arteries and arterioles in the brain and kidney (Fig. 37-2). Other findings may show injury of the affected organs (e.g., cerebral edema).[3,10] Hypertensive emergency may rarely present as a thrombotic microangiopathy, in particular if associated with scleroderma (see Chapter 29).

In normotensive or minimally hypertensive individuals, such as children or pregnant women, the symptoms and signs of a hypertensive emergency occur at lower BP levels than in hypertensive patients because adaptive chronic vascular changes are absent. In most patients, however, the development of a hypertensive emergency occurs in the presence of chronic hypertension. This may relate to other mechanisms contributing to impaired autoregulation, such as progressive arteriolar disease (both cerebral and renal circulation) and

pharmacologically impaired autoregulation (e.g., use of dihydropyridine calcium channel blockers, or furosemide).

EPIDEMIOLOGY

The exact incidence of hypertensive emergencies and urgencies or the demographic distribution is not known, but an estimated 1% to 2% of individuals with hypertension develop hypertensive crises.[11] One study with more than 14,000 emergency department (ED) visits showed that hypertensive urgencies accounted for 76% and emergencies for 24% of hypertension-related visits.[12] In this study, the most common presentations of hypertensive emergency were associated with cerebral infarction (24.5%), acute pulmonary edema (22%), hypertensive encephalopathy (16%), and acute heart failure (14%), followed by myocardial infarction (12%), cerebral hemorrhage (5%), eclampsia (5%), and aortic dissection (2%). In a different series of 435 hypertensive ED visits, 40% were hypertensive urgencies, almost all with some degree of preexisting kidney disease, and 60% were emergencies.[13] Hospitalization for hypertensive emergency occurs at a rate of 1 to 2 cases per 1 million population per year in the United States.[10]

In developed countries, widespread use of antihypertensive agents has reduced the incidence of hypertensive emergencies, as supported by indirect observations.[10] Use of any antihypertensive drug reduces the risk of hypertensive emergency because poor treatment compliance and outpatient BP control are predictors of subsequent hypertensive crises.[14] Further, hospitalization for hypertensive emergency is more common in developing countries, ethnic minorities of developed countries,[5] and individuals of low socioeconomic status who often have poor BP control.

DIAGNOSTIC EVALUATION

The primary goal of the diagnostic process is differentiation of a true hypertensive emergency from a hypertensive urgency, because of the different therapeutic approaches. The second goal is rapid assessment of the type and severity of ongoing target organ damage. In some hypertensive emergencies, the history (e.g., acute head trauma, preeclampsia, scleroderma) or overt symptoms and signs (e.g., chest/back pain, dyspnea, throbbing abdominal mass) may guide the diagnosis; whereas in other cases (e.g., severe hypertension with altered mental status), the evaluation is more comprehensive.

The diagnostic approach begins with the patient's history, with attention to duration, severity, and treatment of preexisting hypertension and associated conditions[6,8] (Box 37-2). BP measurements should be performed in both arms (if possible, in both sitting and standing positions) and a leg[2] (see Chapter 33). A careful examination and assessment of cardiac, pulmonary, peripheral vascular, and neurologic systems with assessment of mental status should follow, along with a thorough funduscopic (ophthalmoscopic) examination for hemorrhages, exudates, and papilledema.

Signs of secondary hypertension should not be missed in this initial examination. For example, an abdominal bruit may indicate renovascular hypertension; a palpable abdominal mass suggests abdominal aneurysm or polycystic kidneys; a radial-femoral pulse delay suggests aortic coarctation; abdominal striae and central obesity are observed with Cushing syndrome; and exophthalmos may indicate hyperthyroidism. Patients with features of hemolytic anemia and thrombocytopenia should be evaluated for causes of thrombotic microangiopathy.

The initial laboratory studies in a hypertensive emergency include a complete blood count with peripheral smear, urinalysis, creatinine and urea concentration, and electrolyte values.[6,8] Comparison of kidney function with a patient's recent measurement is important. Severe hypertension accompanied by acute deterioration in kidney function, microscopic hematuria with red blood cell casts, or nephritic urine sediment suggests acute glomerulonephritis. If a secondary form of hypertension is suspected, samples for plasma renin activity, aldosterone concentration, and plasma free catecholamines and metanephrines should also be drawn *before* initiation of treatment. Testing should be performed with the patient supine, and ideally, the patient should not be receiving β-blockers, especially labetalol, because of false-positive metanephrine and total catecholamine values. Electrocardiography to rule out myocardial ischemia and left ventricular strain or hypertrophy, as well as chest radiography, should be performed in every patient.[6] Renal ultrasound is also useful to rule out abnormalities such as differences in size or perfusion, especially in patients with altered renal function or with abnormalities on urinalysis.

Neurologic syndromes associated with hypertension, including subarachnoid hemorrhage, intracerebral hemorrhage, thrombotic stroke, and hypertensive encephalopathy, are difficult to distinguish from one another. Computed tomography (CT) or magnetic resonance imaging (MRI) provides a definite diagnosis of a hemorrhagic or thrombotic stroke. Echocardiography, thoracoabdominal CT or MRI, or abdominal ultrasound may be needed in patients with suspected aortic dissection or pheochromocytoma.[6]

TREATMENT

General Principles for Managing Hypertensive Emergencies

Although therapy with parenteral antihypertensive agents may be initiated in the ED, patients with a hypertensive emergency should be admitted to an ICU for continuous BP monitoring, clinical surveillance, and continued parenteral administration of an appropriate agent (Tables 37-1 and 37-2). Specific BP levels do not determine the severity and the emergency of the situation because the autoregulatory structural and functional changes may vary among individuals, such that some may develop target organ damage at lower BP.

Understanding of autoregulation is crucial for therapeutic decisions; sudden lowering of BP into a "normal" range could lead to inadequate tissue perfusion.[10] Clinical data document that lowering BP in hypertensive emergencies is beneficial: papilledema and exudates regress, hypertensive encephalopathy vanishes, pulmonary edema resolves, and renal function improves. However, there is also evidence that abrupt lowering of BP can be harmful. For example, the use of sublingual nifedipine with potent but unpredictable BP lowering may shunt blood away from the penumbra of the brain

Treatment of Hypertensive Emergencies

Drug	Mechanism of Action	Dose	Onset of Action	Duration of Action	Adverse Effects*	Special Indications
Vasodilators						
Nicardipine hydrochloride	Calcium channel blocker	5-15 mg IV every hour	5-15 min	15-30 min, may exceed 4 hr	Tachycardia, headache, flushing, nausea, vomiting, local phlebitis	Most hypertensive emergencies except acute heart failure
Fenoldopam mesylate	Dopamine-1 receptor agonist	0.1-0.3 μg/kg/min IV infusion	>5 min	30 min	Tachycardia, headache, nausea, flushing	Most hypertensive emergencies; caution with glaucoma
Clevidipine butyrate	Calcium channel blocker	1-2 mg/hr IV infusion; increase every 5-10 min up to 16 mg/hr	2-4 min	5-15 min	Tachycardia, headache, flushing, heart failure deterioration	Most hypertensive emergencies; caution with severe aortic stenosis, acute heart failure
Sodium nitroprusside	↑ Cyclic GMP, blocks intracellular Ca^{2+} increase	0.25-10 μg/kg/min IV infusion†	Immediate	1-2 min	Nausea, vomiting, muscle twitching, thiocyanate and cyanide intoxication, impaired cerebral autoregulation, coronary steal syndrome	Caution in situations associated with CNS manifestations, hepatic or renal failure; probably should be avoided if given other agents, especially fenoldopam
Nitroglycerin	↑ Nitrate receptors	5-100 μg/min IV infusion	2-5 min	5-10 min	Headache, vomiting, methemoglobinemia, tachyphylaxis, tolerance with prolonged use	Coronary ischemia, pulmonary edema
Enalaprilat	ACE inhibitor	1.25-5 mg every 6 hr IV	15-30 min	6-12 hr	Precipitous fall in BP in high-renin states, variable response, acute renal failure	Acute left ventricular failure; avoid in acute myocardial infarction
Isradipine	Calcium channel blocker	0.15 μg/kg/min IV, increase by 0.0025 μg/kg/min every 15 min. Maintenance infusion 0.15 μg/kg/min	1-10 min	1-2 hr	Headache, flushing, peripheral edema, dizziness, tachycardia	Perioperative, pregnancy
Hydralazine hydrochloride	Opens K^+ channels	10-20 mg IV	10-20 min	1-4 hr	Tachycardia, flushing, headache, vomiting, aggravation of angina	Must be given with concomitant IV β-blockers to avoid precipitation of angina but *not* a preferred initial choice or treatment
Adrenergic Inhibitors						
Labetalol hydrochloride	α_1-, β-Blocker	20-80 mg IV bolus every 10 min *or* 0.5-2 mg/min IV infusion	5-10 min	3-6 hr	Nausea, vomiting, scalp tingling, bronchoconstriction, dizziness, heart block, heart failure	Most hypertensive emergencies except acute heart failure
Esmolol hydrochloride	β_1-Blocker	0.5-2.0 mg/min IV infusion *or* 250-500 μg/kg/min IV bolus, then 50-100 μg/kg/min by infusion; may repeat bolus after 5 min or increase infusion to 300 μg/min	1-2 min	10-30 min	Nausea, asthma, first-degree heart block, heart failure, thrombophlebitis, COPD	Aortic dissection, perioperative, increased heart output or heart rate
Urapidil	α_1-Blocker, serotonin (5-HT1A) receptor agonist	12.5-25 mg IV bolus followed by 5-40 mg/hr IV infusion	3-5 min	4-6 hr	Headache, dizziness	Perioperative
Phentolamine	α-Blocker	5-15 mg IV bolus	1-2 min	10-30 min	Tachycardia, flushing, headache	Catecholamine excess

Management of Specific Types of Hypertensive Emergencies

Type of Emergency	First-Choice Drug(s)	Second-Choice or Additional Drug(s)	Drugs to Avoid	Aim of BP Reduction
Cardiac				
Coronary ischemia/ infarction	Nitroglycerin, nicardipine, clevidipine	Sodium nitroprusside, labetalol, esmolol if heart failure absent	Diazoxide, hydralazine	Improvement in cardiac perfusion
Heart failure, pulmonary edema	Nitroglycerin, fenoldopam	Sodium nitroprusside, enalaprilat; diuretics	Diazoxide, hydralazine; β-blockers	Decrease in afterload
Aortic dissection	Labetalol or combination of esmolol with sodium nitroprusside or fenoldopam or nicardipine		Diazoxide, hydralazine	Decrease of aortic wall stress with systolic BP reduction <100-120 mm Hg in 20 min (if possible)
Renal				
Acute glomerulonephritis, collagen vascular renal disease, or renal artery stenosis	Fenoldopam	Nicardipine, labetalol, clevidipine; diuretics for volume overload	Sodium nitroprusside; ACE inhibitors and ARBs	Reduction in vascular resistance and volume overload without compromise of renal blood flow or glomerular filtration rate
Scleroderma crisis	Enalaprilat or other ACE inhibitor	Angiotensin receptor blocker, fenoldopam	Corticosteroids,* diuretics	Decrease in BP to <140/90 mm Hg with long term goal of <130/85
Neurologic				
Hypertensive encephalopathy	Nicardipine, fenoldopam, labetalol, clevidipine	Nitroprusside, esmolol, urapidil		20%-25% reduction in mean BP over 1-2 hr
Ischemic stroke	Nicardipine, labetalol, clevidipine	Nitroprusside, nimodipine, esmolol, urapidil		Reduction of BP if above 220/120 mm Hg (mean BP >130) by no more than 10%-15% within first 24 hours to avoid impairing cerebral blood flow in penumbra
Intracerebral hemorrhage	Nicardipine, labetalol, clevidipine	Fenoldopam, nitroprusside, esmolol, urapidil, nimodipine for subarachnoid hemorrhage		Decrease in BP below 185/110 to prevent further bleeding and hypoperfusion. For subarachnoid hemorrhage in normotensive patients, reduction to systolic BP of 130-160 mm Hg
Catecholamine Excess States				
Pheochromocytoma	Phentolamine or labetalol	β-Blocker in the presence of phentolamine	Diuretics	Control of BP paroxysms from sympathetic stimulation
Ingestion of cocaine or other sympathomimetic	Phentolamine or labetalol	β-blocker in the presence of phentolamine	Diuretics	Control of BP paroxysms from sympathetic stimulation
Perioperative/Postoperative Hypertension				
Coronary artery surgery	Nitroglycerin, nicardipine, clevidipine	Esmolol, labetalol, fenoldopam, isradipine, urapidil		Protection against target organ damage and surgical complications (keep BP<140/90 or mean BP <105 mm Hg)
Non-cardiac surgery	Esmolol, labetalol, fenoldopam, nicardipine, clevidipine, urapidil, nitroglycerin			Protection against target organ damage and surgical complications
Pregnancy Related				
Eclampsia	Labetalol, urapidil	Isradipine, $MgSO_4$, methyldopa, long-acting nifedipine	Nitroprusside, ACE inhibitors, ARBs	Control BP (typically <90 mm Hg diastolic but often lower) and protect placental blood flow

Table 37-2 Management of specific types of hypertensive emergencies. *BP,* Blood pressure; *ACE,* angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers. *Corticosteroids may worsen hypertension in scleroderma renal crisis.

(ischemic penumbra), resulting in a vascular infarct.[15] Thus, the goal of antihypertensive therapy is not to normalize BP rapidly, but to prevent target organ damage by gradually reducing BP while minimizing the risk of hypoperfusion.

For most patients with hypertensive emergency, the mean BP should be reduced by no more than 20%-25% within the first hour.[6] A diastolic BP target between 100 and 110 mm Hg or a reduction of 25% compared with the initial baseline, whichever is higher, is an appropriate goal within the next 2 to 6 hours. Reduction of diastolic pressure to less than 90 mm Hg or by 35% of the initial mean BP has been associated with major organ dysfunction, coma, and death. If the degree of BP reduction is well tolerated and the patient is clinically stable, further gradual reductions toward levels below 140/90 mm Hg should be implemented within the next 24 to 48 hours.

An important consideration before initiation of intravenous (IV) therapy is assessment of the patient's volume status. Because of pressure natriuresis, patients with hypertensive emergency may be volume depleted, and diuretics should not be used; rather, fluid administration may help restore organ perfusion and prevent a precipitous fall in BP.[8] Diuretics especially should be avoided in hypertensive emergencies because of catecholamine excess states (pheochromocytoma, monoamine oxidase inhibitor crisis, cocaine intoxication), since these patients are usually volume depleted.

Major exceptions to these treatment recommendations include (1) patients with acute stroke, in whom there is no clear evidence to support immediate BP lowering, and a more cautious approach is needed (see Chapter 42); (2) patients with aortic dissection, who should have their systolic BP lowered to less than 100 mm Hg if tolerated; and (3) patients in whom BP should be further lowered to enable the use of thrombolytic agents.[6,11]

After BP has been controlled for a suitable period, typically 12 to 24 hours, allowing autoregulation to reestablish, the IV medication is gradually reduced and replaced by oral agents. Typically, a calcium channel blocker (CCB), α- and β-blocker, or RAS blocker can be used, depending on the suspected cause and possible ongoing investigations for secondary hypertension.[10]

Specific Aspects of Antihypertensive Drug Use for Hypertensive Emergencies

The need for gradual and tightly controlled BP reduction requires the use of short-acting IV drugs (Table 37-1), the effects of which can be promptly reversed if response is excessive. Previous systematic reviews and meta-analyses showed minor differences in the degree of BP lowering and no differences in morbidity or mortality among these agents, because of the relative paucity of large, randomized controlled trials (RCTs) with appropriate follow-up.[16,17] Thus, treatment practices were mainly empiric. Recent evidence, however, suggests benefits of novel agents, a result expected to change clinical practice.

For several years, *sodium nitroprusside* was considered the first-choice drug for almost all hypertensive emergencies. It is easily titrated, is inexpensive, and has a long record of effectiveness.[6,10,18] It also has several drawbacks, including accumulation of toxic metabolites (thiocyanate and cyanide) when used for more than 48 hours, especially in patients with renal or hepatic dysfunction, and the need for invasive BP monitoring and an administration system that protects it from light. High-dose nitroprusside increases intracranial pressure. It also obliterates cerebral autoregulation and reduces regional coronary blood flow. These attributes of nitroprusside limits its usefulness in patients with neurologic complications or acute coronary syndromes.[8,11]

Clevidipine butyrate is a new, ultra-short-acting (within 1 to 2 minutes) third-generation CCB that acts through inhibition of extracellular calcium influx via the L-type channel and reduces peripheral vascular resistance without affecting venous vascular tone or cardiac filling pressure. Clevidipine is rapidly hydrolyzed by blood esterases, and thus its metabolism is not affected by renal or hepatic function.[8,11,19] In clinical studies, clevidipine was shown to be effective and safe in the control of perioperative hypertension and hypertensive emergencies.[19,20] The Evaluation of Clevidipine in the Perioperative Treatment of Hypertension Assessing Safety Events (ECLIPSE) report included three randomized trials with more than 1500 patients with perioperative acute hypertension that compared clevidipine, nitroglycerin, sodium nitroprusside, and nicardipine.[21] In this study, no difference was observed among clevidipine, nitroglycerin, or nicardipine in the primary end point of death, myocardial infarction, stroke, or renal dysfunction at 30 days, but clevidipine was more effective in maintaining BP within the prespecified target range and, most important was associated with lower mortality than nitroprusside.[21] In view of these data, nitroprusside should be abandoned for the treatment of hypertensive emergencies.[7,11]

Nicardipine is a dihydropyridine CCB with intermediate onset and duration of effect, prolonged half-life, and strong cerebral and coronary vasodilatory activity. It is useful for most hypertensive emergencies, especially in patients with coronary artery disease. Nicardipine potentiates curare effects and interacts with inhalant anesthetics.[10,18] In a recent randomized controlled trial of 226 patients with acute systolic BP of 180 mm Hg or higher, those receiving nicardipine reached physician-specified target range slightly more often (92% vs. 83%, $P = .039$) than those receiving labetalol.[22]

Fenoldopam mesylate is a selective agonist of dopaminergic 1 receptors located mainly in the renal and splanchnic arteries, with lesser density in the coronary and cerebral arteries.[8,10,18] IV fenoldopam does not cross the blood-brain barrier and has no central nervous system activity because it is a poorly lipid-soluble molecule. In clinical studies, compared with sodium nitroprusside, fenoldopam demonstrated similar BP-lowering efficacy and beneficial renal effects (increased diuresis, natriuresis, creatinine clearance).[23] Thus, fenoldopam is mostly useful for BP reduction in patients with renal impairment, those with heart failure, and those undergoing vascular surgery. Fenoldopam must be administered with caution, if at all, to patients with glaucoma because it increases intraocular pressures.[10,18]

Labetalol is a nonselective α_1- and β-blocker (in 1:7 ratio) given intravenously that can be used in many hypertensive emergencies because it has rapid onset of action, potent and sustained effect, and low toxicity. Labetalol reduces peripheral vascular resistance without a reflex increase in systolic volume, while cerebral, renal, and coronary blood flow is maintained. Its main indications are aortic dissection, acute coronary syndromes, hypertensive encephalopathy, and adrenergic crisis. Labetalol can be also used in pregnancy-induced hypertensive crisis as little placental transfer occurs because of its negligible lipid solubility.[6,8,11] *Esmolol* is a β_1-blocker with an immediate onset and a short duration of action, whose metabolism is not dependent on renal or hepatic function. Esmolol is used particularly in patients with severe postoperative hypertension, and it can be useful in those with increased cardiac output and heart rate.[8,18] Both labetalol and esmolol are contraindicated in patients with heart failure or heart block. Labetalol may be used in chronic obstructive pulmonary disease if the patient has no history of an asthmatic component.[24]

Table 37-1 provides pharmacologic characteristics and adverse effects of other agents that have been used in the treatment of hypertensive emergencies. Table 37-2 includes a general guide for use of these drugs according to the type of hypertensive emergency.

Treatment of Hypertensive Urgencies						
Drug	**Mechanism of Action**	**Dose**	**Onset of Action**	**Duration of Action**	**Adverse Effects***	**Special Indications**
Captopril	ACE inhibitor	12.5-25 mg PO every 1-2 hr	15-30 min	4-6 hr	Angioedema, cough, acute renal failure	
Clonidine	Central α_2-agonist	0.1-0.2 mg PO every 1-2 hr	30-60 min	6-8 hr	Sedation, dry mouth, bradycardia, rebound hypertension after withdrawal	
Labetalol	α_1-, β-Blocker	200-400 mg PO every 2-3 hr	30-120 min	6-8 hr	Bronchoconstriction, heart block, congestive heart failure	
Furosemide	Loop diuretic	20-40 mg PO every 2-3 hr	30-60 min	8-12 hr	Volume depletion, hyponatremia, hypokalemia	
Isradipine	Calcium channel blocker	5-10 mg PO every 4-6 hr	30-90 min	8-16 hr	Headache, tachycardia, flushing, peripheral edema	

Table 37-3 Pharmacologic agents for treatment of hypertensive urgencies. Shown are short-acting agents that are commonly used in the emergency room setting. However, as noted in the text, sometimes longer-acting drugs can be used. *PO,* Taken orally.

Treatment of Hypertensive Urgencies

There is no proven benefit from rapid BP reduction in asymptomatic patients without evidence of acute target organ damage; thus, all authorities agree that BP lowering should occur over a longer time than for a hypertensive emergency. BP reduction to levels below 160/100 mm Hg may be accomplished within 2 to 4 hours in the ED with the oral drugs described later. This may be particularly important for patients without ongoing target-organ damage, who are judged to be at high risk for cardiovascular events over the next days because of severe hypertension (e.g., those with known history of aortic aneurysm, repeated pulmonary edema). However, there are many different types of patients who may present as a hypertensive urgency. Because there is no proven benefit from rapid reduction of BP in these patients, less aggressive lowering of BP (over several hours to days) is also proposed by some, using strategies like resumption of antihypertensive therapy (in nonadherent patients), initiation of antihypertensive therapy with long-acting agents (if patients are treatment naive), or addition of another antihypertensive drug (in patients who are currently treated). In short, the most important aspect of treatment of hypertensive urgency is not achieving a BP goal but rather ensuring adequate follow-up, generally within 1 week, to an appropriate site of care for chronic hypertension.[6,8,10]

Patients with hypertensive urgency should be provided a quiet room in which to rest because this maneuver was associated with BP fall ≥20/10 mm Hg in one third of such patients.[25] Another major factor to consider before prescribing medication is assessment of pain. Patients with severe pain not secondary to cardiac or cerebral origin should be given analgesics first to improve pain. If such patients present with hypertensive urgency and are given acute acting medications such as clonidine or labetalol, they could become hypotensive once pain is alleviated with nonsteroidal agents, opioids, or steroids.

The choice of drugs for treatment of hypertensive urgencies is much broader than for emergencies, because almost all antihypertensives lower BP effectively over a reasonable time. Captopril, clonidine, labetalol, and other short-acting drugs have been used most often (Table 37-3).[6,8] A careful history to assess chronic antihypertensive treatment and patient adherence to medication is critical for drug and dose selection, and clinical surveillance is always advisable during the first few hours after drug administration. In an acute situation, if uncertain whether the patient may have a pheochromocytoma, it is advisable to avoid β-blockers because they can increase BP. This includes labetalol because its α-blocking effect is very small. An α-blocker should always be a first-line drug in these patients.

Oral *captopril* is typically given in a 12.5- to 25-mg dose; angiotensin-converting enzyme (ACE) inhibitors must be used with caution because they can cause or exacerbate renal impairment in the occasional patient with critical renal artery stenosis.[3,6] Oral clonidine, 0.1 to 0.2 mg, is one of the most common agents used in this setting. However, patients should not be discharged taking clonidine if they have a history of nonadherence to drug regimens, because of the risk of rebound hypertension if clonidine is abruptly stopped. Furosemide can also effectively lower BP if elevated pressure is related to volume overload, especially if renal dysfunction is present. However, a common physiologic response of the kidney to elevated BP is natriuresis, so many patients, especially those with normal renal function, are volume depleted rather than volume expanded.[6,8]

Sublingual short-acting nifedipine, although once frequently used, is now contraindicated secondary to a higher incidence of stroke, myocardial infarction, and death related to precipitous hypotensive episodes after ED release.[15] However, intermediate-acting dihydropyridine CCBs, such as IV nicardipine, may be used. Longer-acting CCBs, such as once-daily nifedipine or nifedipine XL, amlodipine, and sustained-release isradipine, do not have a role in management of hypertensive urgencies or emergencies and are used only in long-term management of these patients.

CHAPTER 38

Interventional Treatments for Resistant Hypertension

Henry Krum, Markus P. Schlaich, and Paul A. Sobotka

This chapter discusses novel procedure-based and device-based strategies in the management of systemic hypertension refractory to conventional treatment. Two of the most promising approaches are percutaneous renal sympathetic denervation and baroreceptor activation therapy.

PATHOGENESIS

Sympathetic Nervous System in Hypertension and Cardiovascular Disease

The contribution of sympathetic activation to the genesis and progression of systemic hypertension and cardiovascular disease (CVD) has been well recognized for many decades.[1] A stepwise increase in muscle sympathetic nerve activity (MSNA) occurs from normal blood pressure (BP), high-normal BP, white coat hypertension, borderline hypertension, and established hypertension, with or without left ventricular hypertrophy (LVH).[2] These data are supported by other measures of sympathetic activation in humans, specifically spillover of noradrenaline into plasma. In a study of renal spillover from the kidneys, a significant increase was noted in patients with primary hypertension compared with normotensive controls.[3] This increase was particularly prominent in younger hypertensive participants (20 to 39 years).

Renal Efferent Sympathetic Activity

Renal sympathetic efferent nerves modulate autonomic control of the kidney. Renin secretion is activated by β1-adrenoceptor stimulation, enhanced tubular sodium reabsorption by α1B-adrenoceptors and reduced renal blood flow by α1A-adrenoceptors[4] (Fig. 38-1). Thus, sympathetic innervation is critical to renal control of regulatory hormones, modulation of total body volume status, and effects on the pressure-natriuresis curve. Renal sympathetic denervation shifts the diuresis and natriuresis curves to the left[5]; that is, an increase in water and sodium excretion for the same renal perfusion pressure is achieved in the denervated compared to the innervated animal.

Abrogation or disruption of renal sympathetic efferents therefore represents an attractive therapeutic target in the management of disorders characterized by renal sympathetic nerve activation. This has been supported through the preclinical literature in both low-renin and high-renin models of hypertension in animals.[6]

Renal Afferent Sympathetic Activity

The kidney and pelvic region is highly innervated by mechanosensitive and chemosensitive nerve receptors.[7] Renal afferent nerves transmit this information to the central sympathetic nervous system, which in turn modulates activity of key organs, including heart, kidney, and vasculature (Fig. 38-2). Indeed, dorsal rhizotomy (afferent denervation) reduces BP in animals with renal disease[8]; the renal afferent denervation abrogates increased CNS catecholamine levels. In renal transplant patients, denervation through nephrectomy of the nonfunctioning kidney reduced both renal sympathetic efferent activity and BP.[9] Similarly, in patients with end-stage renal disease (ESRD) on dialysis, removal of the nonfunctioning kidney has simultaneously reduced MSNA and calf vascular resistance, confirming the kidney as a seminal source of sympathetic stimulation.[10]

Carotid Baroreflex Sensitivity

Abnormalities of the baroreflex are well described in the setting of systemic hypertension.[11] Arterial baroreceptors are rapidly reset in response to sustained BP elevation but also buffer short-term fluctuations in BP.[11] As BP increases, firing of baroreceptor afferents also increases. If BP elevation is sustained despite this, however, the baroreceptor response diminishes over time, and a new threshold for activation is established. Thus, baroreceptors become less sensitive to any given change in BP in patients with chronic hypertension. The reasons for this baroreceptor resetting are not well understood. This contribution of reduced baroreflex activity to chronic hypertension and its associated multiorgan involvement has been widely described.

SURGICAL SYMPATHETIC DENERVATION

In the era preceding the emergence of modern antihypertensive pharmacotherapy, surgical denervation of the renal arteries was perhaps the only effective approach to treating patients with significant elevations in BP. Case series comparing this surgical approach to medical therapies (such as existed) demonstrated about 50% improvement in survival with denervation in patients for the same starting BP values.[12] The magnitude of the BP reduction correlated with the starting preoperative mean BP. However, sympathetic denervation was accompanied by significant adverse events, limiting the clinical utility. In particular, patients experienced impotence, incontinence, and almost invariably, orthostatic hypotension, essentially rendering them unable to maintain upright posture for long periods.[13]

Percutaneous and Minimally Invasive Approaches to Renal Sympathetic Denervation

Novel approaches have been developed to achieve specific renal sympathetic denervation while avoiding the complications of the earlier

surgical approaches, as outlined earlier. Most of these approaches focus on the sympathetic nerve plexus that surrounds the main trunk of each renal artery. These nerves reside within the adventitia of the main artery (or immediately adjacent). These novel methods include various approaches to radiofrequency (RF) energy application, use of ultrasound waves, direct injection of neurotoxins such as guanethidine or ethanol, and even extracorporeal approaches that are completely noninvasive. By far the most advanced and best investigated of these strategies is percutaneous RF ablation[14] (see Fig. 38-2). This procedure involves cannulation of the femoral artery and subsequent placement of the catheter tip in the distal renal artery, where energy is applied to target adjacent sympathetic nerve trunks. The catheter is then withdrawn 1 to 2 cm and circumferentially rotated with further RF energy applications performed, such that four to six applications on average (often more) are applied to the individual renal artery. The same procedure is applied in both main renal arteries.

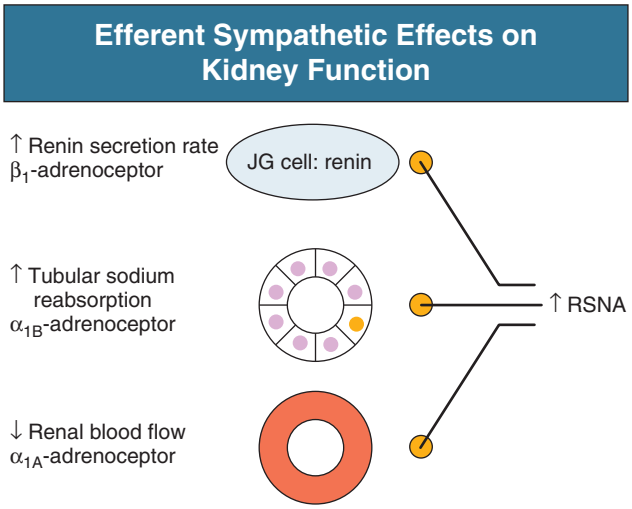

Figure 38-1 Efferent sympathetic effects on kidney function. *RSNA,* Renal sympathetic nerve activity; *JG,* juxtaglomerular.

Published Experience with Percutaneous Renal Sympathetic Denervation

Symplicity Hypertension 1 Study

Symplicity HTN-1 was a 12-month evaluation of safety and BP-lowering efficacy (without a control group) as a first-in-human experience with the denervation procedure.[15] Inclusion criteria involved patients with a systolic BP greater than 160 mm Hg despite three or more antihypertensive medications, including a diuretic or confirmed intolerance to medications. Furthermore, estimated glomerular filtration rate (eGFR) was required to be greater than 45 ml/min/1.73 m^2. The key exclusion criteria included known secondary causes of hypertension, type 1 diabetes mellitus, central sympatholytic drug use, and evidence of renovascular abnormalities, including renal artery stenosis, prior renal procedure, and dual renal arteries. Enrolled patients had a mean BP greater than 170 mm Hg systolic and 100 mm Hg diastolic, despite taking on average five antihypertensive drug classes. Almost all patients were taking ACE inhibitor and/or angiotensin receptor blocker (ARB) as well as diuretics, and 75% were taking β-blockers. After 12 months, BP was reduced by 27/17 mm Hg compared to baseline (Fig. 38-3). Limited ambulatory blood pressure monitoring (ABPM) data showed an increase in patients shifting from "nondipper" to dipper status with the procedure. However, the magnitude of the ABPM response to denervation in this study (and Symplicity HTN-2) was substantially less than that of office BP decreases, suggesting a "white coat" component may be contributory to the observed office response.

The key mechanistic question in Symplicity HTN-1 was whether sympathetic denervation of the kidney is achieved by the renal denervation (RDN) procedure. In humans, evidence of renal

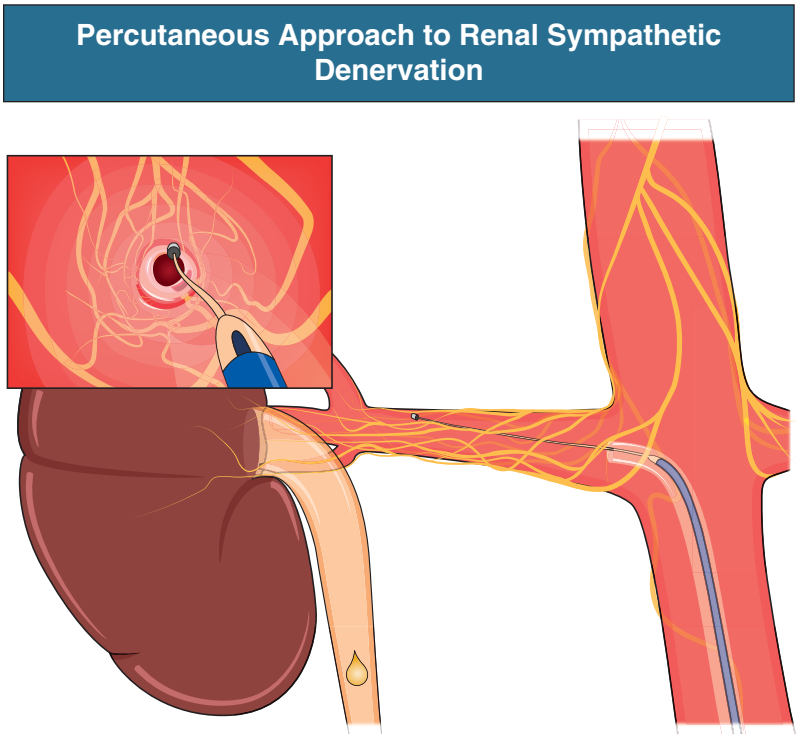

Figure 38-2 Percutaneous approach to renal sympathetic denervation. Using a femoral artery approach, the distal tip of the catheter is placed in distal portion of the renal artery and initial radiofrequency energy applied.

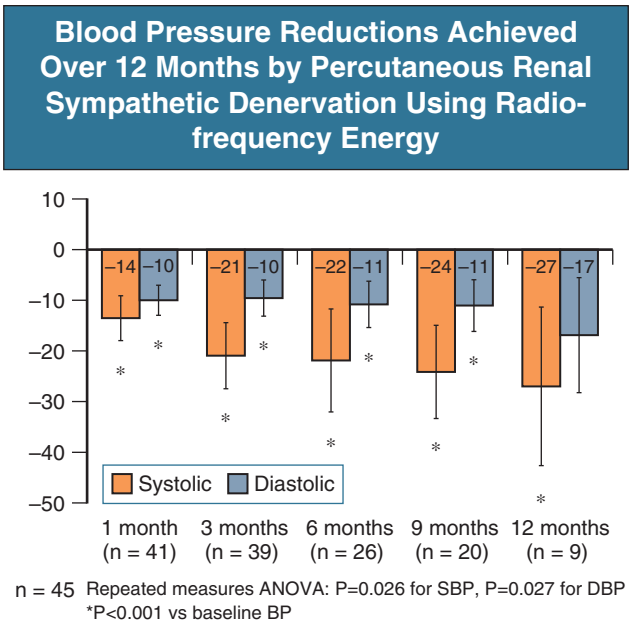

Figure 38-3 Blood pressure reductions achieved over 12 months by percutaneous renal sympathetic denervation using radiofrequency energy. *(Data from Symplicity HTN-1 trial.)*

denervation was observed with a substantial reduction in renal norepinephrine spillover rate in a case study in which BP decreased. In these patients, MSNA (indicative of efferent sympathetic output) also progressively decreased out to 12 months.[16] Sympathetic nerve activity reduction after RDN has been confirmed in a larger series.[17] However, it remains uncertain at the time of the procedure whether denervation has been successfully achieved. The extent of efferent and afferent denervation remains unquantifiable and the importance of complete denervation uncertain; there are as yet no simple clinical tools to address this question.

The Symplicity HTN-1 experience has been extended to 36 months in a larger cohort.[18] Of the 153 patients followed, however, only 24 actually reached the 36-month follow-up visit. Nonetheless, the mean reduction in clinic BP persisted, with a mean 33/19 mm Hg reduction compared to baseline at 36 months. This is consistent with the surgical experience in which many years of improved BP control are observed after the surgical intervention. There is no evidence of loss of BP-lowering effect during the 36 months.

In this cohort, "responders" were arbitrarily defined as those with an office systolic BP reduction greater than 10 mm Hg versus baseline.[18] At 12 months, only 79% had achieved this response in the Symplicity HTN-1 expanded cohort. By 36 months, however, all study patients had achieved this "response." This raises the important issue of what physiologic mechanisms may occur after denervation to produce a late (but not early) BP effect. Possibilities include progressive vascular remodeling, resetting of the baroreflex, and alterations in renal blood flow and sodium excretory status, all of which may require time to "reset." Whether different energy or ablation modalities could alter the responder rate or the time course of BP reduction remains unknown.

To date, no subgroups of patients have been identified who are more likely to respond or not to respond to the procedure. In particular, age greater or less than 65 years, presence or absence of diabetes mellitus, impaired or preserved renal function, and high or low heart rate resulted in no heterogeneity in BP response. However, larger numbers of participants, such as from a global registry, will be required to answer this important question.

Symplicity Hypertension 2 Study

Symplicity HTN-2[19] used similar entry criteria as Symplicity HTN-1.[15] The key differences included a 2-week observation period, after which baseline systolic BP measures were required to remain above 160 mm Hg. In this way, concerns in Symplicity HTN-1 about regression to the mean and Hawthorne effect could at least be partially overcome. Patients who meet BP criteria then underwent anatomic screening with magnetic resonance angiography (MRA), computerized tomography angiography (CTA) or duplex scanning. If renal arteries were free of major atherosclerotic disease, patients were then randomized to a control or treatment group, with a 6-month primary end point assessment of safety and efficacy. The initial 6-month results demonstrated acceptable safety (see later) and a 32/12 mm Hg reduction from baseline in the RDN group ($n = 49$) compared to a 1/0 mm Hg increase in BP in the control group ($n = 51$).This was achieved despite more patients decreasing their medication and fewer patients increasing their medication in the RDN group than in the control group.

At the end of the 6-month primary end point, the control patients were offered the RDN procedure, and all patients were then followed for another 6 months. This analysis found that in the initial RDN group ($n = 47$), BP lowering was maintained for the 12 months, with a reduction of 28/10 mm Hg compared with baseline.[20] In the crossover group ($n = 35$) evaluated 6 months after denervation, mean reduction was 24/8 mm Hg compared to their 6-month pre-RDN value of +7/1 mm Hg versus baseline.

Impact on Renal Function: Studies in Patients with Hypertension and Renal Failure

Although patients in the Symplicity HTN-2 trial had a mean eGFR of 77 ml/min/1.73 m^2, and patients with eGFR less than 45 ml/min/1.73 m^2 were excluded, renal function was unchanged at 6 months.[19] Furthermore, longer-term follow-up data of Symplicity HTN-1 demonstrated that during the first year of follow-up, eGFR remained stable.[18] In no patient did serum creatinine value double. Although it was a nonrandomized study, the relatively modest decline in renal function observed in this 24-month follow-up suggested that there might be an intrinsic beneficial effect of the procedure on the kidney to maintain renal function, which is greater than that achieved with BP reduction alone. Indeed, after successful RDN, renal resistive index decreased from 0.691 ± 0.01 at baseline to 0.674 ± 0.01 and 0.670 ± 0.01 at 3 and 6 months follow-up, respectively; the proportion of patients with microalbuminuria and macroalbuminuria decreased by 10% and 23%, respectively, at 3 and 6 months of follow-up, without effects on GFR.[21]

A pilot study assessed bilateral RDN in 15 patients with resistant hypertension and stage 3 or 4 chronic kidney disease (mean eGFR 31 ± 9 ml/min/1.73 m^2).[22] An average of five ablation treatments per artery were delivered without complications in any of the treated patients. Angiographic evaluation directly after RDN showed no compromise of treated arteries. Importantly, eGFR remained stable in this patient cohort, with five patients followed up to 12 months. Mean baseline BP was 174 ± 22/91 ± 16 mm Hg despite the use of 5.6 ± 1.3 antihypertensive drugs. Office systolic and diastolic BP decreased by 33 ± 20/19 ± 20 at 12 months ($P < .001$). RDN also diminished mean and maximum nighttime BP and restored a physiologic dipping pattern in 9 of 10 patients.

Increased activity of the sympathetic nervous system contributes substantially to the elevated BP often seen in patients with ESRD.[23] Preliminary data were reported on the feasibility of RDN and its effects on BP and sympathetic nerve activity in 12 patients with ESRD and uncontrolled BP.[24] BP was measured on dialysis-free days at baseline and follow-up, and measures of renal noradrenaline

spillover and MSNA were available from five patients at baseline and two patients at 12-month follow-up and beyond. The average office BP was 171 ± 17/89 ± 121 mm Hg despite the use of a mean of four antihypertensive drugs. MSNA and noradrenaline spillover were substantially elevated in all five patients, Of note, 3 of 12 patients could not undergo RDN because of atrophic renal arteries, which made it impossible to position the RF treatment catheter appropriately. Compared with baseline, office systolic BP was significantly reduced at 3, 6, and 12 months after RDN, from 166 ± 16 to 148 ± 11, 150 ± 14, and 138 ± 17 mm Hg, respectively, whereas no change was evident in the three untreated patients. These data suggest that RDN is effective in patients with ESRD as long as it is technically possible.

Safety with Percutaneous Renal Sympathetic Denervation

Initial studies of RDN focused primarily on the safety and tolerability of the procedure. Diffuse visceral pain occurs with the application of RF energy, suggesting that somatic afferent C fibers travel with the sympathetic nerves, which are the targets of the ablation. Patients require prophylactic intravenous analgesia and/or sedation. Imaging studies (e.g., MRA, CTA) at 1 to 2 weeks and 6 months showed no major atherosclerotic progression in response to the RF energy application in denervated arteries.

One episode of renal artery dissection occurred during the catheter procedure (but before application of RF energy) and was successfully stented. Several patients also had impaired hemostasis in the groin, but at a rate consistent with other arterial cannulation procedures involving the femoral artery.

There are rare case reports of renal artery stenosis following RDN, although it is unclear whether the late stenosis is related to mechanical arterial manipulation or the RF denervation. In one report, the patient with late stenosis was successfully treated with dilation and stenting.[25] Alternative technologies developed to minimize renal artery stenosis and other potential local complications include use of catheters with multiple electrodes, to minimize catheter time in the vessel, and ultrasound-based approaches to minimize endothelial damage. No cases of vessel thrombosis or kidney embolization have been reported.

Ongoing Percutaneous Renal Denervation Studies: Symplicity Hypertension 3 Study

Symplicity HTN-1 and HTN-2 have provided strong safety and efficacy data to support the utility of percutaneous renal denervation in refractory hypertension patients. However, the U.S. Food and Drug Administration (FDA) mandated a definitive study (Symplicity HTN-3) that required more aggressive achievement of target dose, or at least highest tolerated dose, of background antihypertensive medications. The qualifying BP requirement included systolic greater than 135 mm Hg by ABPM (as well as subsequent office systolic BP >160 mm Hg), as confirmed after initial screening.[26] The study also concluded a sham procedure performed in the renal artery of controls. Because the operator was aware of which patients received the active procedure, a separate group of investigators performed the end point assessments.

The Symplicity HTN-3 trial has recently reported its full results. The primary efficacy end point was change in office systolic blood pressure between the denervation and the control arm with a superiority margin of 5 mm Hg. However, the decrease in systolic blood pressure in the denervation group was 2.4 mm Hg versus sham control at 6 months, with a starting systolic blood pressure of 180 mm Hg in both groups. There was a nonsignificant interaction effect (p = 0.09) in African Americans versus non–African Americans, suggesting that these subjects derived less benefit in terms of blood pressure reduction. There were no other prespecified subgroup interactions of note.There was no significant increase in safety events with denervation. Thus, the study failed to meet its primary efficacy end point and considerable discussion has ensued as to why that may be the case. This may relate to use of the specific catheter (Flex) with concerns that denervation was not actually achieved in a significant number of patients; the trial design, which allowed background medication uptitration up to 2 weeks prior to the procedure being performed; suboptimal background management of patients referred in from nontertiary centers; and the possibility that denervation itself is not an effective procedure (even if achieved). Further investigation will be required to sort this out and in particular to develop a simple test to ascertain the achievement and completeness of denervation while patients are still on the table during the denervation procedure.

Novel Approaches to Percutaneous Renal Denervation

Radiofrequency Ablation

Newer denervation systems use multiple RF ablation electrodes mounted on steerable basket-shaped catheters (St. Jude Medical EnligHTN system), spiral catheters (Medtronic Multi-electrode Radiofrequency RDN System), and cooled balloon catheter RF ablation (Covidien One-Shot). Preliminary 6-month data on the EnligHTN system ($n = 46$) has shown efficacious BP reduction, with 76% of patients achieving systolic BP reduction of 10 mm Hg or more at 6 months. Mean BP reduction at 6 months was −26/−10 mm Hg from 176/96 mm Hg at baseline. The Covidien One-Shot system uses a saline-irrigated balloon catheter, with a spiral RF electrode on the balloon. The Vessix V2 RSD system is an over-the-wire low-pressure balloon catheter with multiple bipolar RF electrodes mounted on the exterior of the balloon.

Ultrasound

The ReCor Medical PARADISE RSD system uses a catheter with a cylindrical transducer, within a low-pressure balloon, that emits ultrasound energy circumferentially, effecting RDN. It is claimed that this allows complete circumferential denervation and deeper therapeutic penetration, which is hoped to be more consistent and effective, with improved vascular safety, than the standard RF ablation strategy. In a small study ($n = 11$), this ultrasound renal sympathetic denervation (RSD) method was shown to be a safe and effective treatment for resistant hypertension.[27]

All these new devices allow for simultaneous application of ablation energy at multiple different points in the renal artery lumen to denervate the renal sympathetic nerves. This permits shorter procedure time and thus shorter periods of pain during the application of the ablation energy on the renal sympathetic nerves. There is also a theoretical reduced volume of nephrotoxic contrast used. The newer multielectrode catheters will also allow ablation of smaller and shorter renal arteries.

BAROREFLEX ACTIVATION THERAPY

Devices to stimulate the baroreceptor have been commercialized and are currently undergoing preclinical and clinical testing. The Rheos (CVRx, Minneapolis) implantable carotid sinus stimulator has been studied in patients with severe hypertension refractory to drug

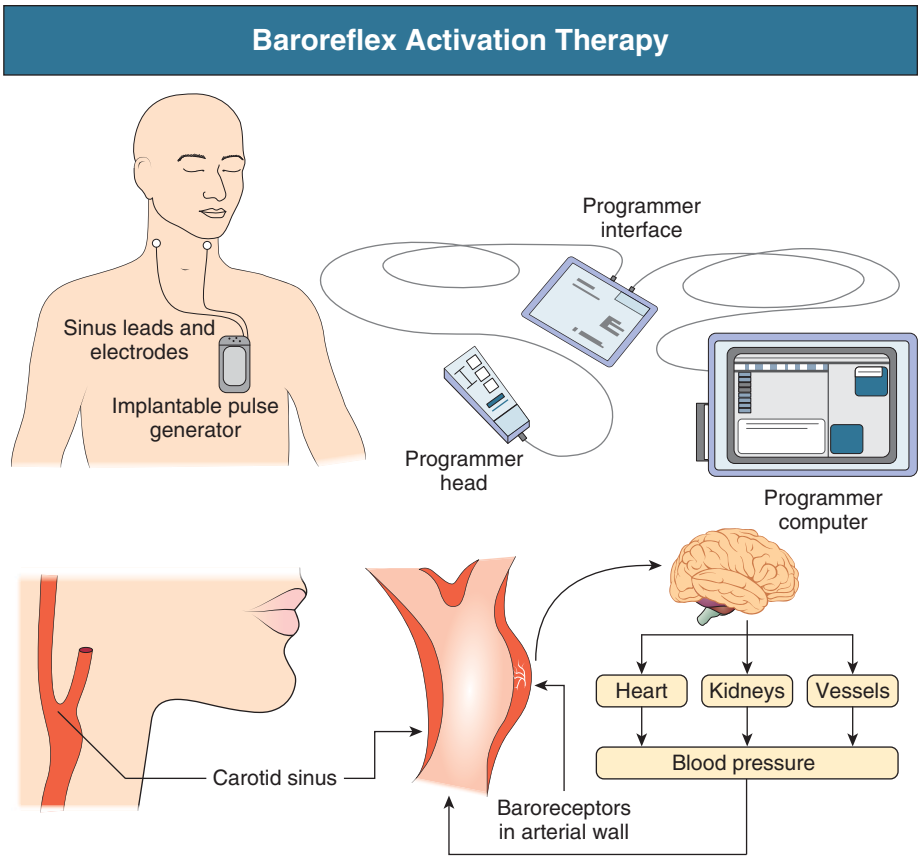

Figure 38-4 **Baroreflex activation therapy.**

therapy[28] (Fig. 38-4). Implantation involves both carotid sinuses being surgically exposed and electrodes placed around the carotid adventitial surface bilaterally. The leads are subcutaneously tunneled and connected to an implantable stimulation device placed in the subclavian subcutaneous position on the anterior chest wall. Electrical baroreflex activation is then initiated on both carotid sinuses simultaneously, with incremental voltage increases until the chronic stimulation level is achieved.

In animal models, activation of central baroreflex pathways results in suppression of medullary sympathoexcitatory cells in both acute and chronically hypertensive dogs, as well as inhibition of renal sympathetic nerve activity. This induces beneficial effects such as natriuresis, along with sustained reductions in BP and heart rate.[29]

DEBUT Study

The multicenter DEBUT feasibility study in patients with treatment-resistant hypertension demonstrated a clinically and statistically significant reduction in office BP of over 20 mm Hg systolic after 3 months of carotid baroceptor stimulation in 37 participants.[30] In 17 participants followed for up to 3 years, BP reductions were sustained (Fig. 38-5). ABPM confirmed the pressure drop during baroceptor activation therapy (BAT), with reductions both during daytime and nighttime. Recent data indicate that lowering BP during activation of the BAT device is associated with a reduction of MSNA.[31]

In DEBUT, 7 of 42 patients experienced a procedure-related adverse event and one a BAT device–related event. One patient had fatal angioneurotic edema (cause unknown) a few days after the procedure but before device activation. Three patients had the device explanted before activation because of infection. Three additional procedure-related adverse events included perioperative stroke with minimal residual effects; tongue paresis (no abnormalities on brain MRI) most likely caused by injury to the hypoglossal nerve; and moderate pulmonary edema that resolved within 6 days. Because most complications occurred early during the study, greater experience with the technique might reduce the number of adverse events.

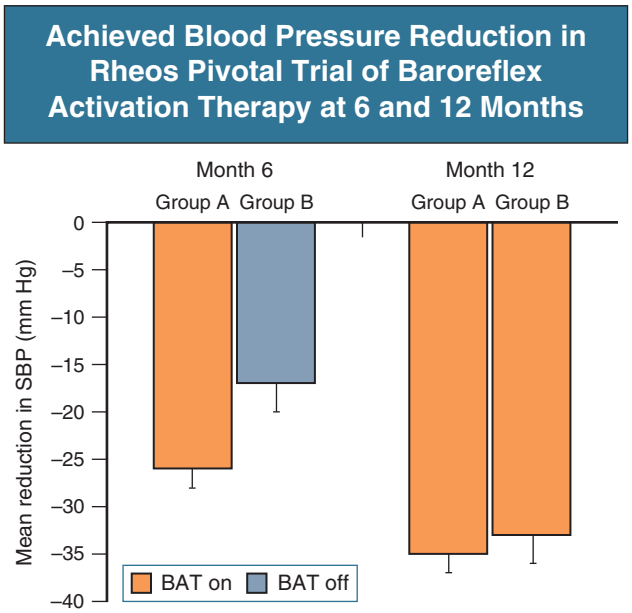

Figure 38-5 **Achieved BP reduction in of baroreflex activation therapy (BAT) at 6 and 12 months.** Group A had BAT device turned on and group B had BAT device turned off for first 6 months. *(Data from Rheos Pivotal trial.)*

A 6-minute walk test at 1 year increased significantly by 48 m (~158 ft) in 14 participants. At the start of the trial, renal function was in the normal range in all patients. Serum creatinine significantly increased after 1 year of therapy in 22 participants, although the rise was less than 20%. In the other 20 patients, it remained stable or even improved. None of the patients developed carotid artery stenosis by the 1-year visit. No evidence for orthostatic hypotension was found, and no events of collapse or syncope were reported in the 32 participants with readings at baseline and after 3 months of BAT.

Rheos Pivotal Trial

The Rheos Pivotal trial of baroreflex sensitization randomized 265 patients to have the BAT device implanted, with half these patients having the device turned on and half with it turned off for 6 months.[32] End point evaluations (efficacy and safety) were performed at this time, and then all patients had the device turned on for longer-term follow-up. Mean BP was 169 to 169/100 to 101 mm Hg, and patients were taking 5.2 different antihypertensive medications. A greater percentage of patients with the BAT device on (42%) achieved systolic BP less than 140 mm Hg at 6 months than those with the BAT device off (24%), but the acute systolic BP responder date (>10 mm Hg reduction) was not significant. Both groups had systolic BP reduction of 25 mm Hg by 12 months.

Ongoing Studies

With the second-generation BAT device, a small European trial has showed a 26 mm Hg reduction in systolic BP at 6 months.[33] Larger studies are planned.

CHAPTER 39

Renovascular Hypertension and Ischemic Nephropathy

Stephen C. Textor and Barbara A. Greco

Few areas in nephrology generate more controversy than management of renovascular disease. Advances in medical therapy, management of atherosclerotic comorbidity, diagnostic imaging, and endovascular intervention have combined to reshape the tools available and the range of clinicians involved with managing these disorders. Restoring blood flow to a critically ischemic kidney offers the potential to improve blood pressure and recover kidney function. However, several recent prospective, randomized controlled trials have failed to identify major additional benefits from revascularizing the kidney when added to optimal medical therapy. Although these trial results have diminished enthusiasm for renal artery revascularization for many patients, nephrologists will continue to encounter patients who can benefit from endovascular or surgical intervention for advanced renovascular disease as well as intensive risk factor management. As with many vascular diseases, the issue is most often one of *timing,* rather than simply choosing one therapy over another indefinitely. This chapter provides an overview of the pathophysiology of renovascular hypertension and clinical management of renal artery stenosis.

DEFINITION AND ETIOLOGY

Renovascular disease with reduced perfusion of the kidney can produce a range of clinical syndromes, most frequently a rise in arterial pressure, designated *renovascular hypertension* (RVH), with or without associated ischemic and hypertensive renal injury. RVH is usually caused by renal artery (RA) stenosis and is a common secondary form of hypertension. Recognition that reduction of renal perfusion pressure activates a series of hormonal and neuronal responses that raise systemic arterial pressure remains one of the seminal observations in blood pressure (BP) regulation. Not surprisingly, high BP in patients with RA stenosis frequently leads to the assumption that the stenosis is the cause of the hypertension. Often, however, patients have preexisting hypertension unrelated to renovascular disease. Final proof that a patient has RVH rests with the demonstration that the hypertension is improved or eliminated by RA endovascular or surgical revascularization or by removal of the kidney distal to the stenosis.

Renovascular hypertension is defined as a syndrome of elevated BP (systolic and/or diastolic) produced by any condition that interferes with arterial circulation to the kidneys. The majority of patients with RVH have significant main RA stenosis with reduced renal perfusion pressure**.** Most conditions cause reduced perfusion to one kidney, while a second "contralateral" kidney is exposed to elevated systemic pressures, called "two-kidney" hypertension by analogy to experimental models of "2-kidney–1-clip hypertension" discussed later. When both kidneys are affected, as may occur with atheroembolic disease or a RA stenosis in a solitary functioning kidney without a normal "contralateral" kidney, the designation "one-kidney" RVH is given.

Of the conditions that may produce the syndrome of RVH, main vessel RA stenosis is by far the most common. The two major causes of main renal artery disease are *fibromuscular dysplasia* (FMD) and *atherosclerotic renal vascular disease* (ASRVD). Box 39-1 lists other conditions that can cause RVH by impairing renal blood supply. Many of these are rare, but all lead to reduced renal perfusion pressure.

The term *ischemic nephropathy* or *ischemic renal disease* (IRD) refers to the reduced glomerular filtration rate (GFR) associated with reduced renal blood flow beyond the level of renal autoregulatory compensation.[1] Critical RA stenosis can lead to renal atrophy and progressive renal impairment. As with RVH, establishing the causal relationship between proximal RA stenosis and the development and progression of chronic kidney disease is often difficult. Collateral renal blood supply can preserve renal viability in the face of proximal atherosclerotic renovascular occlusive disease, and small vessel and parenchymal disease often coexist with main RA atherosclerotic disease. Renal revascularization of ischemic kidneys in some cases can succeed in recovering renal function, but there are few predictors to guide therapeutic choices in these patients, who are often at high risk for complications of interventions.

PATHOPHYSIOLOGY OF RENOVASCULAR HYPERTENSION

Renovascular occlusive disease from any cause can activate pressor pathways that tend to restore renal artery perfusion pressures. Most notable among these is activation of the renin-angiotensin aldosterone (RAAS) system. Activation of plasma renin only occurs after poststenotic pressures fall by at least 10% to 20% compared with aortic pressures.[2] A fall in renal perfusion pressure sufficient to initiate RVH only occurs when luminal occlusion is relatively severe, usually in the 70% to 80% cross-sectional occlusion range (Fig. 39-1, *left*).

When critical stenosis develops and reduces renal perfusion pressure, multiple mechanisms are activated in the kidney to restore renal blood flow. Central to this process is the release of renin from the juxtaglomerular apparatus, leading to activation of the RAAS. This is mediated in part by stimulation of neuronal nitric oxide synthase and cyclooxygenase-2 in the macula densa. Blockade of the RAAS during creation of an experimental RA lesion prevents development of hypertension. Studies in transgenic mice without

receptors to angiotensin confirm that development of RVH requires an intact RAAS.[3] In the absence of RAAS blockade, systemic arterial pressures increase until renal perfusion is restored. Studies in both experimental models and humans indicate that additional mechanisms contribute to long-term BP elevation in the presence of RA stenosis, including activation of the sympathetic nervous system, impairment of nitric oxide generation, and release of endothelin, as well as hypertensive microvascular injury to the nonstenosed kidney.[4]

Mechanisms responsible for sustained RVH differ depending on whether one or both kidneys are affected by significant stenoses, either pathologic or created in animal models using clips (Fig. 39-2). The nomenclature distinguishes between a situation in which one clip is present with a normal contralateral or unclipped kidney ("1-clip–2-kidney hypertension") and a situation in which the entire renal mass is affected with no contralateral kidney ("1-clip–1-kidney hypertension"). Both these situations depend on impaired renal perfusion and initial activation of the RAAS with sodium retention. However, the presence of a normal contralateral kidney allows pressure natriuresis to occur, in which the elevated perfusion pressure mediates natriuresis in the nonstenotic kidney. Because the nonstenotic kidney functions to eliminate the excess sodium, the level of perfusion to the stenotic side remains reduced, leading to sustained activation of the RA stenosis. This sequence of events produces angiotensin II (Ang II)–dependent hypertension and secondary aldosterone excess with hypokalemia (Fig. 39-2, *A*).

By contrast, 1-clip–1-kidney hypertension represents a model in which the entire renal mass is exposed to reduced pressures beyond a stenosis. There is no normal or nonstenotic kidney to counteract increased systemic pressures. As a result, sodium is retained and blood volume expanded, which eventually feeds back to inhibit the RAAS (Fig. 39-2, *B*). Therefore, 1-clip–1-kidney hypertension is typically not angiotensin dependent unless removal of volume is achieved that reduces renal perfusion pressure and activates the RAAS.

These differences have clinical implications. Many diagnostic studies used to evaluate the functional significance of RA lesions depend on comparisons of the different physiologic response of the two kidneys, which may give a false impression if both kidneys are involved. Furthermore, diagnostic tests that depend on differences in responses to alterations in sodium status (e.g., measuring renal vein renin levels after sodium depletion or individual kidney sodium reabsorption) may be problematic, because high levels of Ang II and aldosterone stimulate sodium reabsorption in both the stenotic and the nonstenotic kidney. This partly accounts for the less frequent use of such tests in recent years.[5]

Renovascular Hypertension: Classification

"Two-Kidney Hypertension"*
Unilateral fibromuscular dysplasia
Unilateral atherosclerotic renovascular disease
Renal artery aneurysm
Renal artery embolism
Traumatic arterial occlusion
Arteriovenous fistula
Renal artery dissection or thrombosis
Aortic dissections with compromise to renal ostium
Page kidney (i.e., post-traumatic perirenal fibrosis)
Metastatic tumor compressing renal parenchyma
Pheochromocytoma compressing renal artery
Phakomatosis pigmentovascularis type IIb
Neurofibromatosis
Behçet disease
Covering of origin of renal artery by aortic stent graft
Renal artery spasm

"One-Kidney Hypertension"†
Stenosis to solitary kidney
Bilateral arterial stenosis
Coarctation of the aorta
Vasculitis involving renal arteries
Congenital vascular anomalies
Atheroembolic renal disease

Box 39-1 Classification of renovascular hypertension. Examples of renovascular disease with associated renovascular hypertension or ischemic renal disease. *Two-kidney hypertension implies that a contralateral, nonaffected kidney is present. †One-kidney hypertension implies that the entire renal mass is beyond the vascular lesion, either bilateral disease or a solitary functioning kidney.

Hemodynamic Effects of Stenotic Lesions

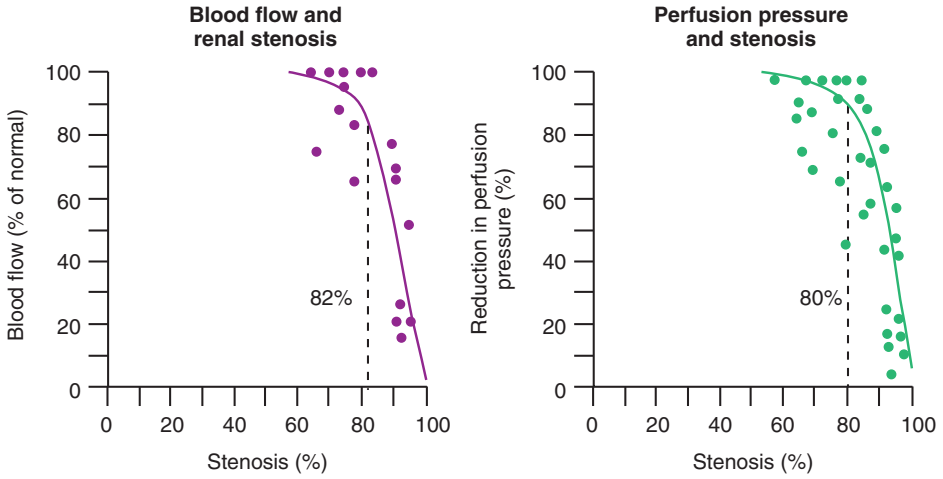

Figure 39-1 Hemodynamic effects of stenotic lesions. Changes in blood flow and arterial pressure across a carefully quantitated arterial lesion are barely detectable until cross-sectional area diminishes by 75% to 80%. *(From reference 91.)*

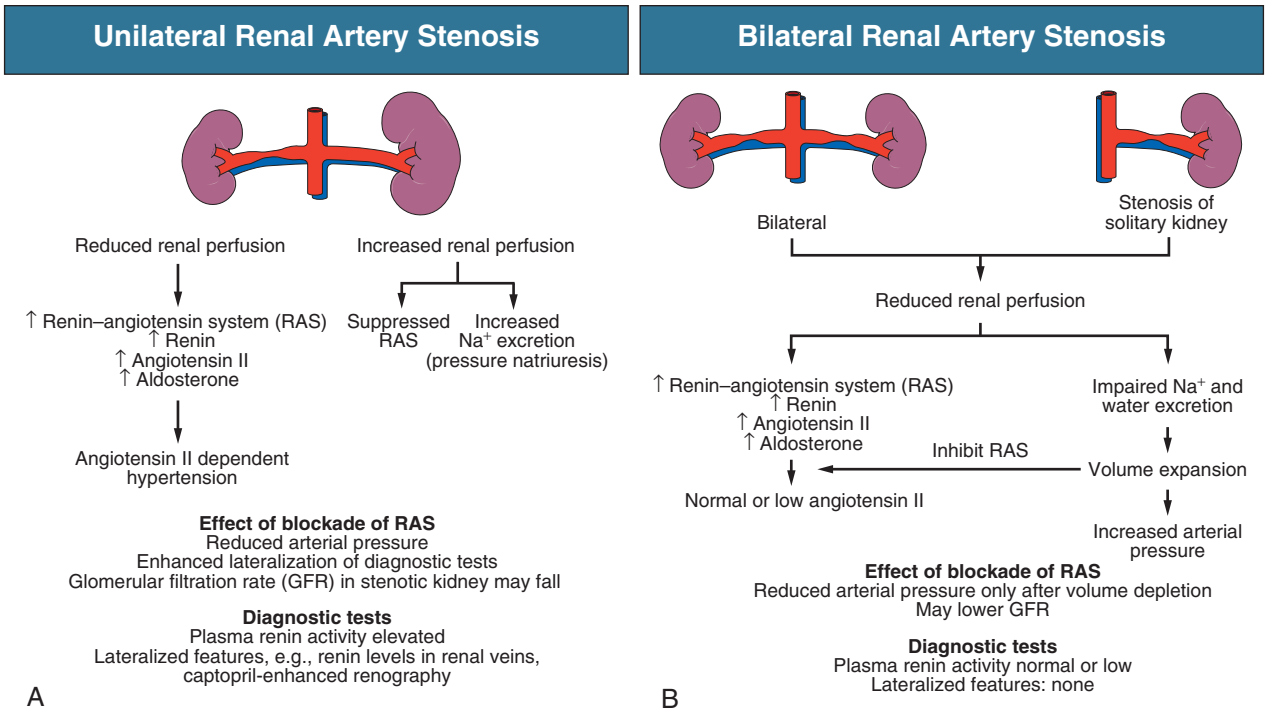

Figure 39-2 Pathogenesis of renovascular hypertension in one-kidney versus two-kidney model. A, In unilateral stenosis with two kidneys, opposing forces between the stenotic kidney, which has reduced perfusion pressures, and the nonstenotic contralateral kidney, which has increased perfusion pressures, result in laboratory and clinical features of angiotensin-dependent hypertension. **B,** In unilateral stenosis with a solitary functioning kidney or in a patient with bilateral critical renal artery stenosis, reduced perfusion pressure to the stenotic kidney in the absence of a normal kidney excreting sodium leads to sodium and volume retention, ultimately associated with hypertension without persistent activation of the RAS.

Variations in the natural history of RVH complicate our understanding of primary pathogenic mechanisms. Rarely is it known exactly when critical levels of stenosis develop. In experimental models, the relative importance of pressor mechanisms, including measurable activation of the RAAS, changes with time. Levels of circulating plasma renin activity decrease, as does the responsiveness of BP to short-term blockade of the renin system. Several mechanisms have been proposed to explain such changes, including a slowly developing pressor action of Ang II, a transition to alternate pressor mechanisms, and intrinsic renal injury to the nonstenotic kidney, which ultimately sustains hypertension despite reversal of the vascular lesion. In experimental models, this translates into a time limit for reversibility of RVH.

There are several clinical correlates with this variable time course. First, it is not known how best to identify when revascularization will fail to improve BP control, although a brief duration of hypertension suggests a more favorable response to intervention. As a result, many of the diagnostic studies that depend on lateralization of effects have only modest predictive value when negative. As a general rule, studies are most reliable when positive, meaning that high-grade lateralization accurately predicts an improvement after revascularization. Second, coexistent intrarenal disease, such as arteriolosclerosis with glomerulosclerosis, is associated with persistent hypertension despite correction of RA stenosis, particularly for patients with ASRVD.[6] In these patients, a long duration of hypertension allows the development of arteriolosclerotic lesions and renal injury in the contralateral kidney (Fig. 39-2, *A*). Thus, older age and a long duration of hypertension (e.g., >3 to 5 years) predict a poorer outcome of intervention in this patient population. Most elderly patients with ASRVD also have impaired renal function related to microvascular renal injury in addition to main RA stenosis.

ATHEROSCLEROTIC RENOVASCULAR DISEASE

Epidemiology

Atherosclerotic narrowing of the renal arteries generally occurs in older patients (>50 years) and is associated with systemic atherosclerosis. Younger patients with premature atherosclerosis are also at risk. ASRVD is the most common cause of RVH and can contribute to loss of renal function, leading to end-stage renal disease (ESRD) (Fig. 39-3). Atherosclerotic plaque often arises in the first or second centimeter of the renal artery or may extend from the aorta into the renal ostium. Aortic and renal vascular calcification is often present. ASRVD is a manifestation of systemic atherosclerosis and is associated with coronary, cerebrovascular, peripheral vascular, and aortic disease.[7,8] The prevalence of ASRVD appears to be increasing. Although this partly reflects improved imaging and selection bias, this trend likely also reflects that more people are surviving to ages when atherosclerotic vascular disease in the visceral abdominal vessels reaches critical levels, producing RVH when the kidney is affected. In patients undergoing angiography of the peripheral or coronary circulation, ASRVD is found in 11% to 42%.[9] Predictors of ASRVD include a history of hypertension, presence of renal functional impairment, coexisting vascular or coronary artery disease, the presence of abdominal bruits, and a history of smoking. RA lesions are bilateral in 20% to 40% of such patients.

Estimates of the prevalence of ASRVD depend on the population screened. One population-based study of 870 patients older than 65 screened with RA duplex ultrasound found a 6.8% prevalence of ASRVD, defined as greater than 60% stenosis. No differences were detected between African Americans and Caucasians.[10] Autopsy

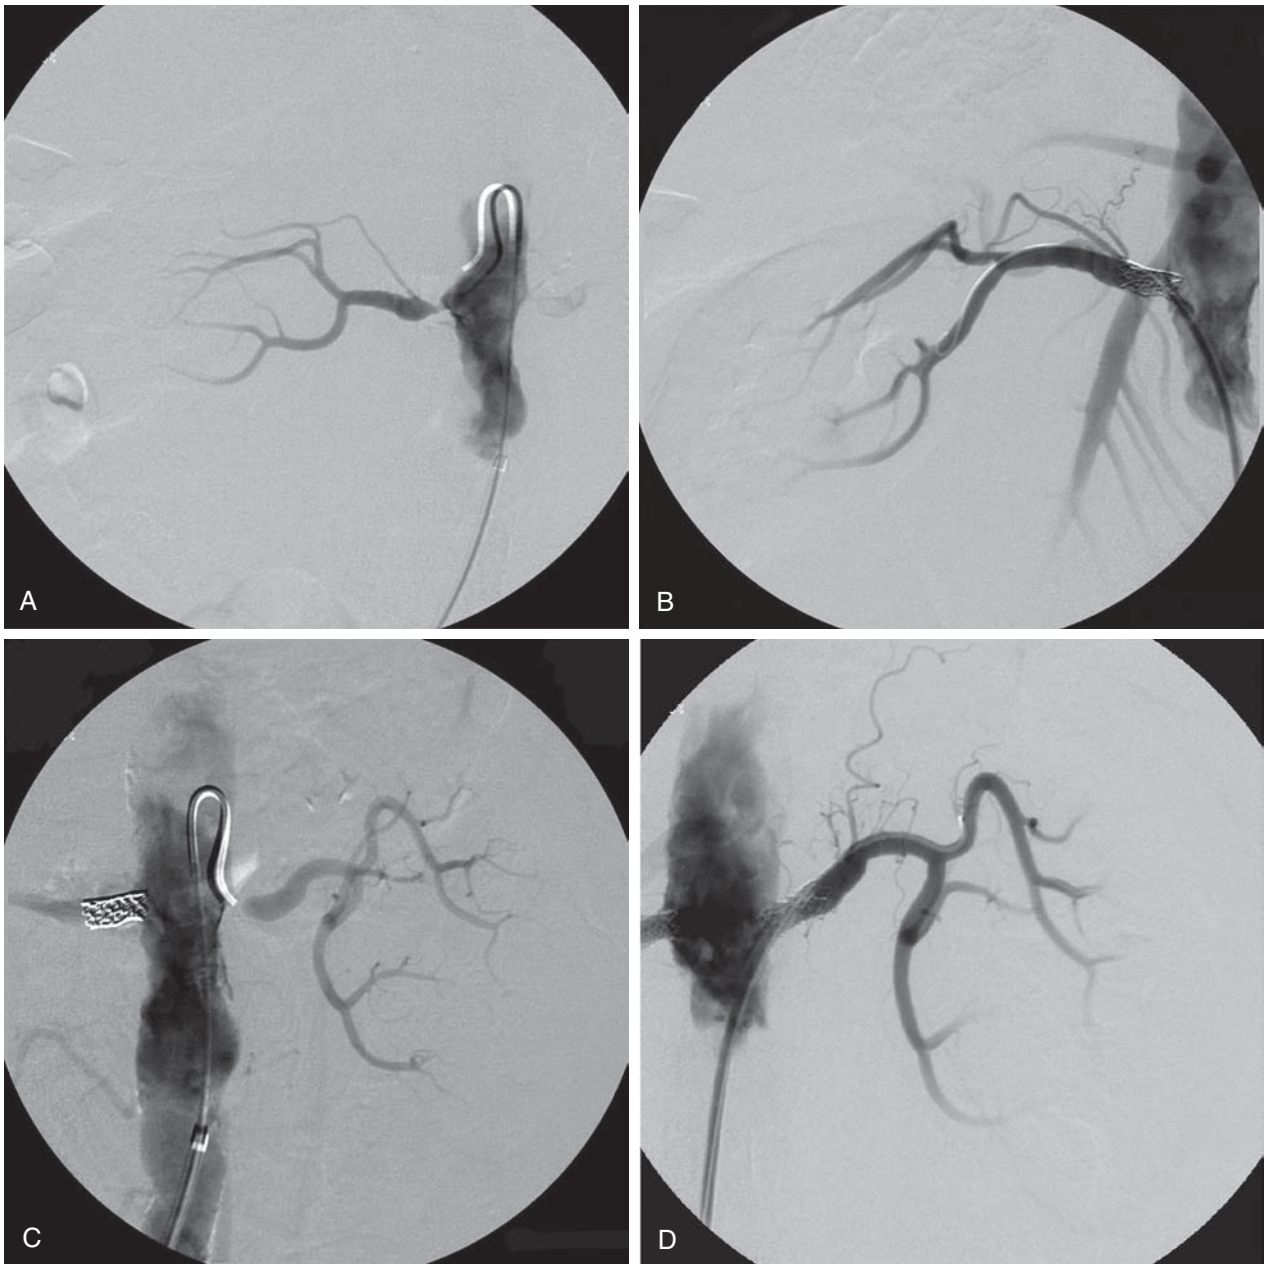

Figure 39-3 Angiograms of atherosclerotic renal artery stenosis. A, Proximal, high-grade stenosis near the ostium. **B,** Restoration of vessel patency by endovascular stent placement. **C,** Image of contralateral, high-grade stenosis of the left kidney. **D,** Improved flow after endovascular stenting.

series report an overall prevalence of 4% to 20%, with progressively higher rates for those older than 60 years (25% to 30%) and 75 years (40% to 60%). These studies suggest that ASRVD is common among elderly hypertensive patients. Furthermore, RA stenosis from ASRVD has been reported to contribute to the decline in renal function in 15% to 22% of patients reaching ESRD.[11,12]

Relationship to "Ischemic" Renal Disease

Activation of pressor mechanisms producing RVH can occur without loss of kidney size or function. However, the more common clinical scenario in patients with ASRVD involves both increasing severity of hypertension and deteriorating renal function, often with loss of kidney volume. Because mechanisms underlying parenchymal renal damage differ from those responsible for generating hypertension, improved BP control after revascularization in some cases may be achieved without improvement in kidney function.

Transition from "reversible" loss of function to "irreversible" tissue fibrosis is not well understood. Basal renal energy requirements are met with less than 10% of blood flow, consistent with its filtration function. Studies using blood oxygen level–dependent (BOLD) magnetic resonance imaging (MRI) indicate that despite reductions in blood flow and GFR, many patients maintain normal cortical and medullary tissue oxygenation.[13] Thus, many poststenotic kidneys have no more "ischemia" than normal kidneys. These observations explain the relative stability and infrequent progression of renal injury in prospective trials of medically treated patients with ASRVD, such as Angioplasty and Stenting for Renal Atherosclerotic Lesions (ASTRAL).[14,15] Nonetheless, reduced renal perfusion ultimately activates numerous mechanisms of tissue injury. Figure 39-4

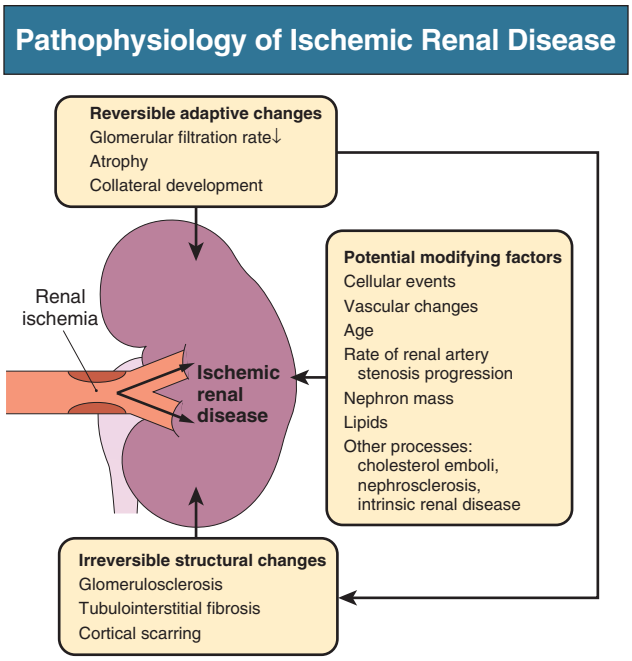

Figure 39-4 Pathophysiology of ischemic renal disease. Chronic ischemia of the kidney is associated with reversible functional involution and atrophy as well as with irreversible structural changes. A number of external factors influence the renal response to chronic ischemia. *(Modified from reference 92.)*

summarizes the activation of vasoactive and inflammatory pathways.[16] Over time, inflammation, fibrosis, and microvascular rarefaction occur, leading to irreversible changes.[16,17]

Activation of the RAAS and endothelial systems such as endothelin and oxidative stress pathways have been demonstrated with RA stenosis models.[16] These systems stimulate inflammation and drive fibrosis. Under acute conditions of reduced blood flow with persistent filtration and tubular function, levels of deoxygenated hemoglobin increase in the renal medulla, representing medullary hypoxia.[18] Medullary oxygen levels are normally lower than cortical levels and are heavily dependent on the level of solute transport. Reductions in GFR and associated energy-dependent solute transport allow "adaptation" to reduced blood flow without development of tissue hypoxia. Only when more severe vascular occlusion develops beyond the limits of such adaptation can one identify overt cortical ischemia associated with increased deoxyhemoglobin.[19] This results in macrophage accumulation with progressive tubular cell loss and fibrosis.[20] Glomeruli are usually preserved, although collapsed.

Clinical Manifestations

Renovascular Hypertension

Clinical studies suggest that for any level of BP, patients with RVH have higher nocturnal pressures ("nondipper") and have more severe target organ manifestations, including left ventricular hypertrophy, than patients with essential hypertension[21] (Box 39-2). Likelihood of RVH in patients with treatment-resistant hypertension increases with elevated cholesterol, impaired renal function, lower body mass index, and smoking; but none of these features is sufficiently sensitive or specific to offer diagnostic precision. Some reports indicate that RVH rarely may be associated with nephrotic-range proteinuria, which can regress with correction of the vascular lesions.[22]

Blood pressure elevations from RVH vary widely. Acute RA occlusion may only gradually produce BP increase or may cause a rapid increase in hypertension that precipitates a hypertensive urgency or emergency (see Chapter 37). Before the current era of antihypertensive agents, 30% of Caucasian patients appearing in an emergency department with hypertensive urgency (defined as grade III or IV hypertensive retinopathy) were ultimately found to have RVH. Syndromes of polydipsia and accelerated hypertension with hyponatremia and hypokalemia, sometimes attributed to the dipsogenic actions of Ang II, also have been observed.

Recent consensus documents emphasize the need for effective population-wide BP control, while limiting the number and expense of diagnostic studies. As a result, most patients with hypertension simply are treated and subjected to few laboratory investigations. For those who reach acceptable BP control without adverse effects, no further studies are performed. Therefore, many if not most cases of RVH are not detected (Fig. 39-5), unless hypertension becomes more difficult to treat or renal dysfunction ensues.

In recent years, widespread application of RAAS blockers for indications other than hypertension, including congestive cardiac failure, diabetic nephropathy, and other proteinuric renal disease, increases the exposure of individuals with undetected RA stenosis to these drugs.[23]

A consequence of these changes has been the emergence of distinctive clinical syndromes that merit evaluation in patients at risk for ASRVD (see Box 39-2). As a result, patients that typically undergo diagnostic evaluation and renal revascularization are a subset of the patient population with RVH. This subset is characterized generally by more severe hypertension, decreasing renal function, propensity for rapid volume accumulation manifested as "flash" pulmonary edema, and occasionally advanced renal failure.

Renovascular Hypertension: Clinical Manifestations

Features of Renovascular Hypertension

- Activation of renin-angiotensin-aldosterone system (RAAS)—early
- Parenchymal symptoms: sympathetic nervous system activation
- Abnormal circadian rhythm: loss of nocturnal pressure fall
- Accelerated target organ damage
  - Left ventricular hypertrophy
  - Microvascular disease
  - Renal injury: fibrosis
- Hyponatremic hypertensive syndrome
- Nephrotic range proteinuria
- Unstable cardiac chest pain

Clinical Syndromes Associated with Atherosclerotic Renal Artery Stenosis

- "Incidental lesion": no hemodynamic effect
- Renovascular hypertension (see above)
  - New-onset hypertension
  - Acceleration in previously hypertensive patient
- Acute kidney injury
  - ACE or ARB-induced acute kidney injury
  - Acute or chronic kidney disease impairment
- Unexplained chronic kidney disease: especially in elderly patients
- Circulatory congestion: "flash pulmonary edema"

Box 39-2 Clinical manifestations of renovascular hypertension. *ACE*, Angiotensin-converting enzyme; *ARB*, angiotensin receptor blocker.

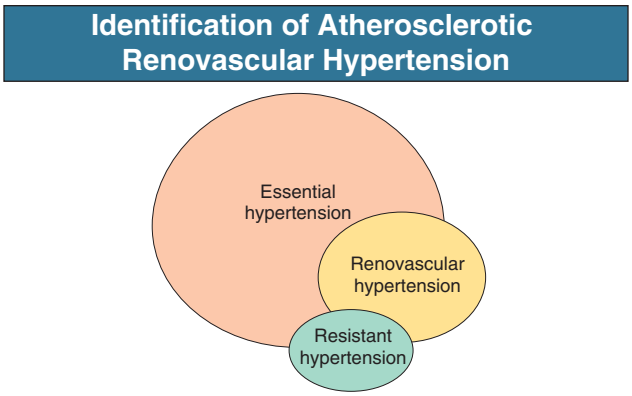

Figure 39-5 Identification of atherosclerotic renovascular hypertension. Venn diagram indicates that many patients with renovascular hypertension are indistinguishable from patients with primary hypertension. A subset develops problematic or resistant hypertension, which brings them to clinical attention and consideration for renal revascularization.

Ischemic Renal Disease

The diagnosis of IRD (ischemic nephropathy) should be considered in several clinical settings (see Box 39-2).

Renal Impairment in Patients with Renovascular Hypertension or in Atherosclerotic Age Range Ischemic nephropathy should be considered as a cause of chronic kidney disease (CKD) in the atherosclerotic age group, particularly when other vascular disease is detected. Many but not all will have a history of hypertension. It remains difficult to separate primary vascular disease from renal parenchymal injury associated with nephrosclerosis from other vascular insults. Clues to IRD include asymmetry of kidney size or recent deterioration of renal function, as opposed to slowly progressive CKD. An asymmetrically small kidney in an adult over age 50 has a 70% chance of being associated with ipsilateral RA stenosis.[24]

The development of renal impairment in patients treated medically for longstanding hypertension should raise suspicion for possible IRD. Given the high frequency of bilateral RA stenosis (30% to 50%), the possibility of IRD should always be considered in patients with known prior RA stenosis. The most common presentation of ASRVD is unilateral involvement in a patient with CKD associated with longstanding hypertension. In this case, renal impairment cannot be attributed solely to IRD because the RA stenosis affects only one kidney. The kidney supplied by the stenotic vessel may have reduced blood flow, resulting in diminished GFR, RVH, and atrophy. The contralateral kidney with a patent renal vessel often hypertrophies and compensates with hyperfiltration. However, over time, this kidney develops parenchymal injury. In some cases, the kidney with the patent RA has worse renal function than the poststenotic kidney.[25]

Acute Kidney Injury After Starting Antihypertensives/RAAS Blockade Patients with hemodynamically significant RA stenosis to the entire functioning nephron mass are at risk for the development of "functional" acute kidney injury (AKI) after starting RAAS blockers. The sudden reduction in systemic BP in the patient with critical RA stenosis may reduce RA pressure below levels needed to sustain glomerular filtration by autoregulation (see Medical Therapy). This can occur with reduction in BP by any antihypertensive agent. With medications that block the production or action of Ang II, alterations in glomerular hemodynamics may result in acute reduction in GFR, which is independent of effects on systemic BP.[26] Normally, activation of Ang II causes efferent arteriolar vasoconstriction, which preserves transcapillary filtration pressures at the glomerulus when preglomerular pressures are reduced, thereby maintaining GFR. The loss of this compensatory mechanism induced by agents that inhibit or block the RAAS can result in functional AKI. This typically occurs within a few days from the start of therapy and is usually, but not always, reversible.

In patients without RA stenosis, AKI can also occur with the use of RAAS inhibitors. This most frequently occurs in patients with cardiac or hepatic dysfunction or patients with intravascular volume depletion because, in these settings, GFR is also Ang II dependent. In a prospective study, the observation of 20% increase in serum creatinine or more after administration of an angiotensin-converting enzyme (ACE) inhibitor detected most cases of bilateral severe RA stenosis.[27] When prospectively challenged, more than 90% of a cohort followed in the United Kingdom tolerated RAAS blockade, including 78% of those with high-grade, bilateral ASRVD.[28] Because of the potential change in GFR, kidney function should be rechecked within 1 to 2 weeks of instituting therapy with RAAS blockers.[29]

"Flash" Pulmonary Edema Some patients with bilateral RA stenosis or ischemic nephropathy develop severe hypertension and extracellular fluid volume excess caused by impaired pressure natriuresis. Such conditions may produce the sudden ("flash") onset of pulmonary edema in association with rapid development of circulatory congestion.[30] This has been attributed in part to rapid loss of contractile strength of the left ventricle caused by sudden increases in afterload. Impaired diuresis can result in exaggerated swings in BP, circulatory congestion, and renal function.[31] Such patients have increased mortality and hospitalization rates compared with those who have congestive heart failure (CHF) without renovascular disease.[32] Case series suggest that renal revascularization can facilitate fluid volume management, reduce hospitalization, and occasionally improve cardiac function independent of interventional procedures for the heart itself, even in patients with poor preoperative cardiopulmonary status.[33,34] In one series, 41% of patients with bilateral RA stenosis had a history of pulmonary edema, compared with 12% with unilateral renovascular disease. Of patients with bilateral RA stenosis, 77% had no further pulmonary edema after RA stent placement in one or both arteries. The patients who did have recurrent pulmonary edema all had evidence of stent thrombosis or restenosis.[35]

No prospective clinical studies have examined the effect of optimal medical therapy of BP and volume status on the frequency of events in these patients. Observational, retrospective studies indicate that ASRVD in patients with CHF imparts a worse survival and that renal revascularization lowers the rates of recurrent pulmonary edema and hospitalization as compared to those treated medically.[32] Reports from prospective, randomized controlled clinical studies such as ASTRAL, however, demonstrate no differences in hospitalizations or episodes of CHF between intensively treated patients with or without RA stenting.[14] An important caveat related to this observation is that patients considered "likely to benefit" from revascularization were excluded from ASTRAL.[36]

Oligoanuric Acute Superimposed on Chronic Kidney Disease Patients with high-grade RA stenosis are at risk for renal artery occlusion. When RA stenosis is bilateral or unilateral in the patient with a single functioning kidney, progression to total occlusion can present as oligoanuric AKI, sometimes associated with a hypertensive emergency. A clinical clue to this diagnosis is abrupt onset oligoanuria. In this setting, the kidney parenchyma may be viable despite lack of filtration; in some patients collateral vessels maintain renal viability in the face of proximal RA occlusion. Clues to renal viability include preserved kidney length and evidence of renal contrast enhancement ("renal blush") seen on delayed or venous phase images during renal angiography. When these factors are present and the clinical course is consistent with recent occlusion, there is a chance of retrieval of renal function if revascularization is feasible clinically and anatomically. In this setting, urgent vascular surgical

consultation should be sought, and the nephrologist should assume that the kidneys may be viable for weeks to months.

Incidental Renal Artery Stenosis As mentioned, ASRVD is highly correlated with disease in both the coronary and the peripheral vasculature. Disease is usually identified incidentally at angiography or computed tomography (CT) for other indications. Most of these patients with coexisting ASRVD and coronary artery disease have only moderate degrees of RA stenosis (50% to 75%) with minimal hemodynamic impact. However, the presence of RA lesions is an independent risk factor for mortality, which may reach 30% over 4 years in high-risk groups.[37] Since no data support intervention for asymptomatic RA stenosis, the use of screening renal aortography at coronary angiography should be limited to patients who have demonstrated clinical manifestations, as summarized earlier, and in whom documentation of RA disease is likely to influence management.

Natural History

Early, retrospective angiographic studies (1980s) suggested ASRVD typically progresses over 2 to 5 years. "Progression" is usually defined as a greater than 25% luminal diameter narrowing or as severe stenosis progressing to vascular occlusion. Over 4 to 5 years, 6% to 16% of stenoses advance to occlusion. Prospective studies between 1990 and 1997 using Doppler ultrasound in patients with atherosclerotic RA lesions indicated hemodynamic progression in 30% over 3 years, varying by degree of initial stenosis, although total occlusion occurred in only 3%.[38] Measurable loss of kidney length (>1 cm) is less common but accompanies progressive vascular occlusion. Changes in serum creatinine are often minimal.[39]

Progression is most likely in patients with more than 60% stenosis. It often occurs without changes in BP control. Therapy with statins appears to reduce the risk of progression and occasionally induces regression of atherosclerotic RA stenosis.[40] Statins also appear to attenuate renal parenchymal injury associated with experimental ASRVD.[41]

Follow-up studies of patients with incidentally detected, high-grade RA stenosis (>70%) treated medically indicate that fewer than 10% required later revascularization for intractable hypertension.[42] Another report noted that few patients with incidental RA stenosis progressed to ESRD over follow-up of 8 to 9 years.[43] Patients followed after simultaneous renal angiography at cardiac catheterization noted no difference in serum creatinine between those with and without RA stenosis at follow-up.

Risk of Mortality

Both ASRVD and ischemic nephropathy (IRD) are associated with limited long-term survival, consistent with widespread atherosclerotic disease. Retrospective analyses report 3-year to 5-year mortality rates of 30% to 35% in patients with RA stenosis, largely caused by cardiovascular events or cerebrovascular accident (stroke). In follow-up of more than 1200 patients who underwent coronary and renal angiography, patients with RA stenosis had a 65% 4-year survival versus 85% for those without RA stenosis at catheterization. The 5- and 10-year survival rates for patients reaching ESRD caused by IRD are as low as 18% and 5%, respectively.[44]

Whether renal revascularization improves overall survival in patients with ASRVD remains controversial.[45] In one study, patients with bilateral ASRVD who were treated medically had better follow-up renal function than those who had undergone revascularization, but there was no difference in survival.[46] Other studies suggest that intervention directed at improving renal function may improve survival in these patients. An observational study reported 2-year survival of 80% in patients with ischemic nephropathy who underwent endovascular stenting.[47] Reports from combined UK and German cohorts treated prospectively indicated that improvement in renal function was more likely in revascularized patients and associated with substantial survival benefit compared with those treated with medications alone.[48] The morbidity and mortality associated with complications of endovascular interventions must be considered in the risk/benefit analysis of optimizing treatment of patients with ASRVD.[49,50] Prospective randomized controlled trials comparing renal artery stenting with medical therapy, including the recently published Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) trial, have failed to demonstrate a benefit of intervention on mortality or cardiovascular or renal end points.[51] CORAL is expected to publish important natural history data from a prospectively studied subgroup followed by serial duplex ultrasound studies.

FIBROMUSCULAR DYSPLASIA

Fibromuscular dysplasia (FMD) is a noninflammatory, nonatherosclerotic arteriopathy and the second most common cause of RVH. It usually involves the middle to distal renal artery or branches (Fig. 39-6). The vascular distribution of FMD involves primarily the renal and cerebral arteries. Renal arteries are involved with FMD in 65% to 70% of cases. Bilateral RA disease is seen in 25% to 35% of adult cases, in up to 78% of syndromic childhood FMD, and in most familial cases.[52] Associated midaortic syndrome should be considered in pediatric cases.[53] Cerebrovascular involvement is present in 25% to 30% of adult cases. Up to 65% of patients with renovascular FMD have concomitant cerebrovascular involvement. Less common extrarenal sites of involvement with FMD include coronary, mesenteric, celiac, splenic, aortic, and peripheral vasculature, with two sites involved in 30%, three sites in 20%, and more than three sites in 10% of patients.

Epidemiology

The prevalence of clinically apparent renovascular FMD is estimated at 4 in 1000, with a lower prevalence of cerebrovascular involvement of 1 in 1000.[54] Data from screening angiography in potential kidney donors suggest that the prevalence may be higher, with FMD observed in 3% to 6% of individuals. FMD has a female predilection, with about 90% of cases occurring in women. FMD is reported to be more common in whites than in blacks. Of those enrolled in the United States registry of patients with FMD, 95% are Caucasian, and the mean age of onset of hypertension 43 years.[55] It is unclear whether this racial predilection represents recruitment or geographic bias. Familial FMD occurs in approximately 10% of patients[54] and has been associated with subclinical evidence of carotid flow abnormalities in first-degree relatives, consistent with an autosomal dominant inheritance pattern.[56] FMD may also complicate other hereditary syndromes (e.g., Alport, Ehlers-Danlos, Marfan). Box 39-3 lists clinical disorders associated with FMD.

Pathophysiology

The pathophysiology of FMD is unknown. No unifying genetic mutations have been identified. It is likely that numerous disturbances in vascular collagen and structural processes can result in the FMD angiographic phenotype. Genes being investigated include collagen III *(COL 3A1),* α_1-antitrypsin, angiotensin I–converting

Figure 39-6 Fibromuscular dysplasia. enzyme, and JAGGED 1 (encodes for a ligand for Notch receptors). Other implicated etiologic factors include cigarette smoking, hormonal influences (based on the female predilection), and vascular trauma or stretching of the renal artery.[57]

Histologically, abnormal vascular wall structure is associated with irregular bands of collagen deposits and in some cases disruption of elastic membrane. Several subtypes of FMD have been described on

Fibromuscular Dysplasia: Clinical Manifestations and Associated Disorders

Clinical Manifestations

- Incidental finding (e.g., living kidney donors)
- Renovascular hypertension
- Renal infarction
- Loin or flank pain
- Hematuria
- Retroperitoneal hemorrhage
- Cerebrovascular accident (stroke)
- Transient ischemic attack
- Headaches
- Pulsatile tinnitus
- Horner syndrome
- Neck pain
- Dizziness
- Imaging finding of aneurysm dissection
- Amaurosis fugax
- Myocardial infarction
- Ischemic chest pain/dyspnea
- Postprandial abdominal pain
- Weight loss
- Hemobilia
- Claudication

Associated Disorders

- Tuberous sclerosis
- Marfan syndrome
- Ehler-Danlos syndrome
- Cystic medial necrosis
- Coarctation of the aorta
- Alport syndrome
- Renal agenesis or dysgenesis
- α_1-Antitrypsin deficiency
- Medullary sponge kidney
- Pheochromocytoma
- Infantile myofibromatosis
- Ergotamine preparation, methysergide
- Cigarette smoking
- Collagen III glomerulopathy
- Atherosclerotic renovascular disease
- Alagille syndrome
- Ask-Upmark kidney
- Celiac disease
- Cocaine exposure—intrauterine
- Crohn disease
- Homocystinuria
- Macrophagic myofasciitis
- Neurofibromatosis
- Williams syndrome

the basis of the predominant layers of the arterial wall involved, but these are not mutually exclusive. In up to two thirds of cases examined histologically, more than one arterial wall layer is involved. The histologic features coincide with the arteriographic phenotypes outlined in Table 39-1. The three main types of FMD are medial fibroplasia, accounting for 85% to 100% of cases, and intimal and adventitial fibroplasia. In *medial* fibroplasia, alternating thin and thick ridges of collagen and elastic tissue deposits result in discrete stenoses alternating with aneurysmal sections characterized by fragmented internal elastic lamina. This produces the recognizable "string of beads" appearance on angiography. The loss of elastic structural integrity leads to ballooning or beading of the vessels such that the diameter of the beaded segment is larger than the diameter of the artery lumen. In *intimal* FMD, the angiographic pattern is smooth focal or elongated lumen narrowing and results from concentric intimal deposition of collagen with fragmentation and duplication of the internal elastic lamina. In *adventitial* or *periarterial* FMD, the rarest histologic variant, dense collagen replaces the normal fibrous tissue in the adventitia, resulting in concentric, smooth narrowing of the lumen.[58] Unlike atherosclerotic RA stenosis, FMD generally appears beyond the first 2 cm from the RA origin. FMD and atherosclerotic disease may also coexist. The differential diagnoses for angiographic lesions consistent with FMD include ASRVD, although this is usually easily distinguishable; renal vasculitis, particularly Takayasu arteritis; segmental arterial mediolysis;

Fibromuscular Dysplasia: Histologic Classification and Angiographic Phenotypes			
Type	**Frequency**	**Histology**	**Angiographic Appearance**
Medial			"String of beads"
Medial fibroplasia	85%-100%, most common	Alternating ridges of collagen/loss of elastic membrane	Medial: bead diameter is larger than lumen diameter
Perimedial fibroplasia	Rarer (10%-15%)		Perimedial: bead diameter is smaller than lumen diameter
Medial hyperplasia	Rarest	True smooth muscle hyperplasia: no fibrosis	Medial hyperplasia: smooth stenosis without beads
Intimal	<10%	Circumferential deposition of collagen in intima: fragmented or duplicated internal elastic lamina	Concentric smooth stenosis: long smooth narrowing
Adventitial	<1%	Dense collagen replaces fibrous tissue in adventitia and surrounding tissue	Smooth stenosis or diffuse attenuation of vessel lumen

Table 39-1 **Histologic classifications of fibromuscular dysplasia and angiographic phenotypes.**

and an artifact of imaging known as "standing arterial waves," thought to be caused by catheter-induced vasospasm.[59]

Renal artery aneurysms may also be seen in FMD. The frequency is unclear. Aneurysms were identified in only 5.6% of the patients in the U.S. FMD registry, but some series report up to 50% having aneurysms. Aneurysms in FMD are most common in the renal vasculature compared with other beds. When present, 17% of patients with an aneurysm at any vascular site have more than one vascular site involved, with some having up to four.[55]

Clinical Manifestations

Clinical manifestations of FMD are summarized in Box 39-3. Because it is usually asymptomatic for many years, FMD is sometimes detected as an incidental finding during angiography. The most common adult clinical presentation is early-onset hypertension between ages 15 and 50 years, more often in women than men. FMD is also the most common cause of RVH in children. Although RVH in women under age 50 is the most common presentation of renal FMD, the presence of lesions in other vascular territories can lead to other symptoms. Headaches, pulsatile tinnitus, and bruits over the carotid arteries, epigastrium, and femoral regions are common. Stroke, transient ischemic attacks, or amaurosis fugax may occur. FMD should be considered in patients with early stroke or subarachnoid hemorrhage caused by cerebral aneurysms or when extrarenal vascular aneurysms or dissection occurs. Therefore, young patients presenting with spontaneous carotid artery dissection or occlusion should be considered at risk for renovascular FMD, and vice versa. In addition, FMD with associated aneurysms of the renal artery can present as renal infarction from renal artery dissection, embolism from clot within the aneurysm, or retroperitoneal hemorrhage with flank pain and hemorrhagic shock (Box 39-3).

Natural History

The natural history of FMD has not been adequately studied. Progression of disease can be manifest as the development of new focal lesions within the same arterial bed, worsening arterial luminal narrowing within a specific lesion, involvement of a new vascular territory, or development or enlargement of arteriovenous fistulas or aneurysms. It appears that up to 27% of patients may demonstrate angiographic progression of FMD when serial studies are undertaken. This appears to be limited to younger patients, with few patients developing new or progressive lesions after age 50 years. FMD rarely causes ESRD unless hypertension remains uncontrolled, or thrombosis or dissection of the renal vessel results in renal infarction. Renal cortical atrophy has been reported in more than half of patients with untreated FMD.[60]

DIAGNOSIS OF RENOVASCULAR HYPERTENSION

In addition to consideration of age of onset and quality of hypertension, the diagnosis of RA disease–induced RVH requires both demonstration of a critical stenotic vascular lesion and activation of the RAAS. From the imaging standpoint, conventional angiography remains the reference standard to define the anatomy of the renal vasculature against which other screening modalities are compared. Common noninvasive screening modalities include RA duplex ultrasound, computed tomographic angiography, and magnetic resonance angiography (see Chapter 5) (Table 39-2). The goal of noninvasive screening is to limit further invasive testing. These methods provide different information and may vary between institutions in both availability and reliability.

Renal artery duplex scanning is often used to identify and to follow hemodynamic effects of vascular lesions serially. It is relatively inexpensive and requires no contrast. It is most effective in detecting lesions of the main RA near the ostium, making it a better screening test for ASRVD than for FMD. However, the reliability of this method depends on the skill of the ultrasonographer and on the body habitus of the patient. Duplex ultrasound provides little functional information regarding the kidney beyond the vascular lesion, although many important structural features may be determined, including kidney size and presence of ureteral obstruction. The diagnostic criteria for hemodynamically significant RA stenosis by duplex ultrasound includes acceleration of blood flow through the stenotic area that exceeds the flow in the aorta, as well as abnormal waveforms representing blood flow in the affected vessel (see Chapter 5). Parameters measured using this modality include peak systolic velocity (PSV) at various sites along the aorta and renal artery, acceleration time and index, and intrarenal resistive index. The resistive index has been associated with intrinsic small vessel renal disease, and a value greater than 80 has a strong negative predictive value on likelihood of BP response to intervention. PSV in the range of 250 to 350 cm/sec is considered the threshold for identifying a 60% to 70% RA stenosis.

Magnetic resonance angiography (MRA) offers the potential to provide both structural vascular imaging and functional information. MRA with gadolinium contrast gives excellent imaging of the

Relative Value of Imaging Methods for Evaluation of Renal Vasculature

Methods	Images of Vessels	Tissue Perfusion	Function (GFR)	Advantages	Disadvantages
Spiral computed tomographic angiography	+++	+	±	Provision of three types of images, examination of venous structures, might be useful for evaluating transplant donors	High contrast requirement
Contrast angiography	+++	++	±	Nephrography estimates volume of viable tissue; gold standard	Risk of catheter-induced injuries and contrast nephropathy
Captopril renography	–	+++	++	Change in GFR might estimate reversibility of lesion; widely available, noninvasive; totally normal renogram effectively excludes significant vascular disease.	
Duplex ultrasound	++	++	–	Precise measurement of flow velocity, suitable for serial studies, relatively inexpensive	Produces little functional information; is not suitable for accessory vessels
Magnetic resonance angiography	++	++	±	No radiation exposure	Gadolinium contrast not used for eGFR <30 ml/mg; concern for nephrogenic systemic fibrosis

Table 39-2 Relative value of imaging methods for evaluating the renal vasculature. The available techniques vary in their ability to image the renal vessels, to assess tissue perfusion, and to measure glomerular filtration rate (*GFR; eGFR,* estimated).

main renal arteries. Limitations of MRA include interobserver variability, a recognized tendency to overestimate luminal narrowing, and limited sensitivity for middle and distal vascular lesions. Caution is advised in the use of gadolinium agents in patients with reduced GFR, based on reports of nephrogenic fibrosing dermopathy in patients with advanced CKD exposed to these agents. Studies are underway to improve the sensitivity and negative predictive value of non–gadolinium-enhanced MRA in the detection of RA stenosis (Fig. 39-7).

Computed tomographic angiography (CTA) with vascular reconstruction achieves image qualities almost equivalent to those of angiography but requires more iodinated contrast. CTA is becoming the noninvasive study of choice in patients whose risk of contrast-associated nephrotoxicity is minimal. However, CTA may overestimate the degree of stenosis with false-positive rates, which vary according to reconstruction protocols, vascular calcification, and regional differences in experience. CTA is highly sensitive for identifying lesions associated with FMD and is a good screening test for these patients, who generally have good kidney function[61] (Fig. 39-8).

Angiography remains the gold standard for defining the degree of stenosis associated with ASRVD and for identification of FMD. Aortography provides important anatomic and functional information in cases of tight stenosis or occlusion, including the demonstration of delayed perfusion of the kidney and distal reconstitution of the proximally occluded renal vessel. This is important in consideration of surgical revascularization for retrieval of renal function. In experienced hands, selective renal angiography to identify significant RA stenosis can be performed with as little as 20 ml of iodinated contrast. In very-high-risk cases, carbon dioxide can be used in place of contrast to assess the renal ostium and proximal vessel where atherosclerosis typically develops.

Unfortunately, few tests can accurately predict favorable response to intervention. Two tests used for this purpose in cases of unilateral RA disease include captopril renography and measurement of renal vein renin levels. Figure 39-9 illustrates a captopril-enhanced renogram in a patient with RA stenosis. This examination provides no direct image of the renal vessel, but does provide a view of the rate of isotope appearance and washout, reflecting the sequence of renal blood flow and filtration. The study provides functional information

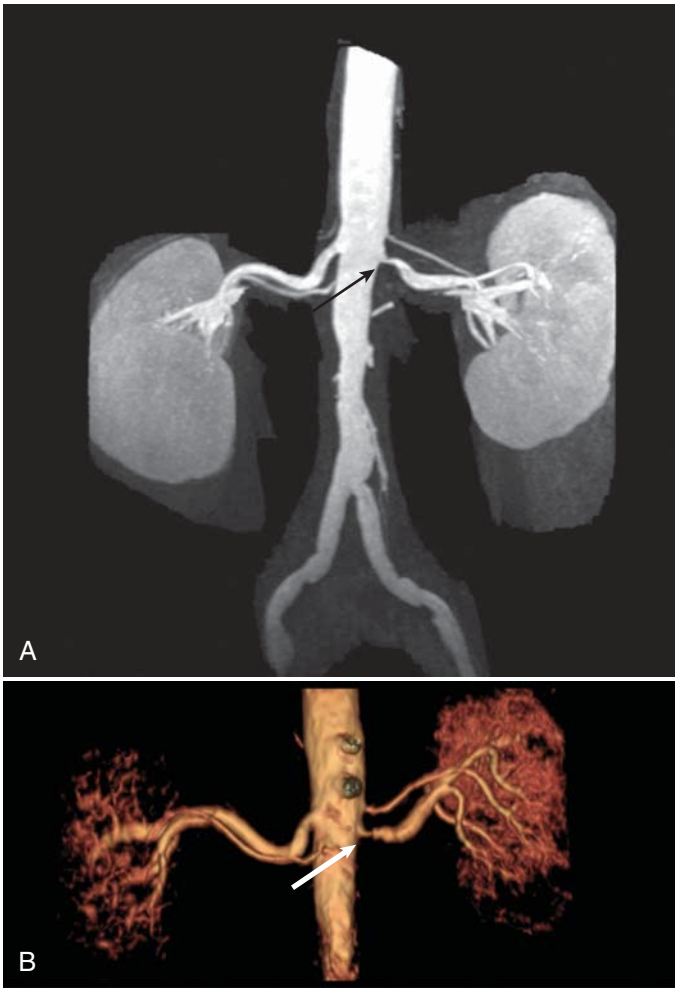

Figure 39-7 Magnetic resonance angiogram with and without gadolinium contrast enhancement. A, High-grade stenosis affecting the left inferior renal artery is evident, with functioning kidney tissue as reflected by gadolinium nephrogram *(arrow)*. Concerns about the role of gadolinium in the development of nephrogenic systemic fibrosis have greatly reduced the use of this contrast agent. **B,** As a result, methods to image the vasculature without contrast material are being developed that produce excellent reconstructed images *(arrow)*.

regarding the size and excretory capacity of the kidney, as well as emphasizing the role of Ang II in maintaining GFR. This test has a high negative predictive value when completely normal.[62] Many intrinsic renal abnormalities unrelated to the main RA may change these curves, which limits its value in the presence of reduced GFR (serum creatinine >2.0 mg/dl, or 176 µmol/l).

Renal vein renin measurements may help predict the BP response to renal revascularization.[5,63] Previous studies indicated that lateralization of renal vein levels (>1.5:1 stenotic-nonstenotic kidney ratio) predicts a favorable BP response for more than 90% of patients. Because failure to lateralize also carried a favorable response in almost half of patients, the negative predictive value is limited. Some

clinicians use these measurements to verify the role of a pressor kidney before undertaking nephrectomy.

TREATMENT OF RENOVASCULAR DISEASE

The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) stated that the goal of hypertension therapy is to reduce morbidity and mortality "by the least intrusive means possible." In RVH, this entails balancing the risks and benefits of several modalities, ranging from medical therapy to surgical or endovascular repair. Whether renal revascularization improves outcomes in the era of effective medical therapy has been the subject of several prospective randomized controlled trials, including ASTRAL and the Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) study in the United States.

Medical Therapy

Most patients with RVH are treated initially with conventional lifestyle modification, control of the metabolic syndrome and antihypertensive medications (see Chapter 36). Regimens using agents that interfere with the RAAS, such as ACE inhibitors, renin inhibitors, and angiotensin receptor blockers (ARBs), as well as the use of diuretics and the dihydropyridine class of calcium channel blockers (CCBs), allow achievement of target BP levels in most patients. RAAS blockade is considered fundamental. Successful renal revascularization rarely leads to withdrawal of all antihypertensive

medications in the current era. Therefore, it may be questioned whether the costs and risks of renal revascularization are warranted for patients whose BP and kidney function are stable on an acceptable antihypertensive regimen.

When there is critical RA stenosis, reduction of arterial pressure has the potential for reduction of renal blood flow below levels needed to sustain glomerular filtration. RA pressures beyond the stenosis may decrease below that needed for autoregulation of blood flow and GFR, estimated at 60 mm Hg in humans.[26] Such a reduction in blood flow can develop with any antihypertensive drug and can rarely lead to thrombotic occlusion.

The RAAS blockers remove the vasoconstrictive action of Ang II at the efferent arteriole. When preglomerular pressures are reduced for any reason, Ang II preserves glomerular transcapillary filtration pressures by constricting the efferent arteriole preferentially. This maintains glomerular filtration despite marginal blood flow. Inhibition of this Ang II effect under these conditions can lead to AKI.[64] The decrease in GFR is apparent clinically under conditions in which the entire renal mass is affected, including bilateral RA stenosis or stenosis to a solitary functioning kidney.[65] Although the functional decrease in GFR induced by RAAS inhibitors is usually reversible, occasionally patients do not recover renal function. Thus, these agents are a double-edged sword in RVH. They have unique properties, allowing more effective BP control than previously possible in this particular situation, but at the same time have the potential for early loss of filtration pressure in patients with critical levels of RA stenosis.

Clinical experience with RAAS blockers in the treatment of RVH is reassuring, however. Postmarketing surveys of >15,000 prescriptions in the United Kingdom after the release of enalapril indicated few, but important, adverse experiences. Most often, these occurred in patients with preexisting renal dysfunction who were taking potassium-sparing diuretics and had other known atherosclerotic disease.[26] Registry data and prospective follow-up studies in patients with ASRVD indicate that blockade of the RAAS is usually well-tolerated and associated with reduced morbidity for patients.[23,28] Nevertheless, hyperkalemia and increasing creatinine values during treatment with RAAS blockade (Table 39-3) in the setting of critical RA stenosis affecting the entire renal mass are indications to consider alternative therapy and/or renal revascularization. Furthermore, medical therapy including RAAS blockade may be insufficient to adequately control BP and cardiac manifestations of RA stenosis including recurrent episodes of pulmonary edema. These patients may benefit from renal revascularization regarding both level of BP control and stabilization of renal and cardiac function.

Guidelines for Limiting Renal Toxicity with ACE Inhibitors

Guideline	Specific Conditions/Interventions
Recognize predisposing condition	Widespread atherosclerotic disease Associated renal artery stenosis Impaired pretreatment renal function Solitary functioning kidney Activated renin-angiotensin system Low sodium intake Diuretic therapy Other volume losses: vomiting, diarrhea Vasodilator administration Low cardiac function: hypotension, hyponatremia Other agents affecting kidney function (e.g., nonsteroidal anti-inflammatory agents)
Monitor effects of initiating ACE inhibitor therapy	Serum creatinine: measure over first days and at weeks 2 and 4, especially in high-risk patients. Elevated serum potassium: withhold potassium supplements; withhold potassium-sparing agents; use low-potassium diet.
Manage volume	Temporarily withhold diuretics. Titrate dose of both diuretics and ACE inhibitor. Liberalize sodium intake, and replace volume; consider rechallenge with ACE inhibitor after volume repletion.

Table 39-3 Guidelines for limiting renal toxicity with angiotensin-converting enzyme (ACE) inhibitors.

Success Rates with Percutaneous Transluminal Renal Angioplasty

Renal Revascularization

Restoring the renal blood supply is a rational goal of treating hypertension related to renovascular disease. In a young person with FMD, a permanent cure of hypertension is sometimes achieved. Revascularization offers such a patient the potential for relief from a lifelong regimen of antihypertensive medications and cardiovascular risk associated with high BP. In practice, however, cures are infrequent. More often, renal revascularization allows improved BP control and stabilization of kidney circulation.

Percutaneous Transluminal Renal Angioplasty for Fibromuscular Dysplasia

Currently most centers treat hypertension associated with FMD with percutaneous transluminal renal angioplasty (PTRA) without stenting.[66] Approximately 86% of patients require less antihypertensive medication after technically successful PTRA. "Complete cure," defined as normal arterial pressure without medications, occurs in 35% to 45% of cases.[67] Predictors of hypertensive response include lower levels of preintervention systolic BP, younger patient age, shorter duration of hypertension, and positive result of simplified captopril renogram.[68] Table 39-4 summarizes 17 reported series assessing technical success and clinical effect of PTRA in patients with RVH caused by FMD.[69] Although primary technical success rates for PTRA are high (>90%) for FMD, restenosis from either inadequate initial treatment or recurrent fibrosis has been reported in up to 34% of cases. This appears to be most common with the "string of beads"

angiographic variant, which has multiple areas of stenosis.[70,71] Some interventionalists recommend the use of intravascular ultrasound to guide adequate endovascular treatment of these lesions, allowing for visualization of web-like membranes often present within them.[72]

Intimal hyperplasia is associated with higher rates of technical failure and early restenosis. Restenosis can be treated by repeated PTRA if needed or, in the case of intimal and adventitial disease, may require surgical revascularization.[73] As patients with FMD age, they are at significant risk of developing essential hypertension or ASRVD, such that the effectiveness of intervention on freedom from hypertension wanes with age.[74]

When FMD is associated with large aneurysmal dilations exceeding 1.5 cm in diameter, surgical revascularization has been the standard of care. Endovascular management of RA aneurysms sometimes can be achieved by use of "covered" stent grafts to exclude the aneurysm. Women of childbearing age with RA aneurysms should be treated surgically or with a covered stent graft before pursuing pregnancy because of the risk of ruptured aneurysm during pregnancy or delivery.

Atherosclerotic Disease: Endovascular Stents

Primary endovascular RA stenting has become standard for the interventional treatment of atherosclerotic RA stenosis in most centers. Comparisons between PTRA alone versus PTRA with stent placement establish superior immediate and long-term results with stents.[75] With current techniques, target vessel patency rates regularly exceed 95%. Short-term use of platelet inhibitors (e.g., clopidogrel) for several weeks to prevent vessel occlusion is standard.

Functional changes and BP changes may develop over weeks and months, when antihypertensive medications can be adjusted. A rise in BP should raise the question of vessel restenosis that occurs in 14% to 30% of patients over the first year. Most occur within 6 months of revascularization and are more common for smaller vessels.

Table 39-5 summarizes results from observational reports of more than 1000 patients undergoing renal artery stent placement for either hypertension or renal function preservation. BP control rates were improved in 50%, with 68% of patients experiencing "stabilization" or "improvement" in renal function over a mean of 17 months.[76] The effects of RA stenting on the course of CKD in patients with RA stenosis remain ambiguous. In almost all studies reporting renal function outcome after stenting, the percentage of patients experiencing improvement in renal function is offset by a group with worsening renal function. Those whose renal function improves the most tend to be those whose renal function was actively deteriorating over the preceding year.[77] Patients with deterioration of renal function after stenting likely experience complications such as cholesterol embolization or contrast nephropathy. Patients with advanced CKD at intervention tend to progress over time to require renal replacement therapy despite technically successful restoration of blood flow.[78]

Common complications of PTRA include contrast nephrotoxicity, which is usually reversible, and atheroembolism, from which patients usually do not recover (Table 39-6). Recent reviews suggest

Complications of Percutaneous Transluminal Renal Angioplasty

Type (Frequency)	Complications
Total (63/691 or 9.1%)	—

Follow-up procedures and definitions of blood pressure cure varied greatly between series. Surgical mortality was 1.3% to 5.8% in patients with stenosis from atherosclerosis and nil in those with fibromuscular disease. *(Modified from references 67 and 94.)*

that 7.5% to 9% of patients have a major, procedure-related complication,[76] including local arterial dissection, aortic dissection, and segmental renal infarction.

Surgical Revascularization

Prior to the introduction of PTRA with stents, surgical revascularization was the standard treatment for patients with IRD and RVH (Table 39-7). Such procedures involve major vascular surgery and carry considerable risk, cost, and morbidity. Risks are reduced with preoperative screening and treatment of associated coronary and carotid disease. As a result, surgical intervention for renovascular disease is reserved for patients refractory to medical therapy for whom endovascular therapy fails[79] or who have associated aortic disease that is not amenable to endovascular therapy.[80] Despite these caveats, successful surgical revascularization in well-selected cases provides durable restoration of kidney blood supply and long-term survival (81% at 5 years).[81] Overall, the effects of surgical revascularization on BP and renal function response in patients with ASRVD mirrors those for endovascular therapy. Diabetic patients form an important subgroup of those with IRD. Surgical revascularization in this group is associated with similar renal functional responses but an inferior rate of BP response and higher postoperative mortality risk or eventual dialysis dependence.

Some dialysis-dependent patients and some with advanced CKD with IRD experience recovery of renal function after surgical revascularization.[82] The best predictor of successful and sustained withdrawal from dialysis is a rapid and recent preoperative decline in GFR, often associated with occlusion of a critically stenotic main RA and a kidney with preserved size and extensive collateral supply.

Some patients develop RVH associated with total occlusion of a preexisting RA stenosis resulting in nonfunctioning of that kidney. Hypertension in these patients may improve with nephrectomy, which can be undertaken with a laparoscopic procedure. Results from a recent series indicate that improved BP can be obtained in such patients without important loss of renal function. Estimates of renal function in this group were 11% in the removed kidney and 89% in the contralateral kidney.[83]

Realistic Outcomes and Controversies with Renal Revascularization

For some patients, technically successful renal revascularization leads to better BP control and improved kidney function. Antihypertensive medication requirements decrease, although rarely are eliminated entirely. Remarkably, the limited prospective data comparing medical therapy with renal revascularization in the current era at most have demonstrated modest benefit regarding renal or cardiovascular outcomes for atherosclerotic disease. Each of three small, randomized controlled trials in the 1990s could identify only minor differences in BP and renal outcomes.[84-86] Despite the lack of prospective trials, application of endovascular RA stenting in the United States rose more than fourfold between 1996 and 2005.[87] Most series report stabilization of renal function, meaning that average serum creatinine levels do not change. Some patients experience improved renal function, whereas others have clinically significant loss of renal function. In most series, this occurs in up to 18% to 20% of patients treated either with PTRA or surgery. Although group average values do not change, some patients experience adverse effects on renal function that should be considered for management decisions.

Among the few prospective, randomized trials related specifically to renovascular hypertension, the most prominent was the Dutch Renal Artery Stenosis Intervention Cooperative Study group (DRASTIC). It included 106 patients with relatively resistant hypertension randomized to medical therapy or PTRA. The lack of difference in BP after 1 year between patients treated with PTRA and treated medically led the authors to conclude that "angioplasty has little advantage over antihypertensive drug therapy."[84] The results of this study were analyzed under "intention-to-treat" statistical rules, but were confounded by 22 of 50 patients assigned to medical therapy (44%) who crossed over to the PTRA arm because of uncontrolled BP levels at 3 months. Despite their inclusion in the medical arm, many authorities reviewing these data argue that this group offers compelling evidence of medical treatment failure in some cases and the benefit of renal revascularization for such individuals.

Since then, additional trials have been undertaken. Reports from prospective registry data from the UK and Germany suggest that revascularization provides measurable slowing of renal functional loss and a survival advantage compared with patients managed with medications alone.[48] This has not been confirmed by randomized controlled trials. ASTRAL compared medical therapy and stenting to medical therapy alone in more than 800 subjects for whom clinicians were "uncertain" as to whether they would benefit from revascularization. Results demonstrated no differences in renal function, BP, CHF, or mortality end points over several years.[14] In ASTRAL, no definition of "certainty" was provided, nor were data regarding outcomes of patients not included in the trial, making it unclear how these results can be generalized to wider groups. The Stent Placement in Patients with Atherosclerotic Renal Artery Stenosis (STAR) trial randomized 140 patients to medical or stent therapy to evaluate loss of creatinine clearance over 2 years.[88] This trial was limited by imprecise definition of stenosis so that 28% of patients assigned to stent therapy were untreated because only trivial stenosis was found at angiography. A small, randomized trial extending more than 9 years failed to detect a mortality benefit with surgical revascularization.[89] The recently completed CORAL trial was the largest randomized controlled trial comparing medical therapy to medical therapy plus stenting in patients with significant renal artery stenosis and hypertension or chronic kidney disease. CORAL randomized 974 patients to well-defined medical therapy including RAAS blockade with or without stenting. CORAL results showed no differences in the composite end point of mortality, cardiovascular and renal events, or any of the individual components. Clinicians caring for patients with ASRVD should embark on aggressive cardiovascular risk factor reduction, incorporate RAAS blockade in the management of hypertension, and individualize consideration of endovascular treatments to avoid unnecessary loss of kidney function and to limit futile interventions.

Integrated Approach to Treating Renovascular Disease

Central to the management of patients' renovascular disease is the recognition of distinctive clinical syndromes, linking acceleration of hypertension with deteriorating renal function and, occasionally, episodic circulatory congestion ("flash" pulmonary edema). Many patients can be managed effectively by medical means, including vigorous measures to prevent atherosclerotic progression with statin therapy and smoking cessation. It must be emphasized that long-term care of such patients is an ongoing process that should be reviewed at regular intervals. When progressively more complex antihypertensive regimens become required, or renal function deteriorates, or for patients with recurrent flash pulmonary edema despite adequate medical and diuretic therapy, consideration should be given to identification and correction of critical vascular lesions affecting the kidneys.

Figure 39-10 provides a general algorithm for evaluating and managing the patient with renovascular disease. In general, a

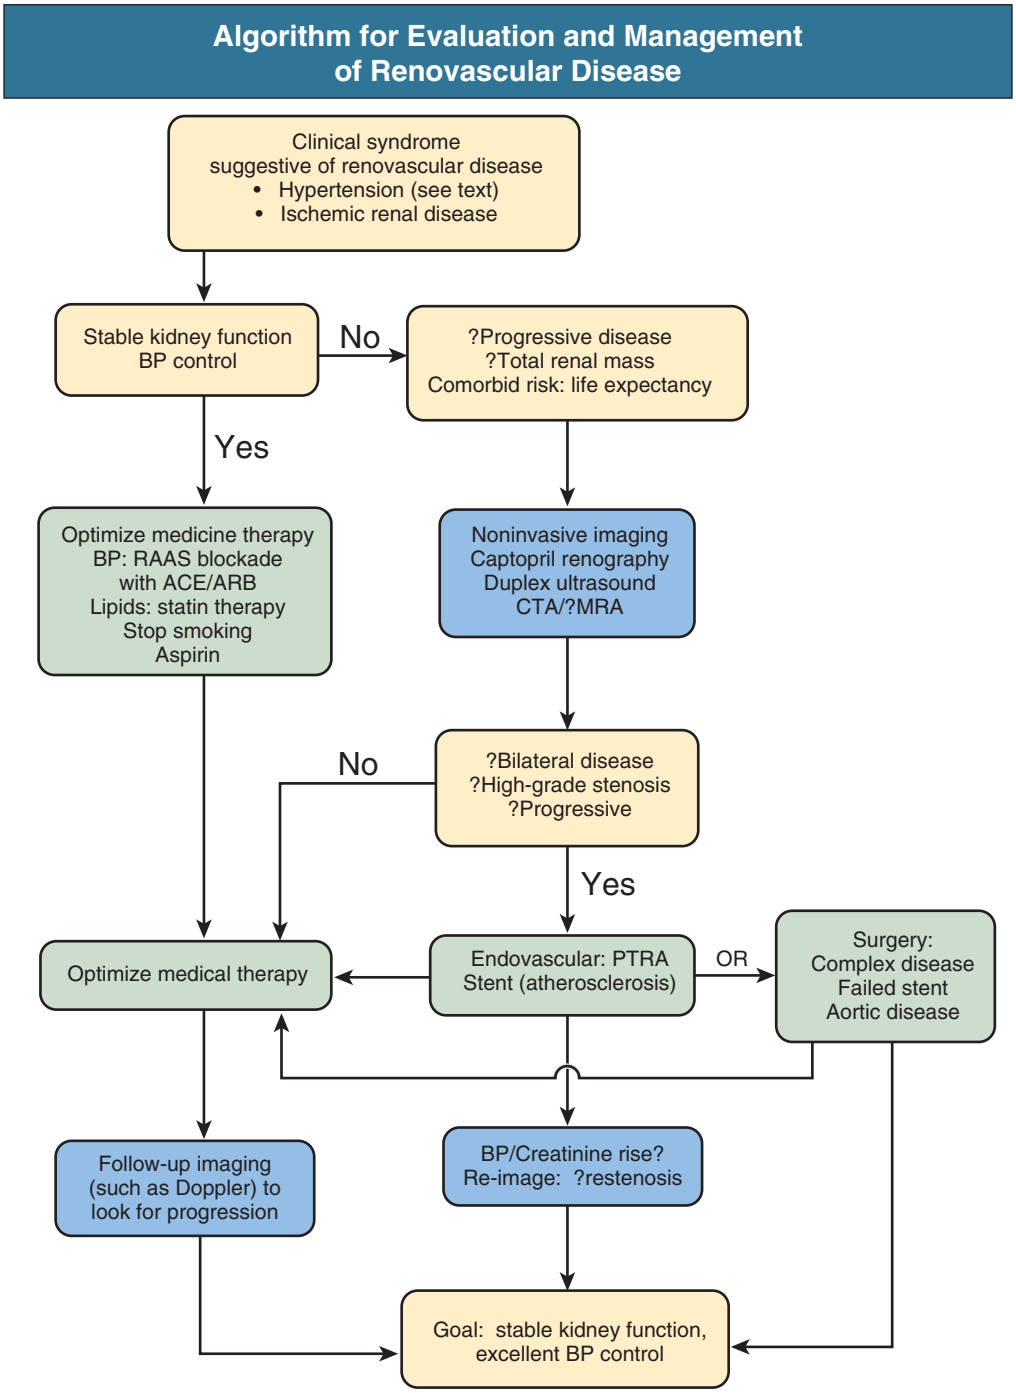

Figure 39-10 Algorithm for evaluation and management of renovascular disease. The intensity of imaging and revascularization depends on both the level of kidney function and the blood pressure, in addition to the comorbid disease risks for the individual patient. The overall goal should focus on stable kidney function and blood pressure levels. As with any other vascular disease, monitoring for disease progression and recurrence is an important element of long-term management. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *BP,* blood pressure; *CTA,* computed tomographic angiography; *F/U,* follow-up; *MRA,* magnetic resonance angiography; *PTRA,* percutaneous transluminal renal angioplasty; *RAAS,* renin-angiotensin-aldosterone system.

reasonable initial approach to patients with ASRVD is to optimize medical therapy for hypertension and cardiovascular risk factors, including smoking cessation, management of hyperlipidemia and diabetes mellitus. When ASRVD is associated with RVH, RAAS blockade is fundamental to control of blood pressure. Often, a multidrug regimen is needed, including diuretics. The decision to pursue diagnostic studies and revascularization should be individualized based on a number of factors, including response to medical therapy, age, kidney function trajectory, estimated risk of intervention, and cardiovascular status.

CHAPTER 40

Endocrine Causes of Hypertension: Aldosterone

I. David Weiner and Charles S. Wingo

Recent advances in the diagnosis of aldosterone-induced hypertension have led to the recognition that primary hyperaldosteronism is more common than previously thought. Effective diagnostic strategies are available, and treatment regimens are highly efficacious.

ETIOLOGY AND PATHOGENESIS

Aldosterone is a steroid hormone normally produced by the zona glomerulosa of the adrenal glands (Fig. 40-1). Aldosterone synthase, which is encoded by the gene *CYP11B2,* is the generally accepted rate-limiting enzyme in adrenal aldosterone production. Table 40-1 summarizes factors known to stimulate or to inhibit aldosterone synthesis by the adrenal gland. Aldosterone exhibits a circadian change in serum concentration, greatest in the late morning and with peak values about 50% greater than the average concentration. The factors accepted as physiologically important regulators of aldosterone production include angiotensin II (Ang II), which stimulates aldosterone production through activation of the AT_1 receptor, and atrial natriuretic peptide and chronic hypokalemia, which inhibit aldosterone production.[1]

Substantial advances have been made recently in our understanding of the factors that lead to primary aldosteronism. In particular, mutations in the gene for the potassium channel KCNJ5 are now recognized as a frequent cause of primary aldosteronism. Germline mutations cause bilateral, familial primary aldosteronism, and somatic mutations are present in about 40% of aldosterone-producing adenomas.[3,4] Mutations in the genes *ATP1A1* (encoding a Na^+, K^+-ATPase) and *ATP2B3* (encoding a Ca^{2+}-ATPase) have also been identified in about 7% of aldosterone-producing adenomas.[5]

A less common genetic cause is *familial hypertension type 1* (FH-1), also known as *glucocorticoid-remediable aldosteronism* (GRA). In GRA, there is crossover between the *CYP11B1* and *CYP11B2* genes, resulting in a chimeric aldosterone synthase gene whose expression is regulated by adrenocorticotropic hormone (ACTH), leading to excessive aldosterone release.[6,7] GRA should be considered in children or young adults with refractory hypertension or in whom there is a family history of hypertension in the same age range or history of premature hemorrhagic stroke.[8] If suspected, genetic testing is the preferred diagnostic approach because of improved sensitivity and specificity over measurement of steroid metabolites or dexamethasone suppression testing.[8,9] If GRA is identified, corticosteroids are administered at the minimal dose necessary to suppress ACTH release, resulting in often dramatic improvement in blood pressure (BP) control (see Chapter 49).

Aldosterone regulates BP by several mechanisms, including effects on the kidneys, vasculature, central nervous system (CNS), and other endocrine hormones (Fig. 40-2). No single effect is sufficient to explain the hypertension that occurs in primary hyperaldosteronism; together the effects explain why primary hyperaldosteronism causes refractory hypertension. Aldosterone has multiple renal effects that regulate BP. First, aldosterone stimulates renal sodium chloride (NaCl) retention by increasing expression of the thiazide-sensitive NaCl cotransporter in the distal convoluted tubule, the amiloride-sensitive epithelial sodium channel (eNaC), in the collecting duct, and the chloride-reabsorbing protein, pendrin, in the cortical collecting duct.[10-12] Aldosterone also has acute effects on sodium reabsorption in these segments through mechanisms that do not require protein synthesis.[13]

Second, aldosterone alters BP through generation of hypokalemia. The increased Na^+ reabsorption enhances K^+ secretion. In addition, aldosterone increases extrarenal cellular potassium uptake by stimulating the ubiquitous Na^+,K^+-ATPase, further decreasing extracellular potassium.[14] As discussed in Chapter 9, potassium depletion raises BP through a variety of mechanisms.

Aldosterone has multiple effects on the vasculature. Aldosterone increases both basal vascular tone and vascular reactivity to circulating vasoconstrictors, including norepinephrine, epinephrine, Ang II, and vasopressin.[15,16] Aldosterone decreases flow-mediated vasodilation, perhaps because of decreased nitric oxide production resulting from decreased endothelial nitric oxide synthase expression.[17] In the central nervous system (CNS), aldosterone stimulates sympathetic nervous system tone, which further increases BP.[18] Finally, aldosterone causes perivascular fibrosis and stimulates vascular endothelin expression.[19]

Aldosterone mediates its physiologic and pathophysiologic effects predominantly by activating the *mineralocorticoid receptor* (MR).[20] The MR is located in the inactive state in the cytoplasm; aldosterone binding to MR promotes a conformational change and translocation to the nucleus, where it regulates gene transcription.

Cortisol is a naturally synthesized glucocorticoid with an affinity for MR similar to that of aldosterone, but cortisol is present in plasma at about 100-fold greater levels than aldosterone. The enzyme 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2) is expressed in the aldosterone-sensitive distal nephron and collecting duct and metabolizes cortisol to cortisone, which binds to MR poorly, thereby preventing glucocorticoid-dependent MR activation. Either the genetic deficiency of or the ingestion of inhibitors of 11β-HSD can result in excessive activation of the MR and development of severe hypertension[21] (see Chapter 49). Aldosterone also has nongenomic effects, but their role in mineralocorticoid-dependent BP regulation remains unclear.[22,23]

Primary hyperaldosteronism may result from either unilateral or bilateral adrenal disease. Typically, unilateral disease results from adenoma and bilateral disease from hyperplasia. This association is not absolute and about 10% of patients with primary hyperaldosteronism exhibit either bilateral aldosterone-producing adenoma, which may be microscopic, or unilateral hyperplasia.

EPIDEMIOLOGY

The exact incidence of primary hyperaldosteronism varies with the patient population and the diagnostic criteria used. Early studies,

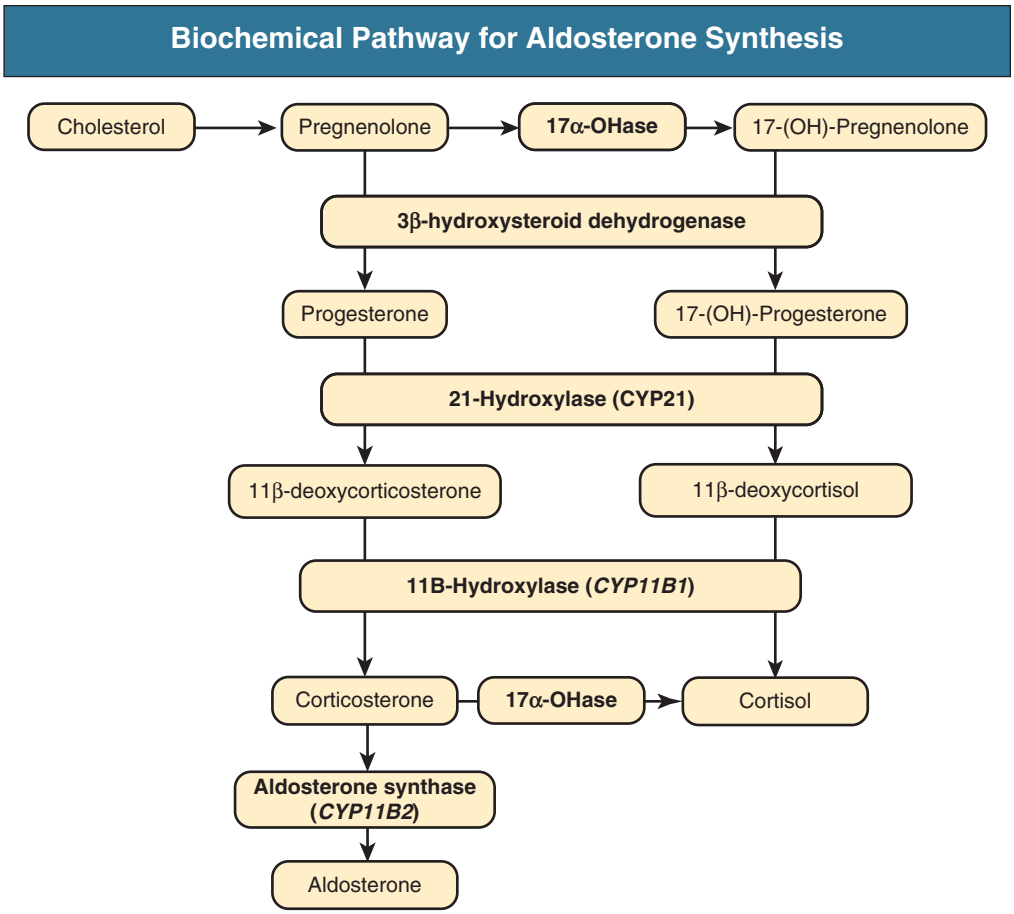

Figure 40-1 **Biochemical pathway for aldosterone synthesis.**

Factors that Regulate Aldosterone Release

Stimulatory	Inhibitory
Angiotensin II	*Atrial natriuretic peptide*
Adrenocorticotropic hormone	*Hypokalemia*
Acetylcholine	Calcitonin gene–related peptide
Adenosine triphosphate	Dopamine
Bradykinin	Nitric oxide
Cholecystokinin	Platelet-derived growth factor
β-Endorphin	Somatostatin
Endothelin	Transforming growth factor β
Enkephalins	Unsaturated fatty acids
Epidermal growth factor	
Hyperkalemia	
Melanocyte-stimulating hormone	
Neuropeptide Y	
Neurotensin	
Norepinephrine	
Parathyroid hormone	
Prolactin	
Serotonin	
Substance P	
Vasoactive intestinal peptide	
Vasopressin	

Table 40-1 **Factors that regulate aldosterone release.** The stimulatory and inhibitory regulators that exert significant effects on aldosterone release under the majority of clinical circumstances are noted in italics. *(Data from references 1 and 2.)*

which only recognized severe cases, suggested that primary hyperaldosteronism was rare, with an incidence less than 1% to 2%.[24] More accurate diagnosis has led to the recognition that primary hyperaldosteronism is relatively common. Patients with treatment-resistant hypertension—inadequately controlled hypertension despite treatment with three medications at appropriate dosages, including a diuretic—are highly likely to have primary hyperaldosteronism, with rates typically of 20% to 40% and as high as 67% in some studies.[25] Some studies have found a 1% to 2% incidence of hyperaldosteronism in normotensive patients (see Fig. 40-3), with the incidence increasing as BP increases.[26]

CLINICAL MANIFESTATIONS

Identifying patients with primary aldosteronism purely on clinical characteristics is difficult. Patients with primary hyperaldosteronism can have characteristics suggestive of secondary hypertension, such as early onset of hypertension or the need for multiple medications for BP control. Sometimes primary aldosteronism presents with either frank or easily provoked hypokalemia. Also, patients may have no distinguishing characteristics that differentiate them from individuals with essential hypertension. Figure 40-3 shows the frequency of primary hyperaldosteronism in individuals with different degrees of hypertension, and Table 40-2 summarizes characteristics of those with primary hyperaldosteronism.[27]

Because of the wide variety of presentations, from one indistinguishable from essential hypertension to one highly suggestive of secondary hypertension, we recommend screening all patients for primary aldosteronism who have characteristics of secondary hypertension, have baseline or easily provoked hypokalemia, or have hypertension not effectively controlled with routine antihypertensive therapy. It is important to recognize that both hypokalemia and metabolic alkalosis are no longer considered hallmarks of primary hyperaldosteronism, and in fact are absent in the majority of patients.

Effects of Aldosterone on Blood Pressure

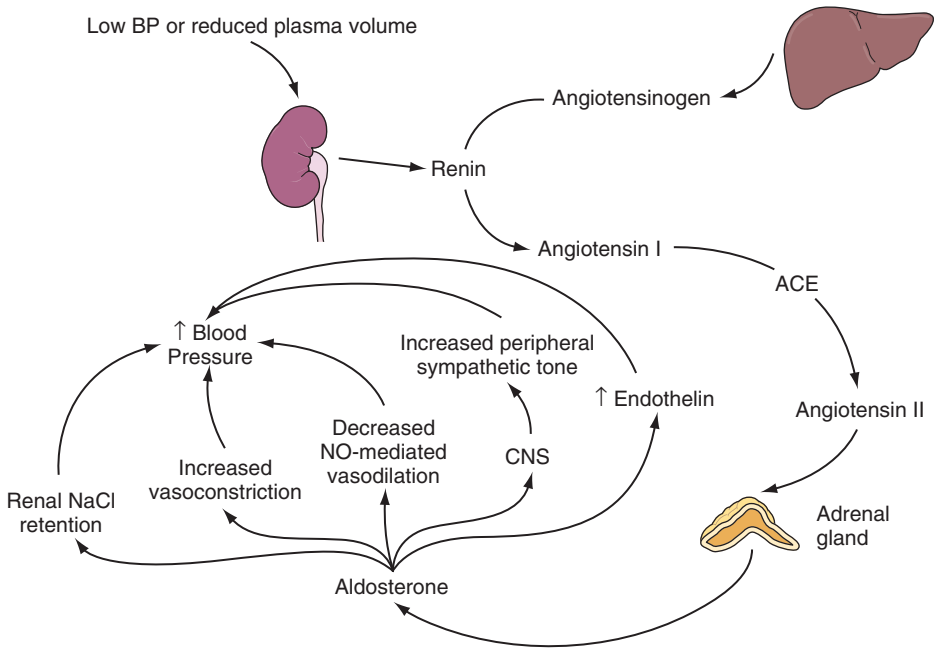

Figure 40-2 Summary of aldosterone's effects on blood pressure (BP) regulation. *ACE,* Angiotensin-converting enzyme; *CNS,* central nervous system; *NO,* nitric oxide.

Incidence of Primary Hyperaldosteronism in Patients with Differing Degrees of Hypertension

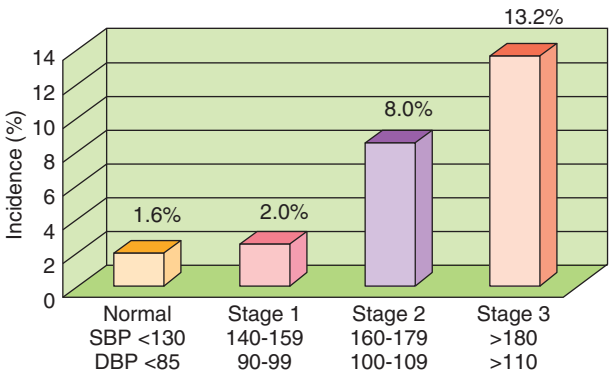

Figure 40-3 Incidence of primary hyperaldosteronism in patients with differing degrees of hypertension. *SBP,* Systolic blood pressure; *DBP,* diastolic blood pressure. *(From reference 26.)*

Typical Characteristics at Diagnosis of Primary Hyperaldosteronism

Patient Factor	Measured Value
Gender (female/male)	43:57 (%)
Age (yr)	52 ± 1 (range 29-74)
Hypertension duration (yr)	10 ± 1
Number of hypertensive medications	2.4 ± 0.1 (range 0-4)
Percentage requiring 3 or more medications	54%
Blood pressure controlled with current medical regimen	20%
Neither hypokalemic nor receiving 3 or more medications	52%
Plasma aldosterone (ng/dl)	
<15	37%
15-40	54%
>40	9%
Plasma renin activity (ng Ang I/ml/hr)	0.39 ± 0.04

Table 40-2 Typical characteristics of patients at diagnosis of primary hyperaldosteronism. *(Data from reference 27.)*

Diagnosing and treating primary aldosteronism is important for two major reasons. First, in many patients primary aldosteronism leads to very severe hypertension, which is poorly responsive to antihypertensive medications and thus increases cardiovascular risk. Indeed, a goal of hypertension management is to be able to identify and treat the underlying causative factor generating the individual's hypertension. Although not feasible for the majority of patients with hypertension, this is possible for the patient with primary aldosteronism. Second, and possibly more important, untreated primary aldosteronism leads to cardiovascular events at rates significantly greater than attributable solely to the hypertension. Diagnosing and treating the primary aldosteronism, whether with adrenalectomy or with MR blockers, as clinically appropriate, corrects this increased risk.[28]

PATHOLOGY

Primary hyperaldosteronism can result either from an aldosterone-producing adenoma (APA) or from hyperplasia of the zona glomerulosa (Fig. 40-4). Most APAs are unilateral and are large enough (>1 cm) to be identified by computed tomography (CT) scanning (Fig. 40-5). However, APAs may also be microscopic and may be bilateral. Hyperplasia is typically bilateral but may develop asynchronously in the two adrenal glands; hyperplasia also may be unilateral. The factors that cause development of either APA or hyperplasia are not completely understood.

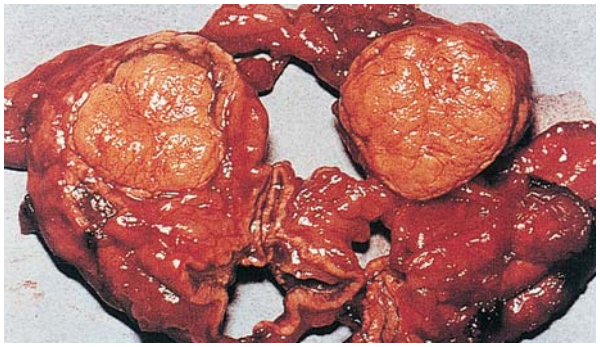

Figure 40-4 Adrenal adenoma. An aldosterone-producing adrenal adenoma with typical cholesterol-rich yellow appearance.

Figure 40-5 Adrenal adenoma by computed tomography scan. A normal linear image of the right adrenal gland *(white arrowhead)* and expansion of the left adrenal with aldosterone-producing adenoma (~1 cm) *(white arrow).*

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Evaluation of patients with suspected primary hyperaldosteronism is directed at (1) identifying those who have autonomous aldosterone release and then (2) determining whether treatment should be based on a medical or a surgical approach (Fig. 40-6).

Evidence of Ang II–independent aldosterone release is used to indicate autonomous aldosterone release and therefore primary hyperaldosteronism. Because Ang II cannot be assayed for routine clinical use, *renin* is used as a surrogate. A random blood sample is used to measure the ratio of plasma aldosterone to renin (ARR, aldosterone-renin ratio). If this value is elevated, there is significant Ang II–independent aldosterone release, thereby providing evidence of autonomous aldosterone production consistent with primary hyperaldosteronism.

Currently, two different renin assays are in routine clinical use. One measures renin activity, assayed as the rate of conversion of angiotensinogen to angiotensin I (Ang I), and the second measures the amount of immunoreactive renin. These two techniques yield results that correlate well with each other, but the units and numerical values obtained differ. For the plasma renin activity, the normal range is 1.9 to 3.7 ng Ang I/ml/hr, and the lower level of detectability is 0.2 ng Ang I/ml/hr, in most clinical laboratories. For the direct renin assay, the normal range is typically 13 to 44 IU/ml, and lower level of detectability is 6 to 8 IU/ml. Therefore, the normal ARR, for a patient with primary hypertension not receiving medications that alter the renin-angiotensin system (RAS), is about 10:1 when using the plasma renin activity, and 1:1 with the direct renin assay. The plasma renin activity assay is more sensitive at lower values than the direct plasma assay and currently is preferred for clinical use.

Whereas an elevated aldosterone and a low renin strongly suggest primary aldosteronism, an elevated ARR may also occur with low aldosterone if renin is suppressed. Combining an elevated ARR and "nonsuppressed" aldosterone levels decreases the rate of "false-positive" screening for primary hyperaldosteronism. The minimal plasma aldosterone level that may be associated with aldosteronism is unclear. We recommend using a minimal value of 10 ng/dl to make a diagnosis of primary aldosteronism.[29] Other investigators use cutoff values greater than 15 ng/dl,[30,31] and some do not recommend a cutoff.[8] This is partly because 36% to 48% of patients with primary aldosteronism have plasma aldosterone levels of 9 to 16 ng/dl,[26,32] and about 20% of those with unilateral autonomous adrenal aldosterone production have levels less than 15 ng/dl.[32]

Many common medicines may alter ARR.[31,33] β-Adrenergic receptor antagonists (β-blockers) can suppress renin release, typically by about 50%. However, β-blockers generally will not result in complete renin suppression and generally do not confound the diagnosis of primary hyperaldosteronism.[33] Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs), along with diuretics, can increase renin release in normal individuals, which theoretically might decrease the sensitivity of ARR measurement. However, the effect of ACE inhibitors and ARBs to increase renin release can also be an advantage; in patients using either an ACE inhibitor or an ARB, a suppressed renin in combination with a nonsuppressed aldosterone (>10 ng/dl) is highly specific for primary hyperaldosteronism. MR antagonists such as spironolactone and eplerenone can elevate the plasma renin activity and impair the sensitivity of testing. How long to hold these medications before testing is not clear; we recommend 2 weeks if this can be done without excessive BP increases developing. Potassium-sparing diuretics such as amiloride and triamterene can generally be continued without difficulty. Other antihypertensive medications typically have little effect on ARR measurement and do not need to be held before testing.

An elevated ARR alone, while sensitive for detecting primary hyperaldosteronism, is not highly specific. In unselected populations or those with only mild or moderate hypertension, as many as 50% of patients with elevated ARR do not have primary hyperaldosteronism. If the diagnosis of primary aldosteronism is in doubt, several confirmatory tests can be used. Table 40-3 summarizes the various confirmatory testing methods in routine use. We recommend using these studies if only mild or easily controlled hypertension is present, if baseline hyperkalemia is present, or if MR antagonists are not well tolerated. However, some groups recommend confirmatory testing in all patients suggested to have primary aldosteronism.[8] Typically, performance of only one test is needed, the choice of which can be based on provider and patient preferences. If results are ambiguous, additional confirmatory testing can be performed.

The clinical importance in routine clinical practice of confirming the diagnosis of primary aldosteronism involves considering both the risks and the benefits of confirmatory testing.[29] None of the confirmatory tests has 100% sensitivity or specificity. Many tests require salt loading, which can raise BP and is problematic in the

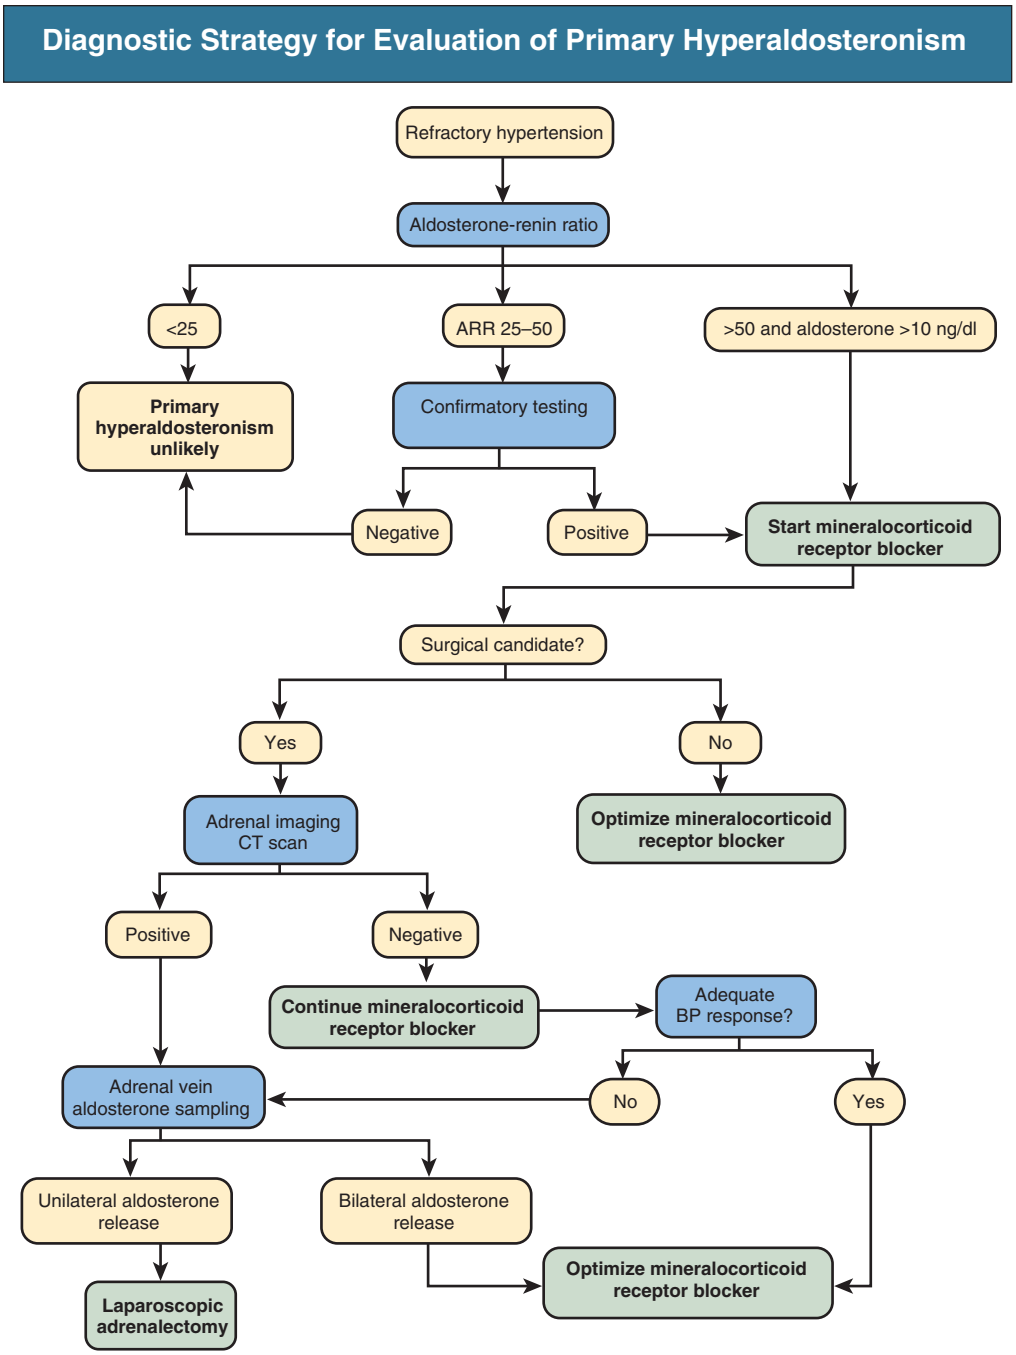

Figure 40-6 Diagnostic strategy for evaluation of primary hyperaldosteronism. Aldosterone-renin ratio *(ARR)* is calculated using measurement of plasma renin activity. If direct renin immunoassay is used, the resulting ARR calculation should be multiplied by 10 for use with this diagnostic algorithm. *BP,* Blood pressure; *CT,* computed tomography.

management of the patient who already has poorly controlled hypertension. Most tests require the patient not to use medications that interact with the renin-angiotensin-aldosterone system, which involves discontinuation of many highly effective antihypertensives, including β-blockers, ACE inhibitors, ARBs, direct renin inhibitors, and diuretics; this can lead to significant worsening of hypertension control.[29] Definitive diagnosis of primary aldosteronism would be necessary if it substantially altered the management of these patients. However, patients with resistant hypertension generally respond well to MR antagonists, with significant BP improvement even in the absence of primary aldosteronism.[34,35] Our experience is that almost all patients with nonsuppressed plasma aldosterone (i.e., >10 ng/dl) and ARR greater than 50 respond to MR antagonists with substantial (>20 mm Hg) decreases in BP. Because of these factors, some centers do not routinely perform confirmatory testing before initiating treatment with MR blockers for patients with presumed primary aldosteronism based on elevated ARR and nonsuppressed plasma aldosterone.

Once primary hyperaldosteronism is diagnosed, the clinician should determine whether unilateral aldosterone release is present, in which case adrenalectomy may be curative. If the patient is not a surgical candidate, this evaluation is not necessary. Because about 90% of patients with unilateral aldosterone release have an APA, an adrenal CT protocol is the next diagnostic step, using 2- to 3-mm slices; conventional abdominal CT using 10-mm slices may fail to identify small adrenal adenomas.

If an adrenal adenoma is identified, it is critical to determine by *adrenal vein sampling* whether the identified adenoma is aldosterone

Confirmatory Testing for Diagnosis of Primary Hyperaldosteronism			
Test	**Method**	**Evaluation**	**Limitations**
Oral sodium chloride (NaCl) loading	Oral NaCl intake >200 mmol/d for 3 days, with oral KCl as needed to prevent hypokalemia, with subsequent 24-hr urine aldosterone measurement	Urine aldosterone <10 μg/d, diagnosis unlikely; >12 μg/d, diagnosis likely	Avoid if severe uncontrolled hypertension, CKD, CHF, cardiac arrhythmias, or severe hypokalemia
Saline infusion test	Patient in recumbent position for 1 hr before testing and then throughout entire test Begin test between 8 and 9:30 AM. Measure plasma aldosterone, plasma renin activity, cortisol, and potassium at beginning of test and then after infusing 2 l NS IV over 4 hr.	Plasma aldosterone at end of infusion <5 ng/dl, diagnosis unlikely; >10 ng/dl, diagnosis likely; 5-10 ng/dl, indeterminate	Avoid if severe uncontrolled hypertension, CKD, CHF, cardiac arrhythmias, or severe hypokalemia
Fludrocortisone suppression test	Oral fludrocortisone, 0.1 mg every 6 hr for 4 days, plus oral NaCl, 30 mmol 3×/d, and high-salt diet combined with sufficient KCl to avoid hypokalemia	Upright plasma aldosterone on day 4 >6 ng/dl and plasma renin activity <1 ng/ml/h, diagnosis likely	Frequently requires hospitalization for patient monitoring of blood pressure and potassium
Captopril challenge test	Oral captopril, 20-50 mg, given with plasma aldosterone, and plasma renin activity obtained immediately before captopril and then 1-2 hr afterward, with patient seated throughout test	Plasma aldosterone decrease >30%, diagnosis unlikely	Probably more false-positive and false-negative results than other tests

Table 40-3 Confirmatory testing for primary hyperaldosteronism. *CHF,* Congestive heart failure; *CKD,* chronic kidney disease; *KCl,* potassium chloride; *l NS IV,* liters normal saline intravenously. *(From reference 8.)*

producing (APA) or is a nonfunctional adenoma ("incidentaloma"). In as many as 20% to 30% of patients with primary aldosteronism and an adrenal adenoma, the adenoma is nonfunctional. A nonfunctional adenoma is relatively unusual in younger patients (<40 to 45 years), so the additional benefit of adrenal vein sampling is less clear in this patient population.

Many issues complicate adrenal vein sampling studies. First, the procedure is technically difficult and should be performed in specialized centers by a specific interventional radiologist using a standardized procedure. Second, biochemical confirmation of successful adrenal vein sampling, by demonstrating cortisol concentrations significantly greater than present in the blood from the inferior vena cava, is necessary. Third, stimulation of cortisol production with ACTH or an analogue increases the ease of confirming successful adrenal vein sampling. However, ACTH and its analogues can alter aldosterone production, which may result in misleading interpretations as to whether aldosterone secretion is unilateral or bilateral and, if unilateral, which side is the predominant source. Thus, interpretation requires careful evaluation of the biochemical studies resulting from adrenal vein sampling, in conjunction with imaging modalities.

Occasional patients will have unilateral aldosterone release but not have an adenoma detectable on CT. These patients may have either unilateral adrenal hyperplasia or micronodular APA. This diagnosis should be considered when the response to MR antagonists such as spironolactone and eplerenone is suboptimal or requires high doses. Despite a negative CT scan, adrenal vein sampling is used to identify whether the patient has surgically treatable unilateral autonomous adrenal aldosterone release.

Many other diagnostic tests have been suggested in the evaluation of primary hyperaldosteronism, but none has widespread acceptance. The postural stimulation test may help differentiate bilateral adrenal hyperplasia from APA. All medicines that affect the RAS, including diuretics, β-blockers, ACE inhibitors, and ARBs, must be discontinued before testing, but the difficulty in controlling BP in these patients without medicines often limits the utility of this test. Its main role is in the evaluation of the patient with an adrenal adenoma and unsuccessful adrenal vein sampling.[8]

NATURAL HISTORY

The natural history of untreated primary hyperaldosteronism is uncertain. Although there are case reports of remission of untreated primary hyperaldosteronism, these all followed adrenal venography, and thus may reflect related complications. However, studies comparing patients with newly diagnosed primary aldosteronism to those with primary hypertension of the same severity and duration suggest untreated primary aldosteronism is associated with numerous end-organ complications, including increased risk of coronary heart disease, atherosclerotic peripheral vascular disease, cardiac arrhythmias, left ventricular hypertrophy, low bone mineral density, and development of chronic kidney disease.[28,36,37] Effective treatment of primary aldosteronism appears to reverse these increased risks. Therefore, treatment either with MR blockers or with adrenalectomy is recommended for patients with primary aldosteronism.

TREATMENT

Patients with an aldosterone-producing adenoma who are acceptable surgical candidates should undergo surgical laparoscopic adrenalectomy. Laparoscopic adrenalectomy is associated with a shortened hospital stay, decreased postoperative morbidity, and a quicker return to normal health than open surgical adrenalectomy. Patients who undergo laparoscopic adrenalectomy have a 30% to 60% chance of hypertension cure.[38-40] Patients most likely to have their hypertension cured are less than 50 years of age and have few family members with primary hypertension. Those not cured have a greater than 95% chance of BP improvement.[39,40] The lack of complete cure may reflect intrarenal microvascular disease that developed as a consequence of the poorly controlled hypertension.

Patients who are not candidates for surgical adrenalectomy or who have bilateral aldosterone production should be treated with MR antagonists, currently spironolactone and eplerenone. These should be started at modest doses and titrated slowly. Most patients find that the responses are delayed, and monthly dose adjustments should be done until an optimal dose is identified. The choice of MR

blocker involves consideration of side effects, cost, and effectiveness. Spironolactone has off-target effects on sex-steroid hormone receptors, which can lead to a dose-dependent risk of breast enlargement (gynecomastia) in men and breast tenderness (gynecodynia) and menstrual irregularities in women. Eplerenone is more selective than spironolactone for the mineralocorticoid receptor, and the risk of these side effects is less but not eliminated. These differences initially led many to prefer the use of eplerenone to spironolactone. However, recent evidence showed spironolactone was significantly more effective than eplerenone at improving blood pressure, with almost twice as great a BP reduction and a substantially greater proportion of patients experiencing a significant BP improvement.[41] The overall incidence of side effects was similar. Accordingly, spironolactone may be the preferred agent for medical treatment of primary aldosteronism.

The clinician should also be familiar with additional side effects of MR blocker therapy. Muscle cramps can occur with both spironolactone and eplerenone. MR blockers can cause neuropsychiatric side effects that are often nonspecific and can include symptoms of feeling out of touch with reality, difficulty thinking, and decreased attention and performance in various memory tasks.[41,42] In general, these effects are temporary and resolve within a few weeks. Hyperkalemia is common when MR blockers are used for conditions other than primary aldosteronism, such as congestive heart failure,[43,44] but is relatively uncommon in patients with primary aldosteronism. However, hyperkalemia can occur late in therapy, often following years of MR blocker administration, and may require either a decrease in the MR dose or addition of diuretics.

Treatment with an MR antagonist usually results in dramatically improved BP control. Many patients will respond to a low dose, 25 to 50 mg daily, as initial therapy. Both systolic BP and diastolic BP frequently decrease by about 25 mm Hg over a few weeks to months. Dosage of the MR antagonists can be increased as necessary but generally should not be changed more than every 2 to 4 weeks. If present, hypokalemia and metabolic alkalosis improve. Potassium supplements can be tapered rapidly with improvement in hypokalemia. With time, BP can be controlled in many patients with an MR antagonist and a single alternative agent. We typically use ACE inhibitors because renin activity, which is suppressed initially, typically increases after starting MR antagonist therapy. Synergistic use of an ACE inhibitor may prevent development of a renin-stimulated, Ang II–dependent component of hypertension. However, many antihypertensive combinations can be used successfully with the MR antagonist.

Inhibitors of the RAS are widely used to slow the progression of chronic kidney disease (CKD) and to decrease cardiovascular mortality in patients with congestive heart failure (CHF). These treatment regimens usually involve either ACE inhibitors or ARBs, which by blocking Ang II–dependent stimulation of aldosterone production, should decrease plasma aldosterone levels. However, many patients develop aldosterone breakthrough, in which the initial decrease in plasma aldosterone level is followed by a later rise in aldosterone levels to greater than that prior to ACE inhibitor or ARB treatment. Aldosterone breakthrough is associated with faster loss of glomerular filtration rate (GFR) in patients with CKD, reduced exercise capacity and reduced venous compliance in patients with CHF, and adverse effects on left ventricular mass index in hypertensive patients.[45-47] In addition to patients taking ACE inhibitors who manifest aldosterone breakthrough, obese individuals may also show higher aldosterone levels in the absence of ACE inhibitors.[48] This may result from adipocyte release of compounds that stimulate adrenal aldosterone production.[49] Neither of these conditions results in the elevated ARR observed with primary aldosteronism. Nevertheless, use of spironolactone in these patients may aid in BP control. In addition, patients with CKD who develop aldosterone breakthrough have a greater rate of GFR loss, and treating these patients with low doses of MR antagonists, such as oral spironolactone 25 mg once daily, appears to decrease proteinuria, predicting a renoprotective benefit.[50]

CHAPTER 41

Endocrine Causes of Hypertension

A. Mark Richards and M. Gary Nicholls

The true incidence and prevalence of hypertension with endocrine etiology are unknown. However, primary aldosteronism may be present in up to 12% of patients with newly diagnosed hypertension, and overall, an endocrine contribution to high blood pressure (BP) may be present in more than 12% of cases. *Endocrine hypertension* often remains undiagnosed because physicians consider it rare and therefore unlikely, and access to the required specialized tests is limited.

Endocrine hypertension may occur in the absence of readily observed signs and symptoms or abnormalities in routine biochemical tests. However, certain features should trigger a simple screen (Fig. 41-1), such as a family history of inherited conditions, including pheochromocytoma, neurofibromatosis, multiple endocrine neoplasia, and aldosteronism. Resistant hypertension (i.e., BP resistant to administration of three antihypertensive drugs of different classes) mandates consideration of secondary hypertension once iatrogenic factors and noncompliance have been ruled out. The differential diagnoses for endocrine hypertension will include renal parenchymal disease and renovascular disease.

Symptoms and signs may be present. Severe hypokalemia is rare but when present may cause weakness, polyuria, and cardiac arrhythmia. Hyperadrenergic symptoms occur with pheochromocytoma. Changes in temperature tolerance, body weight, hair and skin condition, and bowel habit are clues in thyroid dysfunction or hypercortisolism. Thyroid disease, Cushing syndrome, and acromegaly are associated with typical changes in body habitus. Abnormal sweating occurs in pheochromocytoma, thyrotoxicosis, and acromegaly.

Hypokalemia and diabetes mellitus are hallmarks of endocrine pathologic processes in hypertension. Hypokalemia in the absence of diuretic use should suggest diagnoses such as primary aldosteronism, pseudoaldosteronism, renin-secreting tumor, Cushing syndrome, and accelerated hypertension of any cause. Therefore, concurrent high BP and hypokalemia should prompt consideration of endocrine hypertension. Hyperglycemia is common to Cushing syndrome, pheochromocytoma (especially when epinephrine levels are increased), acromegaly, and primary aldosteronism. Diagnosis of endocrine forms of hypertension offers the chance of cure, of altering an otherwise catastrophic natural history (e.g., in pheochromocytoma), and of applying specific and effective therapies that ameliorate other elements of the disease beyond BP control. Chapter 40 discusses aldosteronism; this chapter describes other types of endocrine hypertension.

CUSHING SYNDROME

Definition

This syndrome of sustained glucocorticoid excess is most often secondary to production of adrenocorticotropic hormone (ACTH) by a pituitary adenoma (Cushing disease). Less frequently, Cushing syndrome is the result of cortisol overproduction from an adrenal adenoma or carcinoma, and rarely it may be secondary to ectopic ACTH (corticotropin) secretion.[1] It can also result from exogenous corticosteroid administration. The incidence of endogenous Cushing syndrome is 5 to 10 cases per 1 million population per year. Cushing disease and cortisol-secreting adrenal tumors are four times more common in women than in men. Approximately 0.5% of patients with bronchogenic carcinoma (more common in men than women) develop ectopic ACTH syndrome.

Etiology, Pathogenesis, and Epidemiology

Hypertension is present in 80% of patients with Cushing syndrome (less often when caused by exogenous synthetic corticosteroid administration) and results from an increase in both cardiac output and total peripheral resistance. The mechanisms underlying these hemodynamic changes are complex.[2]

In some patients, Cushing syndrome may be caused by concurrent overproduction of mineralocorticoids such as aldosterone, 11-deoxycorticosterone, and corticosterone. Although cortisol is capable of binding the mineralocorticoid receptor (MR), usually it does not because of the renal enzyme 11β-hydroxysteroid dehydrogenase type 2 (β-HSD2), which inactivates cortisol to corticosterone, thereby preventing its binding to the MR. However, in the patient with low β-HSD2 activity or extremely high cortisol levels (e.g., ectopic ACTH syndrome), there may be sufficient excess cortisol that MR binding occurs. Furthermore, alterations in oxidation-reduction (redox) status, potentially triggered by metabolic disturbance and cytokine activation, may alter the effects of corticosteroids at the MR function, converting cortisol from its receptor antagonist role seen in health to an agonist in inflammatory states.[3]

Subsequent cardiac and vascular MR activation may foster adverse cardiovascular inflammatory, hypertrophic, and fibrotic changes. Inhibition of the vasodilator nitric oxide (NO) by cortisol may also contribute to the hypertension, along with enhanced pressor responsiveness to catecholamines and angiotensin II (Ang II), heightened cardiac inotropic sensitivity to β-adrenergic stimulation, and increased plasma volume.[2] If affected, the sympathetic nervous system (SNS) and renin-angiotensin system (RAS) are suppressed, even though circulating levels of renin substrate are increased. Some have proposed that elevated levels of vasoconstrictor hormones (vasopressin, endothelin-1, thromboxane, insulin) or subnormal concentrations of vasodilator systems (kallikrein-kinins, prostaglandins) contribute to the hypertension of Cushing syndrome, but the evidence is weak.[2] The vasodilator atrial natriuretic peptide (ANP) is elevated in Cushing syndrome, although biologic responses to ANP are impaired; in theory, ANP resistance could also contribute to the hypertension.[4] Adipokines, including leptin and resistin, plus release of proinflammatory cytokines (tumor necrosis factor α, interleukin-6) may also contribute to the increased cardiovascular risk observed in Cushing syndrome.[5]

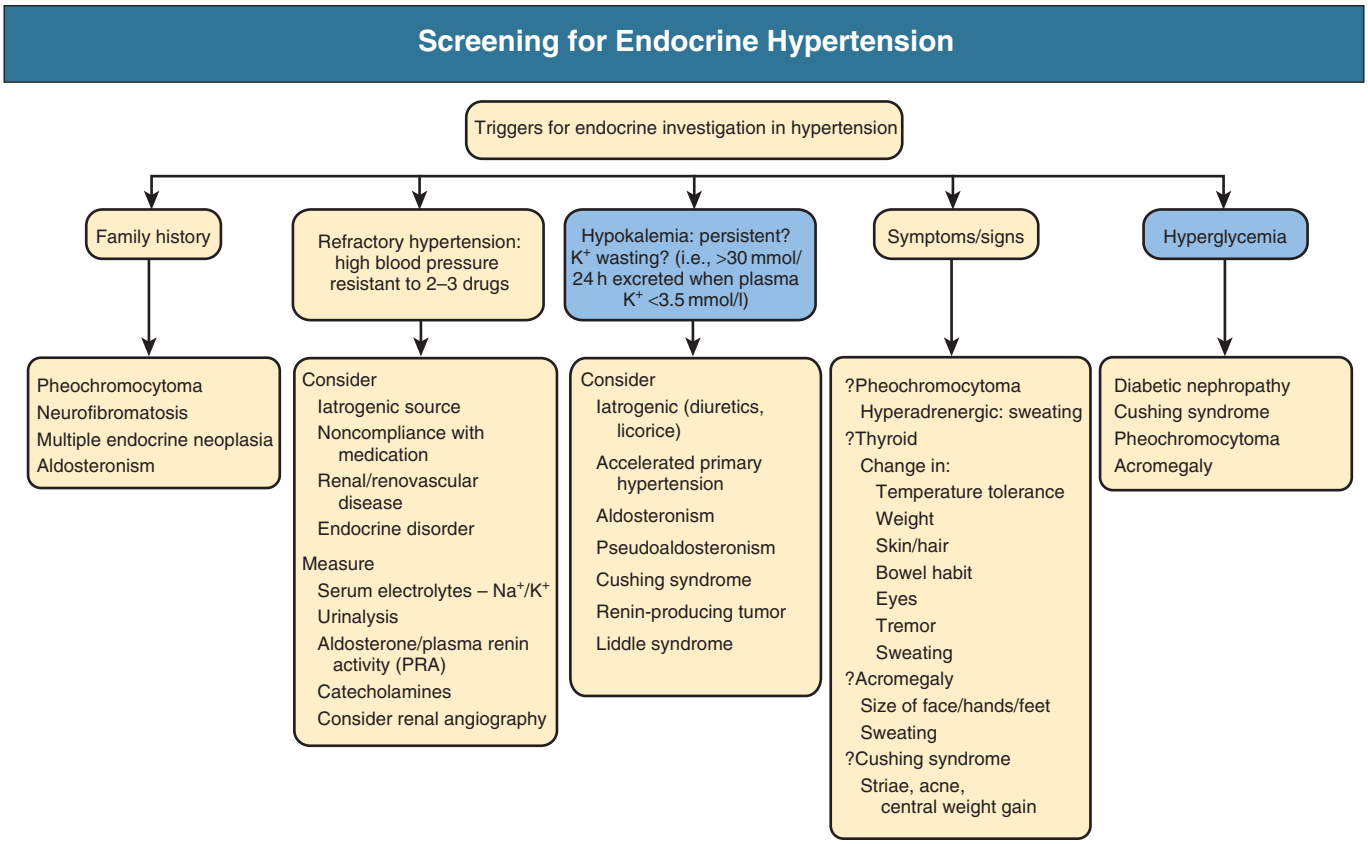

Figure 41-1 Screening algorithm for endocrine hypertension. Clinical observations suggesting investigation into endocrine causes of hypertension in hypertensive patients.

Figure 41-2 Striae and central obesity in a patient with Cushing syndrome.

Successful treatment of Cushing disease or removal of an underlying adrenal adenoma usually results in BP reduction and partial return of the previously impaired nocturnal fall in arterial pressure, although hypertension persists in a sizable minority of patients.

Clinical Manifestations

Clinical features in Cushing disease result from elevated circulating levels of pro-opiomelanocortin hormones, including ACTH (increased pigmentation) and cortisol (central adiposity, insulin resistance or diabetes, muscle wasting/weakness, plethoric facies, purple striae [Fig. 41-2], easy bruising, osteoporosis, psychological problems). In some patients, androgen effects are observed (hirsutism, acne, virilization) and may be striking in those with adrenal adenoma or carcinoma. Ectopic ACTH syndrome caused by small cell bronchial carcinoma or other tumors (e.g., bronchial or thymic carcinoid) presents typically as a wasting disease, often with hyperpigmentation and hypokalemia. Hypertension is often associated with left ventricular hypertrophy, which can be disproportionate to BP, and frank cardiac failure is occasionally the presenting feature.[6]

Differential Diagnosis

Pseudo–Cushing syndrome can occur with a sustained high intake of alcohol by inducing augmented cortisol secretion and reduced cortisol metabolism caused by hepatic damage. Routine diagnostic tests are unable to distinguish alcoholic pseudo–Cushing syndrome from true Cushing syndrome, and reassessment after alcohol withdrawal may be required.[7]

Depression is associated with increased cortisol level. In obesity, the plasma clearance rate of cortisol is increased, leading to a slightly elevated production rate of cortisol, although plasma levels are normal. Careful psychological and physical screening will usually differentiate these patients from those with Cushing syndrome.

Diagnosis

An elevated urinary free cortisol excretion (or early-morning cortisol-creatinine ratio) and absence of suppression of 8 AM plasma cortisol after a low dose of dexamethasone (1 mg at midnight) are the usual initial tests. Screening may also incorporate checks for elevated late-night salivary cortisol.

Further key investigations include computed tomography (CT) and magnetic resonance imaging (MRI) of the pituitary and adrenal glands and plasma ACTH (suppressed in cortisol-secreting adrenal tumors but elevated in ectopic ACTH syndrome). Further tests will depend on findings at this point. A high-dose dexamethasone suppression test partially suppresses ACTH in patients with pituitary tumors but not with ectopic ACTH. The response of plasma ACTH to a dose of corticotropin-releasing hormone may also help distinguish pituitary from adrenal or ectopic tumors. Simultaneous bilateral inferior petrosal sinus sampling for ACTH measurements is useful in differentiating Cushing disease from ectopic ACTH syndrome, when the previous tests give equivocal results. Imaging of the thorax, abdomen, and pelvis is indicated when ACTH-producing carcinoid tumors are suspected.

Treatment and Prognosis

Untreated, patients with Cushing syndrome have 50% 5-year mortality because of cardiovascular risk from hypertension, along with glucose intolerance and insulin resistance, hyperlipidemia, obesity, and elevated fibrinogen levels.[8]

Cure rates in treatment of Cushing disease are 80% to 90% by selective removal of a pituitary microadenoma and 50% for pituitary macroadenomas. Cushing syndrome caused by adrenal adenoma is almost always cured by unilateral adrenalectomy. However, in adrenal carcinoma, median survival is less than 2 years. The prognosis is also poor when Cushing syndrome results from ectopic ACTH syndrome caused by small cell bronchial carcinoma. If the ACTH-producing tumor is benign and can be located, however, removal usually leads to cure. After cure of Cushing syndrome, approximately 30% of patients have persistent hypertension.[9]

In managing the hypertension from Cushing syndrome, no evidence supports the use of any antihypertensive class over another. Potassium-losing diuretics can exacerbate both hypokalemia and glucose intolerance, whereas potassium-sparing diuretics, usually in combination with other antihypertensive agents, may correct hypokalemia and reduce edema while lowering BP.

PHEOCHROMOCYTOMA

Definition

Pheochromocytoma has challenged and fascinated clinicians since its first description by Frankel in 1886. Because clinical manifestations can mimic a wide spectrum of other disorders, the diagnosis is frequently delayed or missed altogether, sometimes with fatal consequences.[10]

Pheochromocytoma refers to a dusky tumor whose cells stain brown with chromium salts. Such tumors arise most frequently within the adrenal glands (Fig. 41-3), but approximately 10% are extra-adrenal (paraganglioma). Although the majority of pheochromocytomas are benign, 10% metastasize to regional lymph nodes and beyond. Histologic features are not a reliable guide to malignant behavior. The tumors can secrete a wide variety of hormones but most characteristically produce norepinephrine, epinephrine, and dopamine, with patterns differing among patients. Few paragangliomas produce epinephrine. Very high dopamine production is associated with malignant disease or a large tumor mass.

Etiology, Pathogenesis, and Epidemiology

The prevalence of pheochromocytoma in patients with hypertension in general medical outpatient clinics is 0.1% to 0.6%.[11] As with a firm diagnosis, however, the prevalence may be considerably higher because many people die with unsuspected pheochromocytoma.[12]

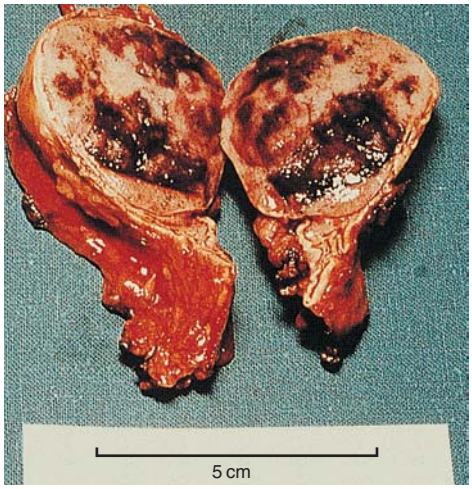

Figure 41-3 **Large adrenal pheochromocytoma with areas of hemorrhagic necrosis.**

Pheochromocytomas can be sporadic or familial. Whereas sporadic cases are usually unicentric and unilateral, familial pheochromocytomas are often multicentric and bilateral. Familial pheochromocytomas are the result of a germ-line mutation in one of five genes: the *RET* gene leading to multiple endocrine neoplasia type 2; the von Hippel–Lindau *(VHL)* gene, which causes the von Hippel–Lindau syndrome; the neurofibromatosis type 1 *(NF1)* gene resulting in von Recklinghausen disease; and the genes encoding the B and D subunits of mitochondrial succinate dehydrogenase (*SDHB* and *SDHD*), which are associated with familial paragangliomas and pheochromocytomas. More recently, mutations in *KIF1Bβ, TMEM127,* and *MAX* genes have also been associated with pheochromocytoma.[13]

Table 41-1 outlines clinical features of syndromes associated with pheochromocytoma. For patients with apparently sporadic pheochromocytomas, an underlying germ-line mutation of the genes mentioned may be present in about 20% of cases and should be considered in younger patients (<50 years) and those with multifocal or extra-adrenal tumors.[10,14] Patients found to harbor a germ-line mutation need to be identified for appropriate guidance of medical management for them and their families.

Clinical Manifestations

Clinical features of pheochromocytoma reflect episodic or continuous overproduction of catecholamines and depend in part on which catecholamine dominates. Symptoms include headache, sweating, palpitations, anxiety, and pallor (Fig. 41-4).[15] Hypertension or diabetes mellitus, with or without symptoms, may be the initial manifestation. Alternatively, pheochromocytoma may present as a tumor mass, usually an enlarging primary lesion in the abdomen or a paraganglioma in the neck, ear, thorax, or abdomen. On occasion, a metastatic lesion may be the presenting sign. Physical examination may reveal labile (66%) or persistent (33%) hypertension, sometimes with strikingly reciprocal changes in BP and heart rate when the tumor secretes predominantly norepinephrine.[16] The patient may have cool, mottled extremities and a low-grade fever with tachycardia and postural hypotension. Patients may also present as an emergency with severe hypertension with or without heart failure and a variety of symptoms attributable to high plasma catecholamine

Main Clinical Features of Syndromes Associated with Pheochromocytoma

Associated Syndrome	Clinical Manifestations
Von Hippel–Lindau Syndrome	
Type 1 (no pheochromocytoma)	Renal cell cysts and carcinomas Retinal and CNS hemangioblastomas Pancreatic neoplasms and cysts Endolymphatic sac tumors Epididymal cystadenomas
Type 2 (with pheochromocytoma)	2A. Retinal and CNS hemangioblastomas Pheochromocytomas Endolymphatic sac tumors Epididymal cystadenomas 2B. Renal cell cysts and carcinomas Retinal and CNS hemangioblastomas Pancreatic neoplasms and cysts Pheochromocytomas Endolymphatic sac tumors Epididymal cystadenomas 2C. Pheochromocytomas only
Multiple Endocrine Neoplasia (MEN) Type 2*	
Type 2A (MEN-2A)	Medullary thyroid carcinoma Pheochromocytoma Hyperparathyroidism Cutaneous lichen amyloidosis
Type 2B (MEN-2B)	Medullary thyroid carcinoma Pheochromocytoma Multiple neuromas Marfanoid habitus
Other Syndromes	
Neurofibromatosis type 1	Multiple fibromas on skin and mucosa Café-au-lait skin spots Pheochromocytomas
Paraganglioma syndromes	Head and neck tumors (carotid body tumors; vagal, jugular, and tympanic paragangliomas) Pheochromocytomas Abdominal or thoracic paragangliomas (or both)

Table 41-1 Primary clinical features of syndromes associated with pheochromocytoma. *CNS,* Central nervous system. *A third type of MEN type 2 consists of familial medullary thyroid carcinoma only (without pheochromocytoma).

Frequency of Symptoms in Pheochromocytoma

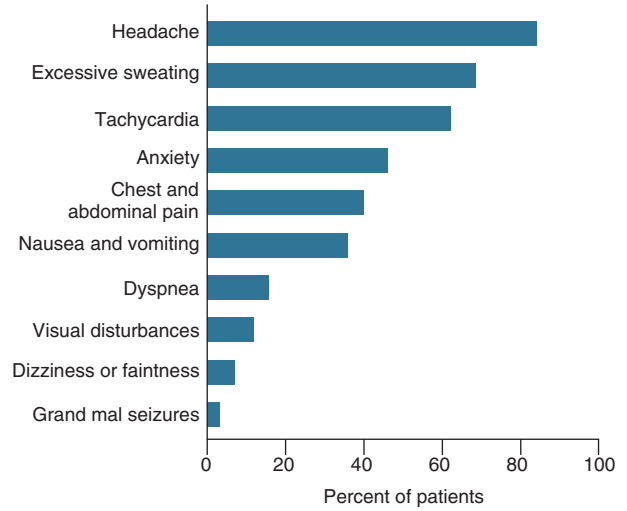

Figure 41-4 Frequency of symptoms in 324 patients with pheochromocytoma. *(Modified from reference 15.)*

levels. This can occur after minor or major trauma, at delivery, and apparently spontaneously from sudden release of catecholamines from the tumor or hemorrhage into it. Pheochromocytoma in pregnancy presents particular difficulties in diagnosis and management.[17]

Diagnosis

Diagnosis of pheochromocytoma is based on clinical suspicion but demands biochemical confirmation (Fig. 41-5). Current evidence is that plasma free metanephrines provide the best biochemical test for diagnosis or exclusion of pheochromocytoma, and the levels are relatively independent of renal function while also providing some guidance for tumor size and location.[18-20] When analysis of plasma free metanephrines is not available, plasma or urinary catecholamines or their other metabolites may be used and typically are 5- to 10-fold greater than normal. When catecholamine levels are at the upper limits of normal, a suppression test with clonidine is useful, which suppresses plasma norepinephrine into the normal range in health but fails to do so in patients harboring a pheochromocytoma.[21]

Once the biochemical diagnosis is secured, the lesion must be localized (Fig. 41-5). Imaging of a pheochromocytoma requires realization that the tumor, as with the clinical syndrome itself, may mimic other lesions.[22] MRI or CT scan of the abdomen and pelvis, concentrating first on the adrenals, is successful in most patients, but additional investigations may be required if no lesion is detected. These may include selective venous sampling to detect a step-up in catecholamine levels, metaiodobenzylguanidine (MIBG) scanning, indium (In-111)–labeled octreotide scanning, measurements of plasma free metanephrines coupled with vena caval sampling, and positron emission tomography (PET).[23] Removal of a pheochromocytoma-containing adrenal can result in compensatory medullary hyperplasia in the contralateral adrenal potentially, giving a false-positive MIBG scan on follow-up scanning, so the clinician must be cautious with interpretation.[24] Confirmation of the presence of a pheochromocytoma should trigger a review, with specialist consultation as needed to exclude associated syndromes, including von Hippel–Lindau syndrome, von Recklinghausen disease, and familial paraganglioma.

Treatment

Once the pheochromocytoma has been localized, the patient should be prepared for surgery with a collaborative team approach by the surgeon, anesthesiologist, and physician. Traditionally, several weeks of α-adrenoceptor blockade, usually with phenoxybenzamine, and the later addition of β-blockade, if necessary to control BP and tachycardia, have been implemented before surgery. β-Blocker monotherapy is contraindicated because of the risk of unopposed α-adrenergic stimulation leading to catastrophic hypertensive crisis. Alternative drugs that have been used successfully before surgery include prazosin (α-blocker) and labetalol (combined α- and β-blocker). However, the need for prolonged presurgical pharmacologic control is now debated, with an emerging view that improved anesthetic management, skilled use of short-acting vasoactive drugs,

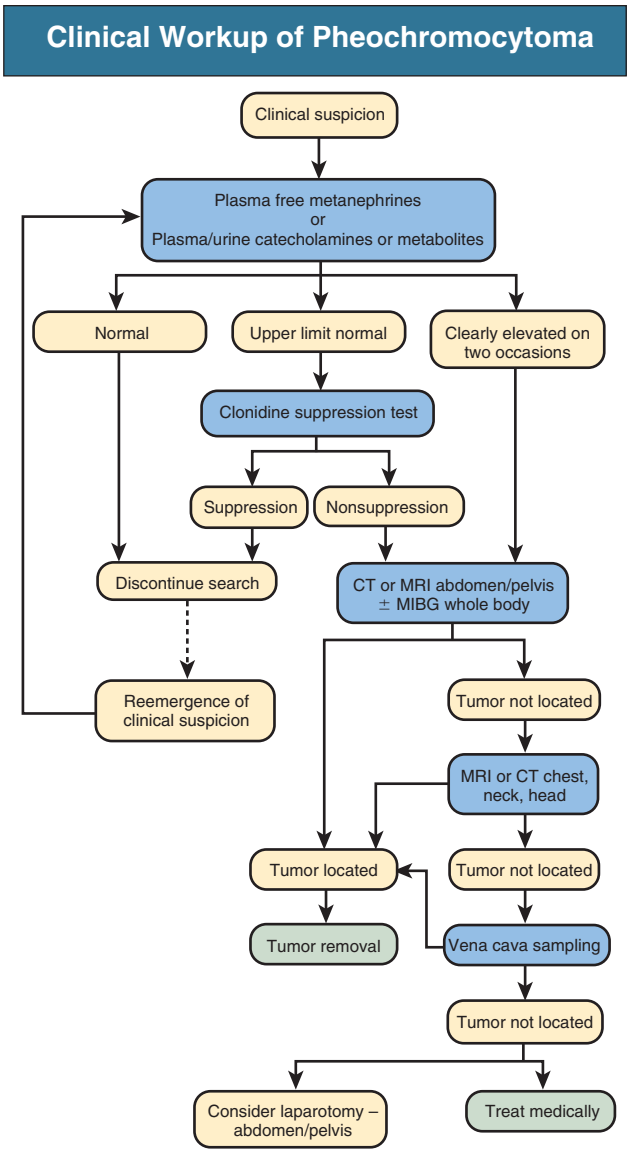

Figure 41-5 Clinical workup of pheochromocytoma. *CT,* Computed tomography; *MIBG,* metaiodobenzylguanidine; *MRI,* magnetic resonance imaging.

and careful intraoperative handling of the tumor may allow safe progression to early surgery, with perioperative mortality close to zero in recent series.[25]

A laparoscopic approach to surgical removal of adrenal pheochromocytomas and some extra-adrenal tumors has gained widespread acceptance, but the laparoscopic approach should be converted to open adrenalectomy for difficult dissection, invasion, adhesions, or surgical inexperience.[26] Laparoscopic surgery has also been used successfully for hereditary bilateral or recurrent pheochromocytoma. Agents used to achieve intraoperative BP control include phentolamine, sodium nitroprusside, and magnesium sulfate.

Hypotension and hypoglycemia are potential postoperative problems. In most patients, surgical removal of pheochromocytoma normalizes plasma catecholamine levels and previously suppressed central sympathetic outflow. BP usually improves with removal of a pheochromocytoma, but especially in those with persistent hypertension versus episodic, BP may remain elevated, necessitating long-term antihypertensive therapy.

For malignant pheochromocytoma, consideration should be given to aggressive surgical resection, particularly when there is a single metastatic lesion. Symptoms should be controlled with α- and β-blocking agents as needed, and irradiation can be useful for bone metastases. Chemotherapy, usually with cyclophosphamide, vincristine, and dacarbazine, should be considered for those with surgically inaccessible metastases producing symptoms that cannot be controlled by α- and β-blockade. Progression of malignant pheochromocytoma is extremely variable. Although median survival is approximately 5 years, survival for decades has been recorded in some cases.

ADRENAL INCIDENTALOMA

Definition and Epidemiology

"Incidentaloma" refers to the incidental discovery of an adrenal mass in the course of investigation for other conditions in the absence of any prior suspicion of adrenal disease.[27] The increasing use and sophistication of abdominal imaging for a wide range of indications frequently leads to the incidental discovery of an adrenal mass. Current prevalence of unsuspected adrenal masses is reported in 4% to 7% of adults undergoing high-resolution CT or MRI abdominal studies (<1% in those <30 years, rising to 7% in those >70 years).[27,28] Hypertension is more common in those with incidentalomas (40%) than in the general population. In a substantial series of more than 1000 incidentalomas, about 75% proved to be nonsecretory benign adenomas. However, an important minority show endocrine activity, including aldosteronoma (frequently normokalemic), pheochromocytoma (>4%, with half normotensive), and most often, cortisol-secreting tumors. Between 5% and 30% of patients with incidentalomas have subclinical hypercortisolism,[27,29] which may be complicated by hypertension, diabetes, obesity, and osteoporosis, as in full-blown Cushing syndrome.[29] The best diagnostic and therapeutic approaches to subclinical hypercortisolism remain to be defined.

Importantly, adrenal carcinoma, although rare at 0.6 to 2.0 cases per 1 million population, accounted for 4% of cases in a large, well-documented series of incidentalomas. Adrenal carcinoma is more likely with increasing size of the adrenal mass: 2% of masses up to 4 cm in diameter, 6% of masses 4 to 6 cm in diameter, and 25% of tumors larger than 6 cm. Adrenal carcinomas may or may not be functional. The prognosis is poor, with 5-year survival of less than 20%. The differential diagnosis of incidentalomas includes metastases, myelolipoma, ganglioneuromas, cysts, hemorrhage, and infections.

Management

Investigation and management should address two key issues: whether the tumor is malignant and whether it is hormonally active. Contrast and noncontrast CT attenuation values provide guidance in distinguishing malignant from benign tumors. CT appearances consistent with malignancy and tumors greater than 4 cm in diameter without benign imaging features should be surgically resected.[28] A careful history and examination should be directed at possible symptoms and signs of endocrine hypertension. Biochemical screening should be undertaken for pheochromocytoma (urine free metanephrines), glucocorticoid excess (urinary free cortisol to creatinine ratio and early-morning plasma cortisol concentration after 1 mg dexamethasone), or primary aldosteronism (plasma and 24-hour urinary potassium levels and plasma renin-aldosterone ratio), as outlined in relevant sections here and Chapter 40. It is reasonable to resect functional tumors. In nonfunctional tumors of benign

appearance, annual biochemical follow-up for 5 years has been recommended if the tumor is larger than 3 cm. Incidentalomas increasing in size by more than 0.8 cm per year should be considered for resection.[28]

RENIN-SECRETING TUMOR

Definition

Primary renin-secreting tumors are rare. Diagnostic criteria include an elevated plasma renin or prorenin level, which decreases on removal of the tumor, and demonstration of renin within the tumor. Most renin-secreting tumors are caused by benign renal juxtaglomerular cell tumors ranging from 5 mm to 6 cm in diameter, but these tumors occasionally occur with nephroblastomas, renal cell carcinomas, and extrarenal neoplasms (bronchial or pancreatic carcinoma, ovarian tumors, carcinoma of ileum or colon, soft tissue sarcomas, orbital hemangiopericytoma).

Etiology and Pathogenesis

Autonomous hypersecretion of renin results in high circulating levels of Ang II, which increase arterial pressure. Secondary hyperaldosteronism, giving rise to hypokalemia, results from stimulation of the adrenal glomerulosa by Ang II. High Ang II levels also induce hyponatremia in a minority of patients, by stimulation of thirst and antidiuretic hormone (ADH) secretion, together with a direct renal water-retaining action of the peptide, and may also cause proteinuria.[30]

Clinical Manifestations

Cases show slight female predominance; 75% of patients are younger than 30 years, presenting usually with severe, occasionally paroxysmal hypertension (average 206/131 mm Hg), hypokalemia (<3.0 mmol/l in ~70% of cases), proteinuria (>0.4 g/day in ~50% of patients), and in a minority, hyponatremia.[31] Glomerular filtration rate (GFR) is normal or high. BP may decrease substantially with the first dose of angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB).

Pathology

Renin-secreting tumors are encapsulated and tan or grayish yellow, with scattered hemorrhages. These masses consist largely of polygonal or spindle cells in close contact with capillary and sinusoidal vessels and contain cytoplasmic renin granules.[31]

Diagnosis and Differential Diagnosis

Patients presenting with hypertension and hypokalemia together with elevated renin (and prorenin) and aldosterone levels may harbor a renin-secreting tumor, most often a renal juxtaglomerular cell tumor. Renal artery stenosis or occlusion must first be ruled out by CT or MRI angiography or renal arteriography. These investigations also might reveal a radiolucent, relatively avascular, usually peripheral juxtaglomerular cell tumor (Fig. 41-6).[32] CT and MRI scans showing an isodense or hypodense lesion with little or no enhancement after injection of contrast material have proved helpful in the provisional localization of these tumors. Bilateral, simultaneous renal vein sampling may enable lateralization of the tumor. Because renal blood flow to the culprit kidney is not impaired, however, a renin ratio of more than 1.2:1 between the two renal veins may not be present, in contrast to the situation of unilateral renal artery stenosis, in which reduced blood flow to the stenosed kidney and renin oversecretion contribute to an often high renal vein renin ratio. Selective segmental renal vein renin sampling may help localize the tumor. When no renal lesion can be visualized and lateralization of renin secretion is not evident, an extrarenal renin-secreting lesion must be considered and sought by appropriate

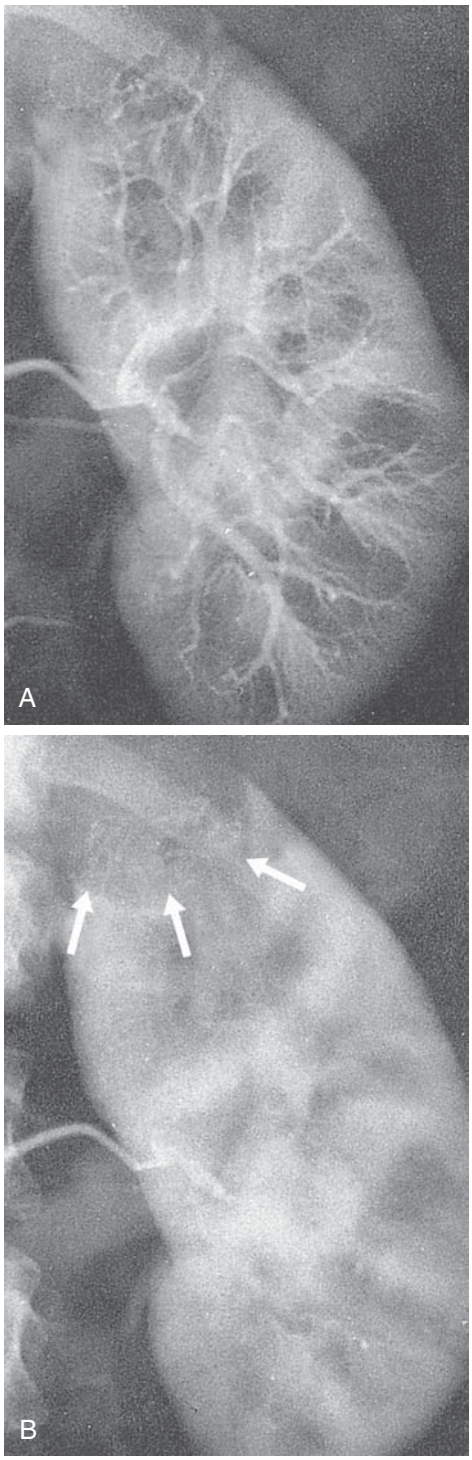

Figure 41-6 Renin-secreting tumor. Left renal angiography arterial **(A)** and nephrogram **(B)** phases revealing a 2.5-cm juxtaglomerular cell tumor with a circumscribed and relatively avascular appearance at the upper pole *(arrows). (Modified from reference 32.)*

radiographic investigations and venous sampling for renin measurements.

Apart from renal artery stenosis or occlusion, it may be necessary to exclude other renin-producing lesions, including Wilms tumor, renal carcinoma, neuroblastoma, hepatocellular carcinoma, and pheochromocytoma, which can either secrete renin or stimulate renal renin production. A careful clinical history and physical examination with selected radiography and occasionally venous sampling for measurements of renin should differentiate these disorders from a juxtaglomerular cell tumor in most patients.

Treatment

Preoperative control of arterial pressure is based on an ACE inhibitor or ARB, introduced with caution to avoid first-dose hypotension. For juxtaglomerular cell tumors, local excision, where possible, is advisable to preserve nephrons. When doubt exists, an intraoperative frozen section will differentiate a benign juxtaglomerular cell tumor from malignant lesions and guide surgery. Removal of a juxtaglomerular cell tumor results in the return of renin and aldosterone levels to normal. BP decreases rapidly, but not always to normal if there is a background of primary hypertension or hypertensive vascular damage.

ACROMEGALY

Definition and Epidemiology

Acromegaly is caused by excessive circulating growth hormone (GH), usually from a pituitary tumor. It is rare, with an incidence of 5 cases per 1 million population per year and a prevalence of 40 to 60 cases per million. Hypertension is more common in persons with acromegaly than in the general population, with an estimated 35% of acromegalic patients with diastolic BP above 100 mm Hg and a higher frequency in female and older patients. Uncertainty about the prevalence (17.5% to 57% in >20 different reports) reflects variation in definitions of hypertension and the stage of the disease.[33] Acromegalic patients who have additional hypopituitarism or advanced cardiomyopathy may have BP reduction masking prior hypertension.

The pathogenesis of hypertension in acromegaly is complex but reflects sodium retention and volume expansion associated with an inappropriate response of hormonal systems to counteract these effects. Total exchangeable sodium, total body water, and extracellular fluid volume are increased. Volume expansion should suppress plasma renin levels, but although levels are low, they are not consistent with the sodium status. Aldosterone levels are also normal or only slightly suppressed. Plasma ANP, which should be elevated in the volume-expanded state, remains normal in acromegaly. The kidneys are enlarged and GFR is increased, but sodium balance is not corrected unless the acromegaly is cured. Other mechanisms contributing to hypertension may include the presence of circulating endogenous Na^+,K^+-ATPase (digoxin-like substances), endothelial dysfunction and GH-induced vascular hypertrophy resulting in decreased vascular compliance, effects on SNS, and undefined genetic factors.

Clinical Manifestations

Acromegaly is characterized by enlargement of the skull (Fig. 41-7), hands (Fig. 41-8), and feet. Other symptoms result from local effects of an expanding pituitary tumor and include visual field defects and headache. Signs and symptoms include headache (40%), excessive sweating (50%), loss of libido (35%), amenorrhea (45%), carpal tunnel syndrome (25%), diabetes mellitus (19%), and visual field defects (5%).[34,35] Thyroid enlargement occurs in 50% of patients and thyrotoxicosis in 6%. Hirsutism occurs in 24% of women and galactorrhea in 10%. Other complications of acromegaly include cardiac hypertrophy, systolic and diastolic dysfunction, arrhythmia, sleep apnea, osteoarthritis and osteopenia, and disturbed calcium metabolism.[36]

Figure 41-7 Facial features of acromegaly with enlargement of brow, nose, and jaw.

Figure 41-8 Radiograph of the hand in acromegaly. "Arrowhead" distal phalanges, expanded joint spaces, and increased soft tissue can be seen.

Diagnosis

Clinical suspicion should be raised by symptoms and signs. Box 41-1 lists appropriate tests for acromegaly. Elevated plasma GH, especially in response to an oral glucose tolerance test, is strongly suggestive of the diagnosis. Visual field assessment and MRI of the pituitary fossa are necessary to define the tumor and to exclude supratentorial extension. Most patients with acromegaly have a GH-secreting

Tests for Acromegaly

Box 41-1 **Diagnostic tests for acromegaly.**

pituitary adenoma. Rarely, pancreatic or hypothalamic tumors release GH-releasing hormone with secondary GH excess. Breast and bronchial tumors can also produce GH.

Treatment

Transsphenoidal adenomectomy is the treatment of choice for acromegalic patients. Irradiation and drug therapy are valuable when complete removal of tumor tissue is not possible (one third of patients) and when surgery is contraindicated. Dopaminergic agents, such as bromocriptine and cabergoline, and the somatostatin analogue octreotide reduce serum GH in acromegaly. Bromocriptine may induce tumor shrinkage and improve diabetes. The GH receptor antagonist pegvisomant has also been shown to be safe and effective.[37] Radiation therapy may not exert its full effect for months or years. Hypopituitarism may occur late after treatment and necessitate endocrine replacement for ACTH, thyroid-stimulating hormone (TSH), or gonadotropin deficiency. Therefore, regular monitoring of pituitary function is required after treatment.

Management of Hypertension in Acromegaly

Surgical removal of the pituitary adenoma with normalization of GH levels may reduce blood pressure to some extent, but the majority of acromegalic patients will continue to require antihypertensive therapy. Antihypertensive treatment requires a diuretic, given the volume-expanded state. Additional antihypertensive agents are frequently required, and both calcium channel blockers and ACE inhibitors may be effective. β-Blockers may also be used, although theoretically such agents may increase GH hormone concentration.

HYPOTHYROIDISM

Definition and Epidemiology

Hypothyroidism results from deficient production of thyroid hormones, whether through inadequate TSH secretion (from hypothalamic or pituitary lesions) or by impaired functioning of the thyroid itself (loss or atrophy of the gland, autoimmune destruction, iodine deficiency, antithyroid agents, or hereditary defects in hormone synthesis).[38] It is estimated that hypertension is 1.5 to 2 times more common in hypothyroid patients than in the general population.[39]

The pathogenesis of the hypertension is multifactorial and associated with both increased total body sodium and increased peripheral vascular resistance. Even in euthyroid patients, serum free thyroxine index (FTI) is lower and TSH is higher in hypertensive than in normotensive patients, and FTI also independently predicts BP response to increments in dietary sodium in both normotensive and hypertensive individuals.[40]

Figure 41-9 **Hypothyroid facies.**

Hypothyroidism is associated with increased aortic stiffness, loss of sensitivity to vasoconstrictors, and impaired endothelial function with loss of endothelial dependent vasodilation plus reduced vasodilatory responses to NO donors.[41] Observations of short-term hypothyroidism have confirmed increases in arterial pressure, plasma catecholamines, aldosterone, and cortisol, all reversible with thyroid hormone treatment.[42,43] The relationship between plasma catecholamine levels and BP is greater in hypothyroidism. The catecholamine levels of hypothyroid patients also show more variability associated with more variability in BP. This suggests underdamping of swings in sympathetic activity in the hypothyroid state.[44] Hypertension develops despite a low cardiac output.

Thyroid replacement therapy corrects the electrolyte, hemodynamic, and hormone changes and cures the hypertension in most patients.

Clinical Features

Any organ system can be affected in primary hypothyroidism. Symptoms and signs can be protean. The onset of clinical abnormalities is usually gradual, and diagnosis may not be made until gross hypothyroidism is established. Common clinical features include weakness, dry skin, lethargy, slow slurred speech, sensitivity to cold, thick tongue, facial puffiness (Fig. 41-9), coarse hair, failing memory, constipation, and weight gain with reduced appetite. Coronary heart disease is common, with contributions from dyslipidemia and hypertension accelerating the atherogenic process.

Diagnosis

Hypothyroidism should be considered in any patient with hypertension. Because the clinical manifestations of hypothyroidism are often difficult to elicit, especially in elderly patients, thyroid function tests, including TSH when FTI is equivocal, should be performed. In patients with primary hypothyroidism in whom normotension is not achieved by full thyroxine replacement therapy, primary

hypertension likely is a concomitant disorder. For those with gross or longstanding hypothyroidism, replacement thyroxine therapy should be cautious to minimize the chances of exacerbating latent myocardial ischemia.

HYPERTHYROIDISM

Definition and Epidemiology

Hyperthyroidism and thyrotoxicosis may result from Graves disease and less frequently toxic multinodular goiter, toxic adenoma, high iodine intake, trophoblastic tumor, and (rarely) excessive pituitary TSH secretion. Hypertension is common in hyperthyroidism, with a prevalence of 60% in toxic adenoma and approximately 30% in Graves disease.

Clinical Features

The clinical features depend on the underlying cause of the hyperthyroidism, severity of the disorder, rapidity of onset, age of the patient, and concomitant disease. Abnormalities may be evident in the cardiovascular system (tachyarrhythmias, heart failure), skin (increased sweating, increasing pigmentation with vitiligo), eyes (lid lag, exophthalmos), nervous system (hypertension, nervousness), alimentary system (increased appetite yet weight loss, diarrhea), and muscles (proximal weakness).

Hypertension in hyperthyroidism is associated with elevated systolic and normal or low diastolic BP. It may be observed in both postpartum thyrotoxicosis and neonatal thyrotoxicosis. Elevation of diastolic BP is unusual unless there is concomitant primary hypertension.

The hemodynamic characteristics in hypertension of thyrotoxicosis are an increased cardiac output, increased myocardial contractility, tachycardia, decreased peripheral vascular resistance, and expanded blood volume. These indices return to normal in most patients on achieving the euthyroid state. Interestingly, catecholamine levels tend to be low (inversely to hypothyroid hypertension), and there is no heightened activity of the sympathetic system. The RAS tends to be activated and the aldosterone levels increased in hyperthyroidism, which may contribute to the development of systolic hypertension. Experimental hyperthyroidism is characterized by enhanced endothelial responsiveness, perhaps reflecting increased sheer stresses from the hyperdynamic circulation. There is also a resetting of the pressure-natriuresis relationship, possibly attributable to increased renin-angiotensin activity.[41]

Suspicion of hyperthyroidism should be high in the elderly patient with hypertension and a high pulse pressure, particularly if there is also atrial fibrillation. Such patients are prone to developing cardiac failure, in which case the increased systolic arterial pressure will diminish, masking previous hypertension. Hypertension with a high pulse pressure, although typical of hyperthyroidism, is observed in many elderly patients with primary hypertension because of the loss of compliance of the aorta with aging.

Diagnosis and Treatment

Diagnosis of hyperthyroidism is confirmed by thyroid function tests, including measurement of TSH. β-Blockers are often effective first-line therapy for hyperthyroidism-associated hypertension. Treatment of hyperthyroidism, whether by antithyroid drugs, surgery, or radioiodine, will often normalize the increased systolic arterial pressure, although this is by no means invariable in the elderly patient, who may have concomitant primary hypertension.

CHAPTER 42

Neurogenic Hypertension, Including Hypertension Associated with Stroke or Spinal Cord Injury

Venkatesh Aiyagari, Sean Ruland, and Philip B. Gorelick

The nervous system and blood pressure (BP) are closely interrelated.[1] It is well recognized that the elevated BP response to stressors is mediated by the sympathetic nervous system (SNS). However, the role of the SNS in the long-term regulation of BP and the initiation and maintenance of hypertension is also increasingly appreciated. Several studies of plasma catecholamine levels, renal norepinephrine spillover, microneurography, and heart rate variability support the hypothesis that sympathetic activation plays a major role in hypertensive patients.[2] The SNS also has an important role in hypertension after neurologic injury. This chapter describes the physiology and management of hypertension in such injury.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Neural Control of Blood Pressure

The brainstem, especially the ventral medulla, has a key role in the maintenance of BP (Fig. 42-1). BP is controlled by the nucleus tractus solitarius (NTS), which receives inhibitory baroreceptor afferents, and by the rostral ventrolateral medulla and rostral ventromedial medulla, which are the source of excitatory descending bulbospinal pressor pathways. In addition, a depressor center in the caudal ventrolateral medulla composed of γ-aminobutyric acid (GABA)–containing neurons receives afferents from the NTS and projects to the rostral ventral medulla. These inhibitory GABA-containing neurons are tonically active, and reduced activity of these neurons leads to hypertension.[3-5]

The ultimate effector units are the sympathetic neurons located in the intermediolateral cell column of the spinal cord and the parasympathetic neurons found in the dorsal motor nucleus of the vagus and nucleus ambiguus located in the medulla. In addition, impulses from the limbic system, cerebral cortex, and hypothalamus also directly or indirectly project to the intermediolateral cell column of the spinal cord and influence BP regulation.

The factors that lead to increased sympathetic activation in hypertension are poorly understood. In recent years, however, the role of low-grade inflammation and reactive oxygen species (ROS) has been recognized. Some studies also suggest that activation of low-grade inflammation in the kidney may activate afferent sympathetic nerves that stimulate the central SNS. Hypertension is also associated with increased levels of circulating inflammatory markers such as tumor necrosis factor α, interleukin-6, C-reactive protein, monocyte chemoattractant protein 1, and adhesion molecules such as P-selectin and intercellular adhesion molecule 1. Angiotensin II (Ang II) and aldosterone also play a crucial role in vascular inflammation, and both candesartan and mineralocorticoid antagonists have been shown to decrease the levels of inflammatory markers. In addition, Ang II–mediated hypertension has been associated with brain microglial activation and increased brain levels of inflammatory cytokines and ROS. An increase in ROS may directly activate or sensitize sympathetic neurons and scavenge nitric oxide, which tonically inhibits sympathetic outflow. Thus, a dysfunction of the neural-immune-vascular triad leading to an increase in central oxidative stress may be the driving force behind sympathetic activation, which then increases Ang II and promotes further inflammation and vascular dysfunction.[6]

Cerebrovascular Autoregulation

Under normal conditions, cerebral blood flow (CBF) of the adult brain is 50 ml/100 g/min. CBF is regulated by the following relationship between cerebral perfusion pressure (CPP) and cerebrovascular resistance (CVR):

$$CBF = CPP/CVR$$

Cerebral perfusion pressure is defined as the difference between the mean arterial pressure (MAP) and the intracranial pressure (ICP). If ICP is increased, systemic BP needs to be higher to maintain CPP and CBF.

Cerebrovascular autoregulation maintains a constant blood flow over a wide range of CPP. Normally, changes in BP have little effect on CBF because of compensatory changes in cerebrovascular resistance. An increase in BP produces vasoconstriction, and a decrease in BP produces vasodilation, thus keeping CBF constant (Fig. 42-2). Autoregulation is effective over a range of CPP from about 60 to 150 mm Hg. In chronically hypertensive individuals, the cerebral arterioles develop medial hypertrophy and lose the ability to dilate effectively at lower pressures. This causes the autoregulatory curve to shift to the right.[7] In these individuals, a rapid reduction of BP may lead to a drop in CBF even though the BP might still be within the "normal" range. With effective control of hypertension for several months, the normal range for autoregulation can be reestablished.[8]

Above the upper limit of autoregulation, there is *breakthrough vasodilation* leading to damage of the blood-brain barrier and cerebral edema and possibly cerebral hemorrhage. Below the lower limit of autoregulation, decreases in CPP lead to a decrease in CBF. Under these circumstances, increased extraction of oxygen and glucose maintains normal cerebral metabolism and brain function. When CBF decreases to less than 20 ml/100 g/min, the increase in oxygen extraction is no longer able to supply the metabolic needs of the brain, leading to impaired brain function.

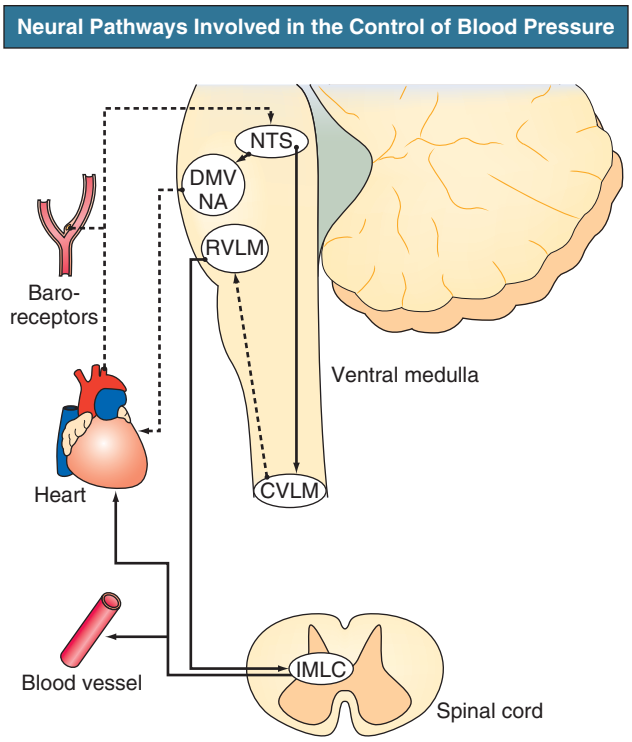

Figure 42-1 Neural pathways involved in the control of blood pressure. The ventral medulla has a key role in generating both excitatory *(solid line)* and inhibitory *(dotted line)* pathways, largely through the rostral ventrolateral medullary neurons *(RVLM)* and nucleus tractus solitarius *(NTS),* respectively. Ultimate effector control is provided by sympathetic activation originating in the intermediolateral cell column *(IMLC)* and parasympathetic action through the nucleus ambiguus *(NA)* and dorsal motor nucleus of the vagus nerve *(DMV)*. *CVLM,* Caudal ventrolateral medullary neurons.

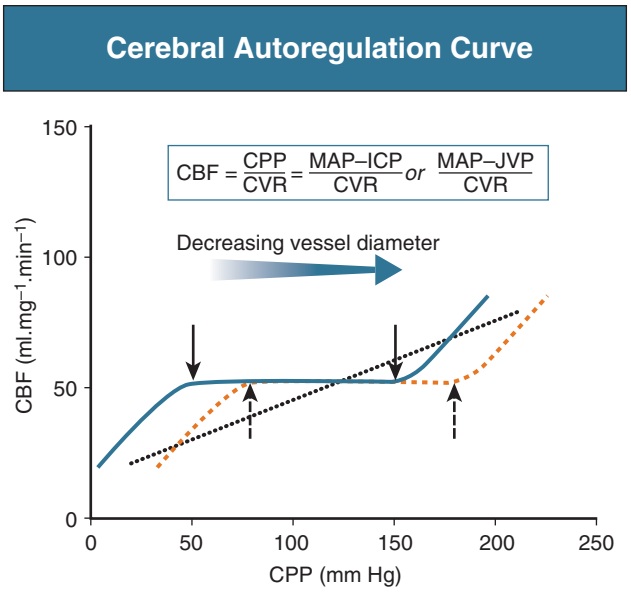

Figure 42-2 Cerebral autoregulation curve. In the normal state *(solid line),* cerebral blood flow *(CBF)* is held constant across a wide range of cerebral perfusion pressure (*CPP;* 60 to 150 mm Hg). In chronic hypertension *(dashed line),* the autoregulation curve shifts to the right. In the presence of acute cerebral ischemia *(dotted line),* cerebral autoregulation may be impaired, and CBF becomes dependent on CPP. *CVR,* Cerebral venous resistance; *ICP,* intracranial pressure; *JVP,* jugular venous pressure; *MAP,* mean arterial pressure. *(From reference 14.)*

HYPERTENSION AFTER STROKE

Epidemiology

Hypertension is the most important modifiable risk factor for cerebrovascular accident (stroke), and reduction in BP is effective in the primary prevention of stroke, improves outcomes in patients who have had an ischemic stroke, and may be especially beneficial for lowering risk of stroke among those with a history of intracerebral brain hemorrhage.[9] Combined data from 40 trials of antihypertensive agents have demonstrated that a 10% reduction in systolic BP lowers stroke risk by one third.[10] A 5-mm lower diastolic together with a 9-mm lower systolic BP confers a 33% lower risk of stroke, and a 10-mm lower diastolic together with an 18- to 19-mm lower systolic confers more than a 50% reduction in stroke risk.[11] In patients who had a stroke, the Perindopril Protection against Recurrent Stroke Study (PROGRESS) showed that a reduction in BP was associated with a significant reduction of total stroke recurrence by 28% and a reduction of major coronary and vascular events by 26%, even in patients with a normal initial BP.[12]

However, the management of BP in the immediate aftermath of a stroke is controversial.[13] A high proportion of patients have elevated BP immediately after a stroke, and BP has been shown to decrease spontaneously over 1 to 2 weeks to the prestroke baseline in most patients. Box 42-1 lists some postulated causes of elevated BP. Increased BP after stroke is associated with higher mortality. Nonetheless, it is uncertain whether the increased BP directly contributes to poor outcome, or whether immediate lowering of BP will lead to better outcomes.

Postulated Causes of Hypertension After Stroke

- Preexisting hypertension
- "White coat" effect
- Stress of hospitalization
- Cushing reflex*
- Catecholamine and cortisol release
- Lesion of brainstem or hypothalamus
- Nonspecific response to brain damage

Box 42-1 Postulated causes of hypertension after stroke. *A hypothalamic response to raised intracranial pressure or ischemia consisting of hypertension with bradycardia.

Pathophysiology

An understanding of cerebrovascular pathophysiology is essential to understand the pros and cons of treating hypertension in these patients (Table 42-1).

In patients with an ischemic stroke, vascular occlusion leads to a central region of irreversibly ischemic brain surrounded by an ischemic zone where blood flow is reduced but brain tissue is still viable. After 2 or 3 days, the ischemic areas either recover completely or undergo infarction. In the first few days, perfusion in this zone is marginal, and a further decrease in blood flow might lead to infarction. Because cerebral autoregulation is impaired with acute ischemic stroke, a fall in BP could lower blood flow and extend infarction, and a very high BP could lead to hemorrhagic transformation, especially if thrombolytic agents have been given.

At times, it can be difficult to distinguish between *hypertensive encephalopathy,* in which lowering of BP is clearly indicated, and

Acute Treatment of Hypertension in Stroke: Advantages and Disadvantages	
Advantages	**Disadvantages**
Acute Ischemic Stroke	
Might lower mortality Might decrease stroke progression Might decrease hemorrhagic transformation (especially after tPA) Might decrease cerebral edema formation Might be helpful for systemic reasons (e.g., associated myocardial ischemia) Patients likely to be more compliant with antihypertensive use if treatment initiated in hospital	BP decreases on its own No proven benefit Ongoing ischemia around infarct (ischemic penumbra) Altered autoregulation from chronic hypertension, ischemia Large-vessel stenosis might have resulted in reduction of perfusion. Chance of propagating thrombus Anecdotal case reports and trial results demonstrating deterioration with BP decrease Principle of "do no harm" *(primum non nocere)*
Acute Intracerebral Hemorrhage	
Might lower mortality Might decrease hematoma expansion Might decrease cerebral edema formation Might be helpful for systemic reasons (e.g., associated myocardial ischemia) Patients likely to be more compliant with antihypertensive use if treatment initiated in hospital	BP decreases on its own No proven benefit Possible zone of ischemia around intracerebral hematoma Chronically hypertensive patients require higher CPP, because of shift in autoregulatory curve. ICP may be elevated, and lowering BP reduces what could be marginal CPP. Principle of "do no harm" *(primum non nocere)*
Aneurysmal Subarachnoid Hemorrhage	
Might decrease rebleeding rate Might help if there is cardiac ischemia (stunned myocardium)	No proven benefit ICP may be elevated, and lowering BP reduces what could be marginal CPP. Might lead to cerebral ischemia in presence of vasopasm.

Table 42-1 Advantages and disadvantages (pros and cons) of acute treatment of hypertension in stroke. *BP,* Blood pressure; *CPP,* cerebral perfusion pressure; *ICP,* intracranial pressure; *tPA,* tissue plasminogen activator.

ischemic stroke with hypertension. The level of consciousness, the presence of focal neurologic deficits, and the ophthalmoscopic (funduscopic) examination can help make this distinction. Hypertensive encephalopathy is a syndrome of global neurologic dysfunction, usually with papilledema, and focal neurologic deficits are usually less prominent. In acute ischemic stroke, the focal neurologic deficit is more prominent, and alterations of consciousness are less common, except with brainstem strokes or "malignant" brain edema from massive hemispheric infarction.

In patients with intracerebral hemorrhage, the considerations are different.[14] Hematoma expansion occurs in one third of patients, with an intracerebral hemorrhage in the first 24 hours.[15] Therefore, BP is often lowered in these patients to decrease hematoma expansion. However, the evidence does not support a clear association between high BP and hematoma expansion.[16] On the other hand, some patients with intracerebral hemorrhage might have increased ICP from the hematoma volume or associated hydrocephalus. In these patients, lowering of BP is not warranted because it might critically lower CPP; monitoring of ICP and CPP may be helpful.

Patients with aneurysmal subarachnoid hemorrhage have significant risk of rebleeding; tight BP control is recommended to decrease the risk. Some patients with subarachnoid hemorrhage have associated myocardial dysfunction ("stunned myocardium"), in which case high BP might worsen myocardial function. Again, in patients with hydrocephalus or an associated intracerebral hemorrhage, monitoring ICP and CPP can help guide BP management. In the latter half of the first week and in the second week after subarachnoid hemorrhage, many patients develop vasospasm of the intracranial arteries. Reduction of BP may lead to worsening of cerebral ischemia in this situation. Therefore, once the aneurysmal rupture has been adequately treated with surgical clipping or coiling, BP is usually maintained at a normal or slightly elevated level in these patients.

Diagnosis and Treatment

Definitive studies adequately powered to assess the benefits and risks of BP lowering after ischemic and hemorrhagic stroke have not yet been performed. A Cochrane review concluded that evidence is insufficient to evaluate the effect of altering BP on outcome during the acute phase of stroke.[17] The following sections summarize the available evidence. Figure 42-3 outlines recommendations for treating BP in different clinical situations.

Acute Ischemic Stroke

The Acute Candesartan Cilexetil Evaluation in Stroke Survivors (ACCESS) trial studied early or late treatment with candesartan after a stroke in patients who were conscious, had a motor paresis, and were hypertensive. The combined end point of total mortality, cerebral complications, and cardiovascular complications at the end of 3 months was reduced by 48% for patients treated with candesartan (4 to 16 mg) initiated within 72 hours after stroke compared with those starting candesartan 7 days later. However, this difference in outcome was not associated with any difference in BP.[18]

The larger Scandinavian Candesartan Acute Stroke Trial (SCAST) was designed to confirm to benefit of candesartan in patients with acute stroke. Patients with a systolic BP of 140 mm Hg or more within 30 hours of an acute stroke (85% were ischemic) were randomized to treatment with candesartan or placebo for 7 days, with dose escalation from 4 mg on day 1 to 16 mg on days 3 to 7. The primary outcome of the composite of vascular death, myocardial infarction, or stroke at 6 months was not significantly different between the two groups. Functional outcome was slightly worse at 6 months in the candesartan group but did not meet statistical significance.[19]

In the Controlling Hypertension and Hypotension Immediately Post-Stroke (CHHIPS) trial, hypertensive patients with an ischemic or hemorrhagic stroke were randomized within the first 36 hours to labetalol, lisinopril, or placebo, titrated to a systolic BP goal of 145

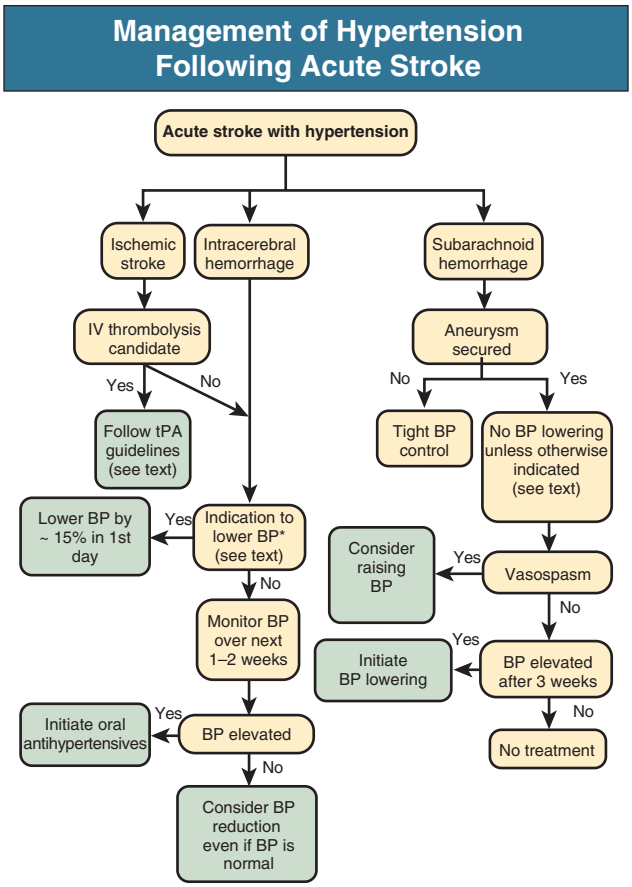

Figure 42-3 Management of hypertension after acute stroke. *BP,* Blood pressure; *IV,* intravenous; *tPA,* tissue plasminogen activator. *Indication for treatment includes systolic BP above 220 or diastolic BP above 120 mm Hg for ischemic stroke, the presence of associated conditions such as aortic dissection or myocardial infarction, and in patients with cerebral hemorrhage, systolic BP above 180 or mean arterial pressure above 130 mm Hg.

Guidelines for Blood Pressure Management After Acute Ischemic Stroke

AHA/ASA	ESO
Patients Eligible for Thrombolytic Therapy	Routine BP lowering is not recommended.
Before Thrombolytic Therapy	Cautious BP lowering is recommended in patients with extremely high BP (>220/120 mm Hg) on repeated measurements, or with severe cardiac failure, aortic dissection, or hypertensive encephalopathy.
Lower BP if SBP >185 or DBP >110 mm Hg.	Abrupt BP lowering should be avoided.
After Thrombolytic Therapy	BP must be below 185/110 mm Hg before, and for the first 24 hours after, thrombolysis.
Lower BP if SBP >180 or DBP >105 mm Hg.	
Patients Not Eligible for Thrombolytic Therapy	
Patients with markedly elevated BP may have their BP lowered. Lowering BP by ~15% in these patients is reasonable. Antihypertensive drugs should be withheld unless SBP >220 or DBP >120 mm Hg.	

Table 42-2 Guidelines for blood pressure (BP) management after acute ischemic stroke. *AHA,* American Heart Association, *ASA,* American Stroke Association; *ESO,* European Stroke Organisation; *SBP,* systolic blood pressure; *DBP,* diastolic blood pressure.

to 155 mm Hg or a systolic BP reduction of 15 mm Hg from the BP at randomization. The primary outcome of death or dependency at 2 weeks in the treated group was not significantly different from that of the placebo group; however, mortality was halved at 3 months in the treatment groups compared with placebo.[20]

The Continue or Stop Post-Stroke Antihypertensives Collaborative Study (COSSACS) was a prospective randomized trial to determine the efficacy and safety of continuing or stopping preexistent antihypertensive drugs in patients with a recent stroke. The trial was prematurely stopped because it lacked research support and was underpowered. At the end of 2 weeks, however, there was no difference in mortality or dependency between the group continuing antihypertensives and the group stopping the drugs.[21]

Early decrease in BP had no effect on outcome in the Glycine Antagonist in Neuroprotection (GAIN Americas) trial. In the Intravenous Nimodipine West European Stroke Trial (INWEST), a more than 20% reduction of diastolic BP on day 2 was associated with a worse outcome.[22,23]

The Chinese Antihypertensive Trial in Acute Ischemic Stroke (CATIS) studied 4071 hypertensive patients with nonthrombolyzed ischemic stroke within 48 hours of onset. Patients were randomized to receive antihypertensive treatment (aimed at lowering systolic blood pressure by 10% to 25% within the first 24 hours after randomization, achieving blood pressure less than 140/90 mm Hg within 7 days, and maintaining this level during hospitalization) or to discontinue all antihypertensive medications during hospitalization. There was no difference in the combined outcome of death and major disability at 14 days, at hospital discharge, or at 3 months between the two groups.[23a]

Table 42-2 summarizes the currently recommended guidelines of the American Heart Association and American Stroke Association (AHA/ASA) and the European Stroke Organisation (ESO) for BP management in acute ischemic stroke.[24,25]

Intracerebral Hemorrhage

A small, controlled study of 14 hypertensive patients with a small to moderate-sized cerebral hemorrhage within 24 hours showed that treatment with nicardipine or labetalol to reduce MAP by 15% to a lower MAP limit of about 120 mm Hg produced no change in CBF.[26] In contrast, a decrease in MAP by more than 20% or a systolic BP below 110 mm Hg in patients with cerebral hemorrhage has been shown to decrease CBF.[27]

The Antihypertensive Treatment in Acute Cerebral Hemorrhage (ATACH) study used intravenous (IV) nicardipine infusion for 18 to 24 hours in patients with cerebral hemorrhage with a systolic BP above 200 mm Hg presenting within 6 hours of symptoms. Patients with small hematomas (mean volume <20 ml) were treated to three different systolic BP goals (170 to 200, 140 to 170, and 110 to 140 mm Hg) with no difference in 3-month mortality among the groups.[28]

The Intensive Blood Pressure Reduction in Acute Cerebral Hemorrhage Trial (INTERACT) randomized hypertensive patients within 6 hours of symptom onset to achieve a target of 140 or 180 mm Hg. Treatment was for 7 days or until hospital discharge. The lower BP target resulted in less hematoma expansion at 24 hours, but this difference was not significant after adjustment for initial hematoma volume and time from onset of symptoms to computed tomography (CT) scan. There was no significant difference in adverse event rate or outcome at 90 days.[29]

Although neither ATACH nor INTERACT was powered to detect a difference in clinical outcome, the results indicate that acute BP

Guidelines for Blood Pressure Management After Acute Cerebral Hemorrhage

AHA/ASA	EUSI
If SBP >200 mm Hg or MAP >150 mm Hg, consider aggressive BP reduction. If SBP >180 mm Hg or MAP >130 mm Hg and there is evidence of or suspicion of elevated ICP, consider monitoring ICP and reducing BP to keep CPP >60 to 80 mm Hg. If SBP >180 mm Hg or MAP >130 mm Hg and there is no evidence or suspicion of elevated ICP, consider modest BP reduction (e.g., MAP of 110 mm Hg, target BP of 160/90 mm Hg)	Routine BP lowering is not recommended. Treatment is recommended in patients *with* known history of hypertension or signs (ECG, retina) of chronic hypertension: SBP >180 or DBP >105 mm Hg. If treated, target BP should be 170/100 mm Hg (or MAP 125 mm Hg). Treatment is recommended in patients *without* known hypertension: SBP >160 and/or DBP >95 mm Hg. If treated, target BP should be 150/90 mm Hg (or MAP 110 mm Hg). Reduction of MAP by >20% should be avoided. These limits and targets should be adapted to higher values in patients undergoing monitoring of increased ICP, to guarantee sufficient CPP >70 mm Hg.

Table 42-3 Guidelines for blood pressure (BP) management after acute cerebral hemorrhage. *AHA,* American Heart Association; *ASA,* American Stroke Association; *EUSI,* European Stroke Initiative; *SBP,* systolic blood pressure; *DBP,* diastolic blood pressure; *ECG,* electrocardiogram; *MAP,* mean arterial pressure; *ICP,* intracranial pressure; *CPP,* cerebral perfusion pressure.

reduction in intracerebral hemorrhage may be safe. Based on the results of INTERACT, the main-phase study, INTERACT2 randomized 2839 hypertensive patients with acute cerebral hemorrhage within 6 hours to blood pressure targets of <140 mm Hg or <180 mm Hg. There was no significant difference in the rate of the primary outcome of death or severe disability between the two groups. However, the group randomized to the lower blood pressure target had significantly lower modified Rankin scores. There was no significant difference in hematoma growth between the two groups.[29a] ATACH-II, a similar follow-up trial to ATACH, is currently under way.

Table 42-3 summarizes the currently recommended guidelines of the AHA/ASA and the European Stroke Initiative (ESI) for BP management in acute cerebral hemorrhage.[30,31]

Subarachnoid Hemorrhage

Before definitive treatment of the ruptured aneurysm, systolic BP is usually kept below 140 to 160 mm Hg, although there is no conclusive evidence that higher BPs increase rebleeding rate. In patients with suspected elevation of ICP, it is important to monitor ICP and to keep CPP above 70 mm Hg. The AHA/ASA guidelines recommend monitoring and control of BP to balance the risk of stroke, hypertension-related bleeding, and maintenance of CPP. A systolic BP goal of below 160 mm Hg is considered reasonable.[32] The ESO recommends keeping the systolic BP below 180 mm Hg but keeping MAP above 90 mm Hg.[33] After the ruptured aneurysm has been secured, aggressive treatment of BP should be avoided, and in the patient with cerebral vasospasm, BP is usually elevated until the neurologic deficits resolve, generally up to a systolic BP of 200 to 220 mm Hg.

HYPERTENSION AFTER CAROTID ENDARTERECTOMY AND ENDOVASCULAR PROCEDURES

Definition, Incidence, and Clinical Features

Hemodynamic disturbances such as hypotension, bradycardia, and hypertension are common (10% to 40%) after carotid endarterectomy and endovascular procedures such as angioplasty and stenting. A small percentage of these patients develop the *carotid hyperperfusion* (or reperfusion) *syndrome*. This syndrome occurs in the first week after surgery or angioplasty-stenting and manifests as transient or permanent contralateral neurologic signs, ipsilateral pulsatile headache, seizures, cerebral hemorrhage, or reversible cerebral edema.[34-36] Some patients with cerebral hyperperfusion after revascularization may not manifest clinical signs acutely but may later develop cortical neuronal loss and cognitive impairment.[37]

In a recent review of hypertension and hyperperfusion syndrome after carotid endarterectomy, the incidence of postoperative severe hypertension was 19% and that of carotid hyperperfusion syndrome was 1%. Most cases occurred in the first week, and the average time to symptoms was the fifth postoperative day. Seizures (36%), hemiparesis (31%), or both (33%) were the common presenting features, and 59% of patients had headache.[38]

Pathophysiology

Preexisting hypertension, baroreceptor impairment after surgical manipulation, and elevated catecholamine levels after cerebral hypoperfusion during intraoperative cross-clamping may contribute to postoperative hypertension that contributes to cerebral hyperperfusion. The hyperperfusion syndrome may be caused in part by impaired autoregulation from chronic vasodilation of the distal vascular bed ipsilateral to a hemodynamically significant internal carotid artery stenosis.[39] Other postulated mechanisms include activation of the trigeminovascular axon reflex and derangement of the carotid baroreceptors.[40] Patients at risk for development of hyperperfusion syndrome are those with extensive microvascular disease, preoperative hypoperfusion and impaired autoregulation, or postoperative hyperperfusion.

Diagnosis and Treatment

Cerebral hyperperfusion has been defined as a postoperative increase in cerebral blood flow of more than 100% compared with preoperative flow. However, this CBF increase may be only approximately 20% compared with the contralateral side.[41] Bouri and colleagues[38] believe that making a diagnosis of cerebral hyperperfusion syndrome based on CBF doubling alone leads to a significant overestimation of the incidence and suggest the following four criteria:

1. Onset within 30 days after carotid endarterectomy
2. Evidence of hyperperfusion (on transcranial Doppler, single-photon emission computed tomography [SPECT], or CT/magnetic resonance [MR] perfusion imaging), *or* systolic BP above 180 mm Hg
3. Clinical features such as new headache, seizures, or hemiparesis (Glasgow coma scale <15) *or* radiologic features such as cerebral edema or intracerebral hemorrhage
4. No evidence of new cerebral ischemia, postoperative carotid occlusion, or metabolic or pharmacologic cause

Because of the risk for development of carotid hyperperfusion syndrome after carotid endarterectomy or stenting, all patients should have continuous intraoperative and postoperative BP

monitoring. Most authors advocate strict BP control (systolic BP <120 mm Hg) from the time of intraoperative internal carotid artery unclamping or angioplasty, particularly in high-risk patients.[42] Others suggest aiming for a systolic BP of 140 to 160 mm Hg or preoperative systolic BP if lower. Elevated BP should be treated with IV labetalol or clonidine. Vasodilators such as nitroglycerin and sodium nitroprusside should be avoided.

HYPERTENSION AFTER SPINAL CORD INJURY

Definition and Epidemiology

Autonomic dysreflexia occurs in up to 70% of patients after spinal injury, most often during the first 2 to 4 months after injury. Autonomic dysreflexia is defined as an increase in systolic BP by at least 20%, associated with a change in heart rate and accompanied by at least one sign (sweating, piloerection, facial flushing) or symptom (headache, blurred vision, stuffy nose).[43] If unrecognized, dysreflexia can result in serious sequelae, such as posterior leukoencephalopathy, cerebral hemorrhage, subarachnoid hemorrhage, seizures, arrhythmia, pulmonary edema, retinal hemorrhage, and rarely coma or death.[44]

Pathophysiology and Diagnosis

Autonomic dysreflexia is most often seen in patients with complete injuries. The spinal cord lesion is typically at or above the sixth thoracic spinal nerve level. Immediately after the injury, the patient has initial loss of supraspinal sympathetic control similar to the initial period of muscle flaccidity. This often leads to hypotension and bradycardia (spinal shock). After a few weeks to months, there is extrajunctional sprouting of the α-receptors, denervation hypersensitivity, and impaired presynaptic uptake of norepinephrine. In addition, derangement of spinal glutaminergic interneurons may occur. Noxious stimuli below the neurologic level of the lesion trigger a spinal reflex arc that results in increased sympathetic tone and hypertension.[45] The most common inciting events are an overdistended urinary bladder and fecal impaction. However, autonomic dysreflexia may be secondary to other precipitants, including infections, pressure ulcers, urologic and endoscopic procedures, sympathomimetic medications, and sildenafil citrate used for sperm retrieval.[46]

Clinical symptoms of spinal cord injury include pulsatile headache, blurred vision, anxiety, nasal congestion, nausea, and sweating above the spinal nerve level. The flushed sweaty skin above the lesion level is caused by brainstem parasympathetic activation. At and below the lesion, the skin remains pale, cool, and dry. Heart rate can vary from bradycardia to tachycardia. The hallmark physical finding is elevated BP. However, because BP may normally be quite low after spinal cord injury, baseline BP readings may be within the normal range but elevated for a given individual, making clinical suspicion and reliance on other clinical signs and symptoms paramount in the diagnosis if baseline BP is not known.[45]

Treatment

Vigilant preventive measures for autonomic dysreflexia include proper bowel, bladder, and skin care. However, expeditious treatment of elevated BP is critical to avoid the potentially life-threatening consequences. Placement of the patient upright with the legs lowered, to precipitate orthostatic BP lowering, and removal of any possible noxious stimuli, such as binding clothing and devices, are the initial treatment steps. Checking for urinary overdistention and changing, flushing, or insertion of a new catheter if the patient receives intermittent catheterization are important.

Pharmacologic treatment with rapid-acting, short-lived agents may be indicated for systolic BP elevation of 150 mm Hg or more that persists after the preceding interventions. Nitroglycerin is often used to treat hypertension associated with autonomic dysreflexia. However, to avoid precipitating hypotension, nitrate-containing agents should not be given for 24 hours before use of sildenafil or similar agents. Calcium channel blockers and angiotensin-converting enzyme (ACE) inhibitors have also been reported to be effective.[47] If the bladder is empty and BP below 150 mm Hg, fecal disimpaction with a topical anesthetic should be attempted. If dysreflexia is refractory or associated with severe clinical presentation, other precipitants should be sought, and hospitalization may be indicated.[48]

Up to 90% of pregnant women with upper spinal cord injury experience autonomic dysreflexia during labor and delivery. Appropriate epidural or spinal anesthesia techniques can ameliorate the risk.[49]

CEREBROVASCULAR EFFECTS OF ANTIHYPERTENSIVE AGENTS

Different classes of antihypertensive agents have different direct effects on cerebral blood flow, intracranial pressure, and autoregulation. The ideal drug would not increase ICP or decrease CBF to ischemic regions. In addition, in treatment of hypertension in the acute setting, drugs that can be given intravenously, have a short half-life, and do not cause sedation are preferable. In the chronic phase after a stroke, there is no clear evidence favoring one class of antihypertensive agent over another. Table 42-4 summarizes the advantages and disadvantages of various classes of antihypertensive agents in the acute stroke setting

β-Adrenergic antagonists (e.g., esmolol) and combined α- and β-adrenoceptor antagonists (e.g., labetalol) do not increase ICP or affect cerebral autoregulation. They are suitable for treatment of hypertension in the patient with cerebral ischemia or increased ICP. However, bradycardia secondary to increased ICP is a relative contraindication.

Vasodilators (e.g., hydralazine, sodium nitroprusside, nitroglycerin) cause cerebral arterial dilation and venodilation and can theoretically increase ICP and cause a "cerebral steal" phenomenon in patients with cerebral ischemia. Other disadvantages of sodium nitroprusside are tachyphylaxis, the need for shielding from light because of its photosensitivity, and the danger of cyanide and thiocyanate toxicity, which may be difficult to detect in patients with brain injury. However, vasodilators may be used in patients with small and moderate-sized intracerebral hemorrhage and in those with subarachnoid hemorrhage if increased ICP is not a concern.

Calcium channel blockers have varying effects on cerebral autoregulation. Nifedipine can lead to severe reduction in BP and is not recommended. Nimodipine is used routinely in patients with subarachnoid hemorrhage because it has been shown to improve outcome, possibly because of a neuroprotective effect. Nicardipine has been used in patients with acute intracerebral hemorrhage without any change in CBF and is often used in patients with subarachnoid hemorrhage. Nicardipine is becoming popular in neurologic critical care units because of its efficacy, ease of titration, predictable response, and favorable cerebral hemodynamic effects.

The ACE inhibitors and the angiotensin receptor blocker (ARB) candesartan have been used in patients with cerebral ischemia and

Preferred Antihypertensives in Treatment of Stroke-Associated Hypertension				
Drug	**Mechanism of Action**	**Intravenous Dose**	**Advantages**	**Disadvantages**
Labetalol	α_1-, β_1-, and β_2-Receptor antagonist	Test dose 5 mg, then 20- to 80-mg bolus every 10 min up to 300 mg; IV infusion 0.5-2 mg/min	Does not lower CBF Does not increase ICP	May exacerbate bradycardia
Esmolol	β_1-Receptor antagonist	500-μg/kg bolus, then 50-300 mg/kg/min	Does not lower CBF Does not increase ICP	May exacerbate bradycardia
Sodium nitroprusside	Vasodilator	0.25-10 μg/kg/min	Potent antihypertensive	May increase ICP Can cause cerebral steal Potential for cyanide toxicity
Nitroglycerin	Vasodilator	5-100 μg/kg/min	Can be helpful for concomitant cardiac ischemia	May increase ICP Can cause cerebral steal
Hydralazine	Vasodilator	2.5- to 10-mg bolus	Can be given as IV bolus when labetalol is contraindicated due to bradycardia	May increase ICP Can cause cerebral steal
Nicardipine	L-type CCB	5-15 mg/h	Does not decrease CBF	May increase ICP Long duration of action
Enalaprilat	ACE inhibitor	0.625-1.25 mg every 6 hours	Does not decrease CBF	Variable response Long duration of action

Table 42-4 Preferred antihypertensive agents in the treatment of stroke-associated hypertension. *ACE,* Angiotensin-converting enzyme; *CBF,* cerebral blood flow; *CCB,* calcium channel blocker; *ICP,* intracranial pressure; *IV,* intravenous.

have no effect on CBF. However, short-acting parenteral forms of these drugs are not available. ACE inhibitors and ARBs shift the lower limit of cerebral autoregulation toward lower BP in rats and humans. However, these agents have a long half-life, which is not desirable in treatment of hypertension in the acute phase.

Similarly, because of its long half-life and sedative effect, the α_2-adrenergic agonist clonidine is not preferred.

The cerebrovascular effects of the newer parenteral antihypertensives, such as fenoldopam, a peripheral dopamine-1 receptor agonist, and the calcium channel blocker clevidipine, have not been extensively studied. However, in small studies, fenoldopam has been shown to decrease global CBF and increase ICP in patients with impaired intracranial compliance.[50] In a single-center study, clevidipine was found to be safe and effective in perioperative neurosurgical patients with hypertension.[51]

SECTION VII

Pregnancy and Renal Disease

CHAPTER 43

Renal Physiology in Normal Pregnancy

Chris Baylis and John M. Davison

There are profound changes in renal function in normal pregnancy that lead to marked alterations from the nonpregnant physiologic norm. An appreciation and understanding of these alterations are essential to recognize both normal and compromised pregnancies.

ANATOMY

In normal pregnancy, there is a progressive increase in renal bipolar diameter, maximally 1 to 2 cm by 26 weeks' gestation, and kidney volume enlarges by about 70% because of increments in both vascular and interstitial fluid compartments.[1] The most striking anatomic change is dilation of the calyces, renal pelvis, and ureter (more prominent on right side), and by the third trimester, about 80% of women show evidence of hydronephrosis[2] (Fig. 43-1). A consequence of the ureteral dilation is urinary stasis, which predisposes pregnant women with asymptomatic bacteriuria to development of symptomatic ascending infection (acute pyelonephritis). Rarely, the anatomic changes may be extreme and precipitate the overdistention syndrome, with massive dilation, recurrent severe flank pain, increasing serum creatinine, hypertension, or even reversible acute kidney injury.[3]

SYSTEMIC HEMODYNAMICS

There are significant alterations in systemic hemodynamics in normal pregnancy. A plasma (and extracellular fluid) volume expansion occurs while red blood cell volume also increases, leading to a large increase in blood volume that correlates with clinical outcome and birth weight. Interestingly, subsequent pregnancies tend to be more successful than the first, with larger babies and greater plasma volume increases. Women with twins and triplets have proportionately greater increments, and those with poorly growing fetuses, as in preeclampsia or with a history of poor reproductive performance, have correspondingly poor plasma volume responses. The increase in plasma volume (maximum increase ~1.25 liters) takes place progressively up to 32 to 34 weeks, after which there is little further change. The plasma volume expansion has a hemodilutional effect, causing decreases in hematocrit: the physiologic anemia of normal pregnancy.[4]

Cardiac output is significantly increased by the fifth gestational week, initially caused by a 10% to 20% increase in heart rate, with stroke volume increased by more than 20% the eighth week. Left atrial and left ventricular end-diastolic dimensions increase, suggesting an associated increase in venous return. Cardiac output increases of 40% to 50% are greatest by the 26th week, despite which systemic blood pressure (BP) substantially decreases in normal pregnancy (representative values are shown in Fig. 43-2 and Table 43-1).[5] The physiologic decrease in BP results from a profound reduction in systemic vascular resistance (SVR) of unknown cause (maximal at 26 weeks), although the loss of responsiveness to vasoconstrictor agents (e.g., angiotensin II, arginine vasopressin) certainly contributes.[6] Inhibition of angiogenic factors in preeclampsia causes vasoconstriction, suggesting that these factors, such as vascular endothelial growth factor (VEGF), may contribute importantly to normal gestational vasodilation through stimulation of endothelial nitric oxide and prostaglandins.[7] The combination of increased cardiac output and peripheral vasodilation means that organ blood flow increases in pregnancy, with the most dramatic changes occurring in the kidney and skin circulation throughout gestation and in the uterus in the second part of the pregnancy.[1] Left ventricular mass continues to increase up to 36 weeks, but thereafter, perhaps related to the increasing SVR toward term, systolic and diastolic cardiac function decrease, with increased ventricular wall stress, as evidenced by decrements in both myocardial contraction and relaxation capacity.[8]

In the third trimester, the enlarged uterus compresses surrounding tissues and can influence hemodynamic measurements, so that attention should be paid to maternal posture during hemodynamic monitoring. In the supine position, there is partial obstruction of the inferior vena cava and decreased venous return, reducing cardiac output and causing a decrease in BP, the supine hypotensive syndrome of pregnancy. It is important to be aware of these postural effects in measuring BP in late pregnancy.[1]

RENAL HEMODYNAMICS

There are striking changes in renal hemodynamics in normal pregnancy, with an increase in glomerular filtration rate (GFR) and consequent decrease in serum creatinine detectable very early.[1,9] The GFR increases about 25% by 4 weeks after the last menstrual period, and a robust early increase in GFR (see Fig. 43-2) is associated with a good obstetric outcome. Longitudinal studies in normal pregnant women show that GFR (measured by inulin or 24-hour creatinine clearance) increases by a maximum of about 50% by midpregnancy, which is maintained until the last few weeks of the pregnancy, when values begin to decrease, but remain above the nonpregnant level (Fig. 43-3).[10] These marked increases in GFR mean that serum creatinine decreases to 0.4 to 0.5 mg/dl (36 to 45 µmol/l),[11] and values considered normal for nonpregnant conditions, at 0.7 to 0.8 mg/dl (63 to 72 µmol/l), can be a cause for concern in normal pregnancy (see Table 43-1). In small women, however, whose total muscle mass may be quite low, significantly elevated serum creatinine levels may be absent, even in the presence of renal dysfunction. The increase in renal plasma flow (RPF) of about 60% is slightly more pronounced than the increase in GFR (see Fig. 43-2), so that the filtration fraction (FF) decreases (see later discussion). At the end of pregnancy, the RPF decreases proportionally more than the GFR, so that FF returns to the nonpregnant value.[10,12]

A similar pattern of renal hemodynamic change occurs during pregnancy in some animals, including the rat, in which GFR increases to a maximum of 30% to 40% above the "virgin" value by midterm,

Figure 43-1 Hydronephrosis in normal pregnancy. Intravenous urogram at 36 weeks' gestation. Note bilateral hydronephrosis, more marked on the right side.

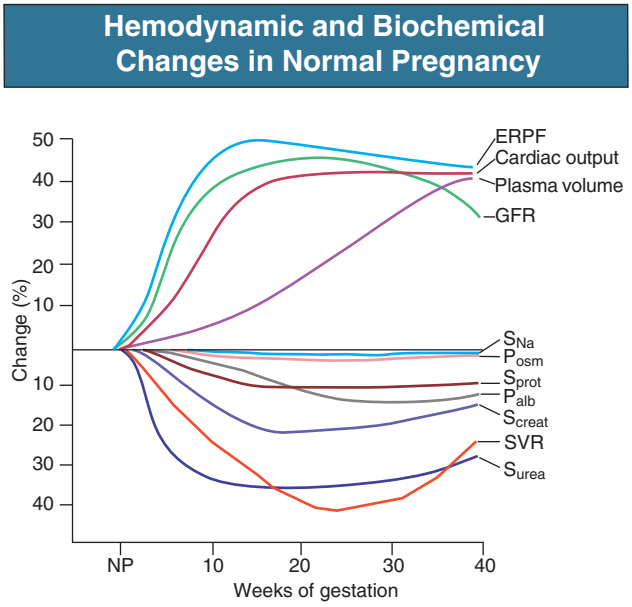

Figure 43-2 Hemodynamic alterations induced by normal pregnancy. Increments and decrements in hemodynamic and biochemical parameters shown as percentage of change from nonpregnant baseline. *ERPF,* Effective renal plasma flow; *GFR,* glomerular filtration rate; *S,* serum; *SVR,* systemic vascular resistance.

with a late return toward the nonpregnant value close to term (22 days). Glomerular micropuncture studies have shown that the increase in GFR is paralleled by increases in single-nephron GFR secondary to increased glomerular plasma flow.[13] Because the preglomerular and postglomerular resistance vessels dilate in parallel, glomerular plasma flow increases without a change in glomerular BP. As shown in Figure 43-4, the glomerular capillary blood pressure

There was uncomplicated spontaneous abortion in two women *(red and green lines)*. The *blue line* represents the mean, and the *yellow area* shows the range for nine women with successful obstetric outcome. *LMP,* Last menstrual period; *MP,* menstrual period. *(Modified from references 9, 10, and 19.)*

Changes in Some Common Indices During Pregnancy

	Nonpregnant	Pregnant
Hematocrit (%)	41	33
Serum protein (g/dl)	7.0	6.0
Plasma osmolality (mOsm/kg)	285	275
Serum sodium (mmol/l)	140	135
Serum creatinine (mg/dl, μmol/l)	0.8 (73)	0.5 (45)
Blood urea nitrogen (mg/dl)	12.7	9.3
Serum urea (mmol/l)	4.5	3.3
pH units	7.40	7.44
Arterial P_{CO_2} (mm Hg)	40	30
Serum bicarbonate (mmol/l)	25	20
Serum uric acid (mg/dl, μmol/l)	4.0 (240)	3.2 (190) early 4.3 (260) late
Systolic BP (mm Hg)	115	105
Diastolic BP (mm Hg)	70	60

Table 43-1 Changes in some common indices during pregnancy. *BP,* Blood pressure; P_{CO_2}, carbon dioxide partial pressure. *(Mean values compiled from references 9-11, 19, and 36.)*

(P_{GC}) remains unchanged throughout the pregnancy despite marked alterations in preglomerular vascular resistance. Similar conclusions have been reached by an indirect modeling approach in normal pregnant women measuring whole-kidney GFR, RPF, and serum protein concentrations; in addition, polydisperse neutral dextran was infused for determination of dextran sieving curves.[9,12] This approach allows (with certain reasonable assumptions) modeling of glomerular hemodynamics. In pregnant women, there is a decrease in serum protein concentration that contributes slightly to the increased GFR. As in the rat, the majority of the gestational increase in GFR in normal women is caused by increased RPF with no change in glomerular BP. The constancy of glomerular BP during sustained renal vasodilation has important implications for the long-term effects of pregnancy on renal function, as discussed later.

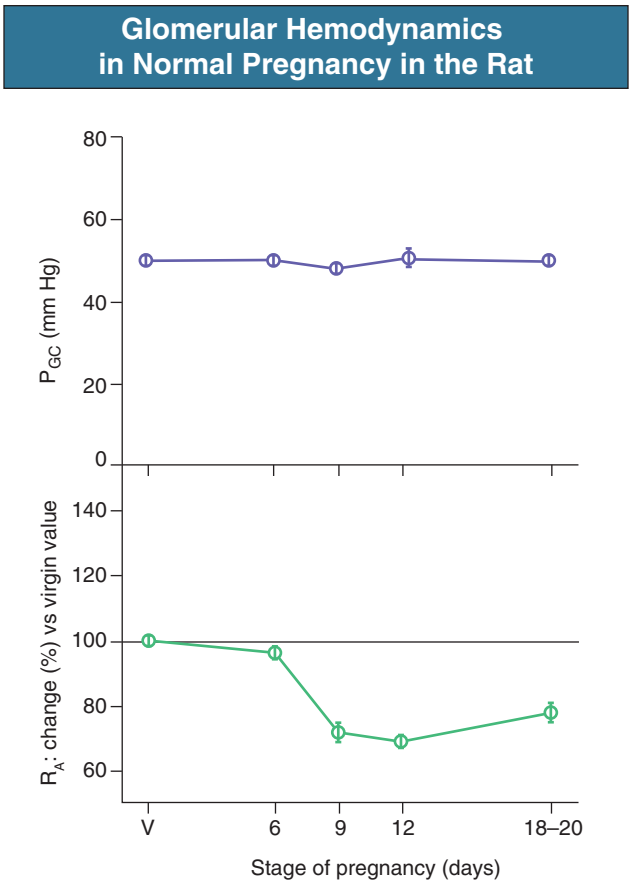

Figure 43-4 Glomerular hemodynamics in normal pregnancy in the rat. Summary of mean glomerular capillary blood pressure *(P_{GC}, upper panel)* and preglomerular arteriolar resistance *(R_A, lower panel)* in Munich Wistar rats in the virgin state (V) and throughout normal pregnancy.[13,14]

It is often assumed that a change in FF reflects a change in glomerular BP, but this is not always the case because FF is also determined by K_f, the product of water permeability of the glomerular wall and total glomerular capillary surface area.[10] Both glomerular wall water permeability and filtration pressure are very high, and thus filtration proceeds rapidly. In some situations, not all the available filtration surface area is used, so that filtration ceases (because the driving pressure is exhausted) before the end of the glomerulus. This state is known as *filtration pressure equilibrium.* When plasma flow increases during filtration pressure equilibrium, a proportional increase in GFR occurs with no change in FF. This is seen in the normal pregnant rat.[13] In contrast, FF decreases during normal pregnancy in women as RPF is increasing.[10] This most likely reflects that humans are closer than rats to filtration pressure disequilibrium, a situation in which the entire glomerular capillary surface area available for filtration is used, leaving a positive driving pressure at the end of the glomerulus. At filtration pressure disequilibrium, GFR becomes less dependent on plasma flow; thus an increase in plasma flow (with no change in other determinants of filtration) leads to a disproportionately smaller increase in GFR, with a decrease in FF.[14]

Despite the prolonged renal vasodilation, the renal vasculature remains fully responsive to various stimuli during pregnancy. For example, in the rat, the intrinsic renal autoregulatory ability remains intact,[15] although the myogenic response of the interlobular artery is blunted in normal rat pregnancy.[16] The tubuloglomerular feedback component of renal autoregulation is reset to recognize the elevated GFR as normal in the pregnant rat,[17] and a recent clinical study reports increased an increased renal artery resistive index during normal pregnancy, suggestive of maintained renal autoregulatory ability.[1] Both pregnant rats and women exhibit a marked additional renal vasodilation in response to amino acid infusion,[18,19] demonstrating substantial renal vasodilatory reserve in normal pregnancy. The cause of the gestational increase in GFR remains uncertain, although studies in the pseudopregnant rat have shown that the fetoplacental unit is not necessary,[20] indicating that a maternal stimulus must initiate the gestational renal hemodynamic changes.

A number of vasoactive factors have been evaluated as possible mediators of the renal vasodilation,[13] and although there are no clinical data, animal studies have implicated a role for nitric oxide (NO).[21-23] A novel splice variant of the neuronal NO synthase is induced in the kidney cortex of the pregnant rat, which parallels the increased renal plasma flow and GFR.[24] Increases in renal cortical antioxidant capacity may also contribute to enhanced renal NO levels in the normal pregnant rat.[25] Studies have suggested a key role for the ovarian hormone relaxin, which may signal increased renal NO production in pregnancy, possibly through an endothelin type B receptor mechanism.[26,27] The renal vasodilatory signal of pregnancy is remarkably robust because women with single kidneys (organ donors) and renal transplant recipients who have already undergone significant compensatory renal hypertrophy and vasodilation can produce further increases in RPF and GFR in pregnancy.[9,10] In the human, the signal is not solely relaxin as there is still a gestational increase in GFR, although blunted, in infertile women who lack corpus luteum function and who conceive from ovum donation and assisted conception techniques.[28]

Furthermore, although relaxin levels do increase steeply early in pregnancy (peaking at 6 weeks, declining thereafter to 36 weeks, but still much higher than pre-pregnancy),[1] there is no correlation between the levels and any hemodynamic parameter and no differences in levels between normal and preeclamptic pregnancies, despite substantial and persistent GFR abnormalities in the latter.[29] Also, although relaxin may be one important renal vasodilator in pregnancy, complementary factors and changes likely permit concomitant GFR increments because to attain levels akin to early pregnancy, women infused with recombinant human relaxin significantly augment RPF but not GFR.[30]

Glomerular hypertension associated with renal vasodilation is considered a primary pathogenic stimulus to progressive renal injury in chronic kidney disease.[31] As discussed, normal pregnancy is also a state of chronic renal vasodilation; however, glomerular BP remains normal. This may account for the findings that repetitive pregnancies in women and rats with normal renal function have no long-term adverse effects on glomerular function or structure.[32] Pregnancy will increase the rate of loss of renal function in some women with underlying renal disease (see Chapter 45), but evidence suggests that this is not by a hemodynamically mediated action.[9,32]

Formulas that use serum creatinine in relation to age, height, and weight to calculate GFR (e.g., Cockcroft-Gault formula) should not be used in pregnancy because body weight or size does not reflect kidney size. The use of estimated GFR (eGFR) from the Modification of Diet in Renal Disease (MDRD) study equation, or the refined Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) formula, which adjusts serum creatinine for age, gender, and race, cannot be recommended in pregnancy, because both significantly underestimate true GFR measured by inulin clearance.[33,34] Similarly, cystatin C is not a useful marker for GFR changes in pregnancy because it also does not correlate with inulin clearance.[35] This unexpected lack of correlation in pregnancy between cystatin C and GFR may be explained by evidence that the placenta may release cystatin C in response to placental ischemia.

Abnormal Renal Hemodynamics

A woman may lose up to 50% of her renal function and still maintain serum creatinine concentration below 1.5 mg/dl (130 µmol/l) because of hyperfiltration in remaining nephrons. If there is more severe compromise, however, further glomerular damage will cause serum creatinine to increase.[9,33,36] Pregnancy in the presence of impaired renal function can have a marked adverse effect on obstetric outcome, as well as increased risk of an accelerated decline in renal function, as previously mentioned[37] (see Chapter 45).

In preeclampsia, both RPF and GFR decrease, although absolute values may remain above the nonpregnant range. A decrease in ultrafiltration coefficient (K_f) of about 50% in combination with reduced RPF is the most likely mechanism for the hypofiltration.[36,38] The endothelium is targeted at an early stage in preeclampsia, and the glomerulus is not spared. The vascular endothelial cell dysfunction (glomerular endotheliosis) results in swollen bloodless glomeruli, associated with glomerular filtration barrier damage, This may involve loss of both glomerular size and charge selectivities, although the exact role of the endothelium and its surface glycocalyx coat is not well defined (see Chapter 44). Most consider glomerular endotheliosis to be merely "characteristic," not pathognomonic, of preeclampsia, although one study reports this lesion in healthy controls.[39] This study has been challenged both regarding concerns about qualitative histologic grading as well as ethical issues.[40]

RENAL TUBULAR FUNCTION IN PREGNANCY

Enormous plasma volume expansion occurs in normal pregnancy, with resultant small decrements in plasma concentration of many solutes (see Fig. 43-2). Nevertheless, the large increase in GFR means that the filtered load of most plasma constituents will increase during pregnancy.[9,10] Increments in excretion are seen for some substances, but this is limited by increases in tubular reabsorption, preventing depletion. Intake also often increases, with net retention leading to positive balance for many of the key constituents. The renal handling of a number of solutes is altered in normal pregnancy.

Uric Acid

Uric acid, an end point of purine metabolism, is freely filtered at the glomerulus and extensively reabsorbed in the proximal tubule, with further downstream reabsorption and possibly some active secretion, such that only about 10% of filtered load is excreted. Serum uric acid concentration decreases during early pregnancy by about 25% (see Table 43-1), which may reflect a decrease in net tubular reabsorption.[10] As the pregnancy advances, fractional excretion of uric acid decreases, leading to an increasing serum uric acid concentration, attaining levels close to the nonpregnant mean. Serum uric acid concentrations are significantly higher in preeclamptic pregnancy, and above a critical level of 6 mg/dl (350 µmol/l), perinatal mortality increases in hypertensive patients (see Chapter 44). However, physiologic variability is such that some healthy women have high serum uric acid levels without problems, so that uric acid values must be interpreted in the clinical context.

Glucose

Excretion of glucose increases soon after conception to approximately 10 times the nonpregnant value and remains high throughout pregnancy, although glycosuria is variable.[10] The glycosuria is not related to changes in serum glucose concentration and reflects decreased tubular reabsorption. In the nonpregnant state, there is usually complete renal reabsorption of glucose, mostly in the proximal tubule, where high capacity exists for glucose transport. This maximum transport capacity (T_{max}) is not usually reached until serum glucose increases to values in excess of about 200 mg/dl (11 mmol/l). The glycosuria of pregnancy is caused by a decrease in T_{max} and the inability of the renal tubules to cope with the increased filtered glucose load, and does not reflect a metabolic disturbance.

Water-Soluble Vitamins and Amino Acids

Nicotinic acid, ascorbic acid, and folic acid are all excreted in increased amounts during pregnancy,[9] which emphasizes the need for adequate vitamin supplementation.

Urinary excretion of most amino acids increases in pregnancy, probably as a result of decreased tubular reabsorption.[41] There are distinct patterns. Glycine, histidine, threonine, serine, and alanine excretion increases early, and values remain elevated throughout pregnancy. Excretion of lysine, cystine, taurine, phenylalanine, valine, leucine, and tyrosine also increases in early pregnancy but later declines. Glutamic acid, methionine, and ornithine are excreted in slightly greater amounts than before pregnancy, isoleucine excretion is unchanged, and arginine excretion decreases.

Acid-Base Balance

The generation of hydrogen ions (H^+) increases in pregnancy because of an increased basal metabolism and greater food intake, but despite this, the blood H^+ concentration decreases; thus plasma pH increases slightly (see Table 43-1). This mild alkalemia is respiratory in origin because pregnant women normally hyperventilate, leading to a primary decrease in arterial carbon dioxide tension ($Paco_2$) and secondary compensatory decreases in serum bicarbonate concentration. A mild chronic respiratory alkalosis is a feature of normal pregnancy.

Potassium

Potassium excretion decreases, and a slow cumulative net potassium retention in pregnancy is distributed between the enlarging maternal tissues and the developing fetus. The decrease in potassium excretion occurs despite the mild alkalosis and high aldosterone values of normal pregnancy and is at least partly caused by the potent antimineralocorticoid action of progesterone[42] (see later discussion).

Calcium

Calcium excretion increases two to three times during pregnancy because of the increased filtered load and despite some increase in tubular reabsorption. This could predispose to the formation of calcium stones, but increased magnesium and citrate, acidic glycoproteins, and nephrocalcin serve to inhibit calcium oxalate stone formation so that the incidence of stone formation is not increased in normal pregnancy.[43]

Protein

Some proposed that increased urinary total protein excretion in pregnancy should not be considered abnormal until it exceeds 500 mg in 24 hours,[9,10,19,22] although many classifications and definitions of the hypertensive disorders of pregnancy still define more than 300 mg/24 h as abnormal.[44] A small increment in albumin excretion usually occurs during the third trimester, which with total

protein excretion may continue into the puerperium, with nonpregnant levels not restored until 5 to 6 months after delivery.[45] The gestational changes may be related to alterations in glomerular size and charge selectivity as well as in proximal tubular function, plus the possibility of the appearance of other proteinaceous material in the urine of pregnant women.[36,38,45] In clinical practice, urine protein above 300 mg/24 h roughly correlates with 30 mg/dl in a random urine sample, but given the problems with dipstick tests, many still prefer a 24-hour or some timed quantitative determination. Use of a random urine protein-creatinine (PC) ratio, however, is a clinically useful alternative, with a threshold value of 30 mg/mmol creatinine (0.3 mg/mg) a reasonable cutoff for defining significant proteinuria.[10,44-46] In preeclampsia, urinary shedding of podocytes (podocyturia), cells with a limited regenerative capacity, may precede and accompany proteinuria, as part of the disruption of the glomerular filtration barrier.[47] Evaluation of proteinuria in pregnancy is discussed further in Chapter 44.

Sodium

A massive, cumulative volume expansion occurs during pregnancy with an associated gradual retention of sodium of about 900 mmol, distributed between the products of conception and the maternal extracellular space. This positive sodium balance develops despite about a 30% increase in filtered load and reflects an increase in tubular reabsorption that allows net additional sodium retention of about 2 to 3 mmol/day.[4] Nevertheless, it is normal for sodium excretion to increase in pregnancy, reflecting the marked increase in sodium intake. Lithium clearance studies in women have indicated enhanced sodium reabsorption in the proximal tubule and distal nephron segments in late pregnancy, whereas animal studies have been contradictory.[48] The reason for the net renal sodium retention in pregnancy is not known. As shown in Table 43-2, there are many factors operating both to increase and to decrease sodium excretion, and exactly how the normal balance of net retention is achieved remains a mystery.

Several antinatriuretic systems are activated in normal pregnancy.[49] Renin, angiotensin, and aldosterone levels are all greatly increased, and the renin-angiotensin-aldosterone system (RAAS) can be appropriately regulated around these new set points when changes occur in extracellular fluid volume. In addition to stimulating aldosterone release, physiologic levels of angiotensin II (Ang II) act directly on the proximal tubule to increase sodium reabsorption. However, a marked refractoriness develops to the vascular actions of Ang II in normal pregnancy,[49] which may blunt Ang II–dependent net sodium retention. The high aldosterone levels of pregnancy will certainly promote renal sodium retention in the distal tubule and collecting duct. Indeed, an increase occurs in the abundance of the regulatory, α subunit of the epithelial sodium channel (ENaC) as well as ENaC activity, which is controlled by aldosterone.[50] The very high levels of deoxycorticosterone (from 21-hydroxylation of progesterone) may also exert mineralocorticoid actions to promote sodium retention.[51] Estrogens increase greatly during human pregnancy and may directly induce renal sodium retention or act indirectly by enhancing the conversion of progesterone to deoxycorticosterone.[51] In addition to hormonal factors, the increased ureteral pressure and the decrease in systemic BP both decrease sodium excretion.[52]

The concentrations of several natriuretic agents also increase in pregnancy. Progesterone increases by 10 to 100 times, and these levels exert a marked anti-mineralocorticoid action by competing with aldosterone for the mineralocorticoid receptor.[51] Plasma atrial natriuretic peptide (ANP) levels are also moderately elevated,[53] as is NO.[23] In addition to natriuretic factors, the large increase in GFR leads to increased filtration of sodium (despite the small decrease in serum sodium concentration), which will also increase sodium excretion. Decreases in serum albumin concentration and the increment in effective renal plasma flow during pregnancy will also enhance sodium excretion by inhibiting sodium reabsorption.[12] Animal studies have suggested that there is a generalized loss in pregnancy of natriuretic responsiveness to cyclic guanosine monophosphate (cGMP)–dependent signals,[23] resulting from increased inner medullary phosphodiesterase-5 activity.

Despite the many conflicting stimuli, net sodium retention and marked plasma volume expansion are normal in pregnancy. In the normal nonpregnant steady state, plasma volume expansion and renal sodium retention cannot coexist. However, pregnancy is not a steady state, and the volume sensing and regulatory systems are dramatically readjusted throughout pregnancy to accommodate and to maintain the volume expansion (see later discussion).

Factors Influencing Sodium Excretion During Pregnancy

Antinatriuretic	Natriuretic
Aldosterone	↑ Glomerular filtration rate
Angiotensin II	Progesterone
Estrogen	Atrial natriuretic peptide
Deoxycorticosterone	Nitric oxide
Supine posture	Prostaglandins
Upright posture	
Decreased blood pressure	
Increased ureteral pressure	
Placental shunting	

Table 43-2 Antinatriuretic and natriuretic factors influencing sodium excretion during pregnancy.

OSMOREGULATION

Early in pregnancy, plasma osmolality (P_{osm}) decreases by about 10 mOsm/kg below the nonpregnant norm because of a reduction in serum sodium and associated anions (see Table 43-1). Whereas a decrease in P_{osm} of this magnitude would completely suppress release of the antidiuretic hormone arginine vasopressin (AVP) in nonpregnant women, in pregnancy the osmotic thresholds for AVP release as well as for thirst are reduced to recognize the reduced plasma osmolality as normal.[54] Figure 43-5 demonstrates the resetting of the relationship between plasma AVP and P_{osm} during normal pregnancy. The placental hormone human chorionic gonadotropin (which stimulates the release of ovarian relaxin)[55] may have a role in this reduction in the osmotic threshold for AVP release.[54] Plasma volume status is a separate, nonosmotic determinant of AVP release, and this system is also reset to recognize the massively expanded plasma volume as normal. The metabolic clearance rate of AVP has increased four times by midpregnancy because of the release of cystine aminopeptidase (vasopressinase) from the placenta,[54] so the rate of AVP production must also be accelerated. Despite these marked alterations, the urinary concentrating and diluting capacity remain good, although there is a slight reduction in the maximum urine concentration in the second part of pregnancy.[54]

VOLUME REGULATION

As discussed previously, continual sodium retention and cumulative volume expansion in pregnancy reflect complex readjustments of the

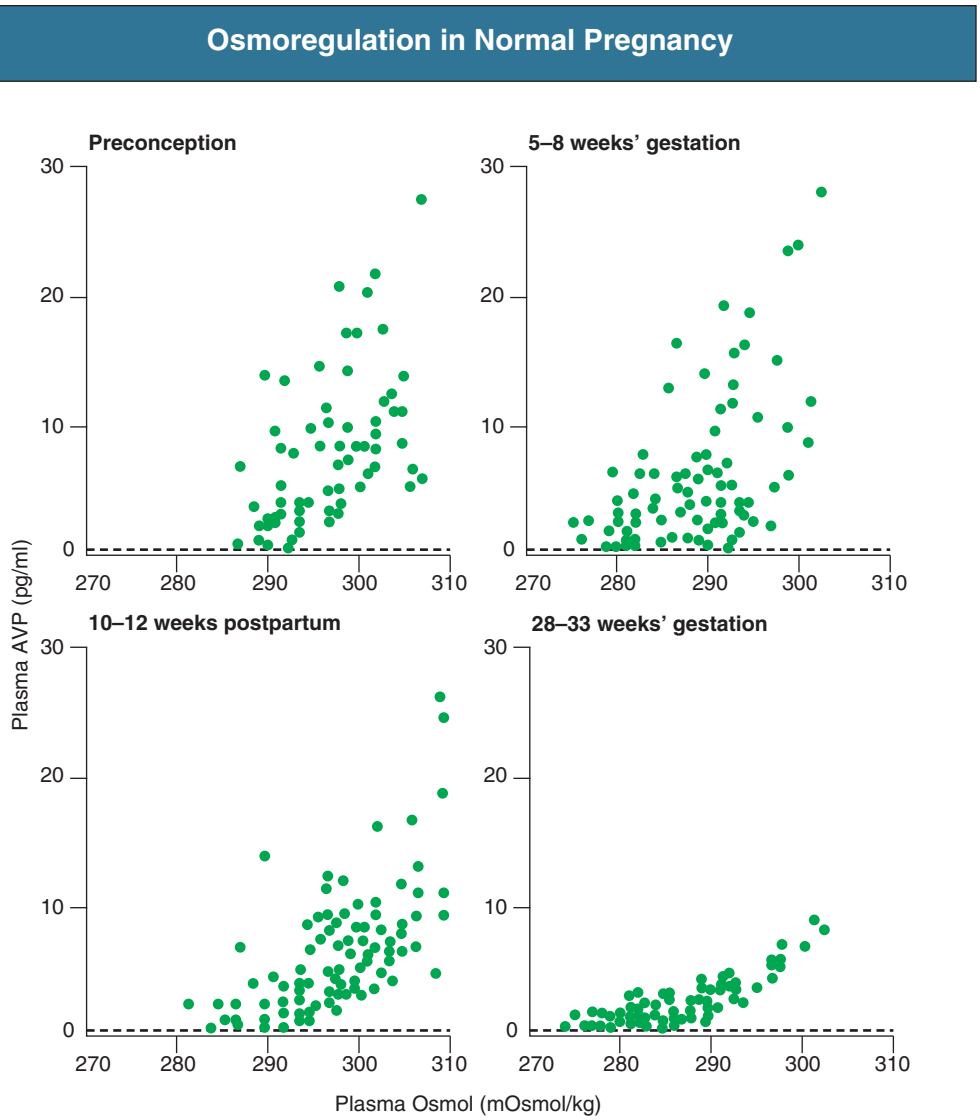

Figure 43-5 Osmoregulation in normal pregnancy. Relationship between plasma arginine vasopressin concentration *(AVP)* and plasma osmolarity *(Osmol)* during several 5% saline infusions in eight women before and during pregnancy. Each point represents an individual plasma measurement. There is a marked decrease in osmotic threshold for AVP release during pregnancy. Values for the osmotic threshold for thirst (not shown) were always 2 to 5 mOsmol/kg above AVP release thresholds and 10 mOsmol/kg lower in pregnancy.[9,54]

various volume regulatory systems. These readjustments also permit volume expansion without increases in blood pressure; in fact, BP decreases substantially as pregnancy proceeds (see Table 43-1).

What happens to volume perception and regulatory systems in pregnancy can be considered in terms of the effective circulating volume.[56,57] The RAAS is an antinatriuretic system activated by volume depletion, and the increase in plasma renin activity and angiotensin and aldosterone concentrations of normal pregnancy suggests an *underfill* signal, despite the absolute increase in plasma volume. The primary event in pregnancy may be *peripheral vasodilation* that generates an underfill signal and leads to renal sodium retention.[56] In contrast to the RAAS, both osmotic and nonosmotic control of AVP release is reset in a manner indicating that the expanded volume of pregnancy is sensed as normal.[54] The tubuloglomerular feedback system is suppressed by volume expansion in the nonpregnant state but is reset in pregnant rats to recognize the expanded volume and increased GFR as normal.[17] Plasma ANP increases slightly in late pregnancy, but this is unlikely to reflect a physiologic response to volume expansion, because even greater increases in ANP are seen in volume-contracted, preeclamptic pregnancies.[53] Whatever the stimulus, increased ANP and intrarenal NO are predicted to exert powerful, cGMP-dependent natriuretic influences, which the increased medullary phosphodiesterase-5 activity of pregnancy will antagonize. In support of the underfill hypothesis, chronic vasodilation of nonpregnant female rats also activates medullary phosphodiesterase-5 and causes renal sodium retention and plasma volume expansion.[58] However, volume regulation in pregnancy remains an enigma.

IMPACT OF MATERNAL HEMODYNAMIC CHANGES ON FETAL PROGRAMMING

Strong evidence indicates that women with normal pregnancy who have suboptimal increases in plasma volume are more likely to deliver babies small for gestational age. Fetal growth restriction and preterm delivery pose serious neonatal risks[59] and are often seen in preeclamptic pregnancies, in which there is usually volume

contraction.[60] Reduction in uterine blood flow, as occurs in preeclampsia or when volume expansion is inadequate, and maternal (and thus fetal) malnutrition have been implicated in the pathogenesis of fetal growth restriction. Considerable epidemiologic as well as animal evidence suggests that adverse events *in utero* leading to fetal growth restriction and preterm delivery[61] can program the offspring for increased risk in adult life for the development of hypertension, other cardiovascular events, diabetes, hypercholesterolemia, and chronic kidney disease, the last at least partly caused by reduction in nephron number.[62,63] Thus, optimal maternal systemic and renal hemodynamic changes have a huge impact not only on fetal well-being but also on the long-term health of the offspring.

CHAPTER 44

Renal Complications in Normal Pregnancy

Annabel C. Martin and Mark A. Brown

Most women have normal pregnancies. The most common renal problem that arises in pregnancy in an otherwise well woman is urinary tract infection (UTI). Also, by far the most common *de novo* "renal disease" in the second half of pregnancy is preeclampsia, usually presenting with hypertension and proteinuria. Fortunately, acute kidney injury in pregnancy is rare in developed countries, but still carries a poor prognosis for this young age group.

URINALYSIS AND MICROSCOPY

Many young women have their first urinalysis and urine microscopy performed during pregnancy, leading to the detection of hematuria, proteinuria, and pyuria, either related to or coincidental to the pregnancy.

Hematuria

Definition and Epidemiology

Microscopic hematuria is detected at some time during pregnancy in about 20% of women.[1] Clinically significant *microhematuria* is defined as three or more red blood cells (RBCs) per high-power field on microscopic evaluation of urinary sediment from two of three properly collected (clean-catch, midstream) urine specimens,[2] or as greater than 2500 RBCs/ml.[3] Microhematuria disappears in about 75% of women after delivery, but secondary to glomerulonephritis, it persists throughout the pregnancy, and can be further investigated postpartum.

Etiology and Outcome

Dysmorphic microhematuria (defined by phase contrast microscopy) during pregnancy is most frequently caused by glomerulonephritis but is occasionally associated with preeclampsia. *Isomorphic* hematuria is more likely to be caused by bladder infection or bladder compression by the fetal head. Pregnant women with microhematuria showed no significant difference in gestational age at delivery, birth weight, gestational hypertension, or preeclampsia compared with controls.[4]

Macrohematuria (gross hematuria) in pregnancy is most often the result of vaginal bleeding or hemorrhagic bacterial cystitis. Other, less common causes include renal calculi, renal arteriovenous malformations, polycystic kidneys, and rarely, bladder or kidney neoplasms.

Differential Diagnosis

When microhematuria is found in the pregnant patient, a urine culture is required to exclude infection. If there is no proteinuria, and blood pressure (BP) and serum creatinine are normal, further investigations can be delayed until postpartum review, usually about 3 months, when microscopy to determine RBC morphology, antinuclear antibody testing, and renal ultrasound can be performed.

When significant numbers of dysmorphic urinary RBCs are present during pregnancy and BP is normal, the most likely cause is glomerular disease, either thin basement membrane nephropathy or IgA nephropathy. If microhematuria is associated with renal angle pain or renal colic, ultrasound will exclude the presence of stone in only two thirds of pregnant women with calculi and may demonstrate other abnormalities such as polycystic kidneys and in rare cases neoplasms. For persistent isomorphic microhematuria, we do not recommend cystoscopy during pregnancy. This often disappears spontaneously after pregnancy, and the likelihood of uroepithelial tumors is very low in this age group.

Treatment

For the pregnant patient with microhematuria, the treatment of associated UTI and calculi is discussed later. There is no specific treatment for glomerulonephritis during the pregnancy, provided renal function is normal and nephrotic syndrome is absent.

Proteinuria

The development of proteinuria during pregnancy warrants investigation and will most often be associated with preeclampsia. A condition known as *gestational proteinuria* may also develop, which has no adverse effects for fetus or mother.

Definition

Normal pregnancy is associated with an increase in protein excretion compared with the nonpregnant state. Some studies suggest this results from a combination of increased glomerular filtration rate and increased permeability of the glomerular basement membrane in normal pregnancy.[5] Others have found 24-hour urinary albumin excretion similar in nonpregnant and normal pregnant women, with more than 20 mg/day considered abnormal; in such patients, increased total proteinuria must be caused by tubular proteinuria.

In contrast to abnormal total protein excretion defined as greater than 150 mg daily in nonpregnant women, proteinuria in pregnancy is generally defined as the excretion of more than 300 mg of total protein per 24 hours. However, more than 95% of pregnant women excrete less than 200 mg/day.[6]

Proteinuria is most frequently detected in pregnancy by dipstick urinalysis, but this method is notoriously unreliable, with a significant proportion of false-positive and false-negative results. Dipstick is generally reliable for confirming either the absence of proteinuria or the presence of true proteinuria, when dipstick readings are 3+ (>3 g/L) or 4+ (>20 g/L). At intermediate levels, false-positive rates are as high as 50%. Detection may be improved using an automated urinalysis device, thereby reducing observer error.[7]

The 24-hour urine collection remains the gold standard for quantitation but is often impractical when a quick assessment of proteinuria is required, as in preeclampsia. A reliable alternative is the protein-creatinine ratio; a ratio greater than 30 mg protein/mmol

creatinine (~0.3 mg/mg) correlates reasonably well with protein excretion of more than 300 mg/24 h.[8]

Although use of the albumin-creatinine ratio may gain a greater role in pregnancy in the future, clinicians currently should continue to use the protein-creatinine ratio until further data are available.[9]

Differential Diagnosis

Proteinuria arising *de novo* in pregnancy should be quantitated and further investigated according to the clinical situation. The course of pregnancy in women with proteinuria present before pregnancy is discussed in Chapter 45.

Persistent proteinuria associated with preeclampsia usually arises in the second half of pregnancy, and generally but not always after the development of hypertension. Occasionally, proteinuria predates all other signs of preeclampsia. The severity of the proteinuria is not indicative of the severity of preeclampsia and should not be used to guide management. Furthermore, proteinuria may be absent in 10% of women with clinical and histologic manifestations of preeclampsia.[10] In the absence of UTI or preeclampsia, isolated proteinuria in an otherwise asymptomatic pregnant woman usually reflects new-onset renal disease such as a primary glomerulonephritis. Alternatively, proteinuria may appear because pregnancy has unmasked renal disease secondary to systemic disorders, such as diabetes mellitus, systemic lupus erythematosus, or essential hypertension. In addition, superimposed preeclampsia occurs in 20% to 25% of women with chronic hypertension.[11] In these patients, it often occurs earlier in gestation and may be severe.

We limit investigation of *de novo* non-preeclamptic, non-nephrotic proteinuria during pregnancy to a renal ultrasound and the measurement of serum creatinine, electrolytes, albumin, and antinuclear antibodies. Renal biopsy is not indicated. When underlying renal disease has been unmasked by pregnancy, appropriate investigations can usually be delayed until the postpartum period. The exceptions to this are women with nephrotic syndrome or renal impairment in whom fetal viability is not yet ensured and whose pregnancy needs to be continued (i.e., <24 weeks' gestation). In these patients, full investigation should be undertaken quickly, usually including renal biopsy, to determine whether specific treatment (e.g., corticosteroids) may be of benefit.

Natural History

Proteinuria occurring as a complication of preeclampsia invariably resolves in the postpartum period, although this may take several months. Proteinuria in women with gestational proteinuria, an entity that describes new-onset proteinuria without features of preeclampsia but with intermediate changes in angiogenic factors (see later), also resolves postpartum. Tradition holds that in both cases, proteinuria disappears within 3 months postpartum, but that many cases take longer.[12] In the absence of renal function or impaired function, we do not investigate non-nephrotic proteinuria until it persists after 12 months postpartum.

Treatment

For women with nephrotic syndrome, an inverse correlation exists between serum albumin and birth weight, although no studies have examined whether reduced fetal growth can be reversed by reducing proteinuria. Antiproteinuric therapy with angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are contraindicated in pregnancy because of their unwanted effects on the fetus.

Intravenous (IV) albumin has little role in managing nephrotic syndrome during pregnancy unless there is progressive deterioration in renal function. We recommend IV albumin infusion when serum creatinine rises above 100 µmol/l (1.2 mg/dl) with no other explanation, acknowledging that this may only provide a temporary benefit to allow the pregnancy to be prolonged. Diuretics and sodium restriction should be avoided unless the woman has severe, intractable edema; the concern is that diuretics will lead to a further reduction in plasma volume and reduced uteroplacental perfusion. The pregnant woman with nephrotic syndrome is at high risk of venous thromboembolism and should receive prophylactic heparin during pregnancy and until the nephrotic syndrome has resolved postpartum.

Pyuria

Isolated pyuria, in the absence of UTI, is common in normal pregnancy, usually from contamination by vaginal secretions. There is also an increased white blood cell excretion rate in normal pregnancy. It requires no further follow-up other than ensuring it disappears, usually by 3 months postpartum.

URINARY TRACT INFECTION

Definitions

In *asymptomatic bacteriuria* (ASB), the urinary tract is colonized by a single species of bacteria in the absence of specific symptoms. Outside of pregnancy, ASB usually should not be treated with antibiotics. However, ASB can lead to serious complications in pregnancy, and there is a cost benefit from its screening and treatment.[13] Although the gold standard for diagnosis is detection of more than 10^5 organisms per milliliter, without epithelial cells, in a midstream urine specimen on two or more occasions, or from a single suprapubic aspiration,[14] in practice such bacteriuria is usually detected by a single routine bacterial culture early in pregnancy. As many as 1% to 2% of pregnancies are complicated by *acute bacterial cystitis*, defined as an acute bacterial UTI accompanied by symptoms such as frequency, dysuria, or strangury. Although more than 10^5 organisms/ml defines ASB, as few as10^2 organisms/ml is sufficient to diagnose cystitis if accompanied by pyuria and characteristic symptoms.[15] In *acute pyelonephritis* there is UTI, generally with more than 10^5 organisms/ml, in association with parenchymal renal infection, usually diagnosed clinically by fever and loin pain and sometimes features of systemic sepsis.

Epidemiology

Asymptomatic bacteriuria affects 2% to 10% of all pregnant women. The prevalence is higher in women from lower socioeconomic groups and increases with age, parity, coexistent genital tract infection, and sickle cell trait. ASB is also more common in women with urinary tract abnormalities such as reflux nephropathy and neurogenic bladder, in diabetic patients, and in women with several previous UTIs. The highest risk of infection is thought to be from the 9th to the 17th week of gestation, although this may simply reflect the stage at which routine screening usually takes place.

The overall incidence of acute pyelonephritis in pregnancy is approximately 1%, but it may occur in up to 30% among women with ASB. It is thought that about 70% of women who develop acute pyelonephritis have preceding covert bacteriuria, but this is difficult to prove. With treatment of ASB, it has been estimated that the incidence of pyelonephritis would be reduced by more than 80%.[15] When possible, urethral catheters should be avoided, even in women having cesarean section, because the incidence of UTI in these women is twice that of those not catheterized.

Organisms Typically Causing Urinary Tract Infection in Pregnancy

- *Escherichia coli* (>70% of infections)
- *Klebsiella* spp.
- *Proteus* spp. (particularly in diabetic women or urinary tract obstruction)
- Enterococci
- Staphylococci, especially *Staphylococcus saprophyticus*
- *Pseudomonas*

Box 44-1 Organisms most often responsible for UTI in pregnant women.

Pathogenesis

Certain host characteristics may increase the risk for UTI or pyelonephritis (see Chapter 53). Women, such as those who do not express the antibody to the O antigen of *Escherichia coli*, may have ASB that predates pregnancy (i.e., are chronically colonized). Pregnancy is a state of relative urinary tract stasis; the calyces, pelves, and ureters dilate, particularly on the right, and this contributes to ASB developing into ascending acute pyelonephritis in pregnant women.

The most common mechanism of infection is through the urethra from perineal bacteria. Box 44-1 lists common organisms causing UTI in pregnancy. Some strains of *E. coli* are particularly virulent and are associated with both ASB and pyelonephritis. They possess P fimbriae, which enable the bacteria to attach themselves to the uroepithelial cells with pili, allowing them to ascend the urinary tract from the perineum.

Clinical Manifestations

Asymptomatic Bacteruria

A meta-analysis indicated that untreated ASB during pregnancy significantly increases rates of low birth weight (LBW) and preterm delivery.[16] However, it is still unclear whether ASB is an independent risk factor for LBW or whether its association with low socioeconomic status is the predictor for LBW. The mechanism by which UTI may cause premature labor is not yet fully understood, but proinflammatory cytokines secreted in response to bacterial endotoxins likely initiate labor in these patients.

Most maternity units operate a policy of screening all pregnant women on at least one occasion, whether by dipstick urinalysis for leukocytes/nitrites or by direct urine culture. Both dipstick and urine culture appear cost-effective compared with no screening when the prevalence of ASB is 2% to 6%. As stated, isolated pyuria on dipstick testing is very common in normal pregnancy, and we recommend screening by primary urine culture rather than the dipstick method.

Women who have threatened premature labor should have further urine cultures even without symptoms suggestive of UTI.

Pyelonephritis

Pyelonephritis most often presents between 20 and 28 weeks of gestation with malaise, fever, loin pain, and rigors. Not all women will have had lower urinary tract symptoms, and pyelonephritis can also manifest in pregnancy as acute abdominal pain, or may be detected only after presentation with premature labor. Pyelonephritis is more common in pregnant women with urologic abnormalities or diabetes and more often affects the right kidney, probably because the ureter is generally more dilated on that side.

The diagnosis of pyelonephritis is usually made on clinical grounds. Definitive diagnosis requires positive urine culture, but this may take about 2 days, and treatment should not be delayed. *E. coli* is the most common infecting organism (>85% of cultures).

Bacteremia is a common and usually transient complication of pyelonephritis. Occasionally, however, women become septicemic and may develop endotoxemia with shock, with sequelae including respiratory failure, disseminated intravascular coagulation, and acute kidney injury. Pyonephrosis and perinephric abscess are rare complications but should be suspected when treatment fails.

Without treatment, the complications of acute pyelonephritis during pregnancy can be severe, probably more so than in nonpregnant women. In the preantibiotic era, maternal mortality was 3% to 4%. Currently, death from pyelonephritis is rare in developed countries but still occurs.

Treatment

Asymptomatic Bacteruria

Antibiotic treatment of ASB significantly reduces the incidence of pyelonephritis in pregnancy. A systematic review also suggests treatment results in a significant reduction in the risk of preterm delivery.[18]

In choosing treatment, the clinician must consider the safety of the antibiotic in pregnancy. In most women, treatment with cephalexin, amoxicillin–clavulanic acid, or nitrofurantoin is first-line therapy. Overall, trials demonstrate that longer duration of treatment is likely to be more effective than single-dose therapy, although data are limited.[18] Until evidence from new trials is available, a 4- to 7-day treatment regimen is recommended, although some authorities allow for a 3-day rather than 7-day course of antibiotics.[17]

Without treatment, ASB will persist in 80% of women, and even with treatment, 20% will still have ASB. Those with persistent colonization are difficult to treat, with eradication achieved in only 40% after a second course of antibiotics. Where eradication is not achieved, we recommend prophylactic antibiotics, usually cephalexin (250 mg at night), throughout pregnancy to prevent pyelonephritis and its consequences; however, no studies specifically address this situation. The incidence of pyelonephritis after effective treatment of ASB is reduced from about 30% to 3%, comparing favorably with a 1% prevalence of pyelonephritis for the overall pregnant population.

Cystitis

Treatment of cystitis at the first presentation should be for 5 days with an appropriate antibiotic. As for ASB, it is important to obtain a follow-up urine culture to be certain infection has been eradicated.

Pyelonephritis

It is usual practice to admit pregnant women with pyelonephritis to the hospital, although a trial has reported successful outpatient management for milder cases.[18] Treatment may occasionally require resuscitation with IV fluids, but usually a short course of IV antibiotics followed by oral antibiotics, once the woman is afebrile, is adequate therapy.

It is desirable to choose an antibiotic that produces a high blood level that will concentrate in the renal parenchyma, usually a cephalosporin as first-line treatment. An aminoglycoside is a useful adjunct in more severe cases, used for 24 to 48 hours while awaiting urine cultures, provided maternal renal function is satisfactory. The risk of irreversible fetal ototoxicity precludes prolonged use, and aminoglycosides are not recommended in the first trimester. The full

duration of treatment is generally at least 2 weeks, and it is imperative to repeat urine culture 1 week after treatment to ensure eradication.

Renal ultrasound is generally not indicated during an initial infection, because urinary tract dilation is still likely to be present, and it is impossible to distinguish this from significant urinary tract obstruction. However, if infection persists, ultrasound is indicated to help exclude pyonephrosis, perinephric abscess, and renal calculi. If pyelonephritis persists despite adequate antibiotic therapy and urinary tract dilation is confirmed, percutaneous nephrostomy should be performed under ultrasound guidance. In our experience, this is rarely necessary and should be a last resort in management of these cases, but nephrostomy is the only way to be certain urinary tract obstruction and pyonephrosis have been properly treated.

Clinicians also should remain alert for premature labor in the presence of pyelonephritis and institute appropriate treatment while aggressively treating the infection. When more than two UTIs have occurred in pregnancy, prophylaxis is indicated until delivery with either nitrofurantoin (50 mg) or cephalexin (250 mg) at night. Table 44-1 outlines some antibiotic regimens suitable for use in pregnancy.

RENAL CALCULI

Epidemiology

Despite the physiologic state of pregnancy being an ideal environment for renal stone formation, the incidence of renal calculi remains similar in pregnant and nonpregnant women, in the range of 0.03% to 1%.

Antibiotic Regimens for Treatment of Urinary Tract Infections in Pregnancy

Antibiotic	Dose	Duration
Acute Cystitis		
Amoxicillin	500 mg three times daily	3-7 days
Nitrofurantoin	100 mg twice daily	3-7 days
Cephalexin	500 mg two or three times daily	3-7 days
Asymptomatic Bacteriuria		
Cephalexin	500 mg three times daily	3 days
Amoxicillin	500 mg three times daily	3 days
Amoxicillin–clavulanic acid	500 mg three times daily	3 days
Nitrofurantoin	50 mg four times daily	3 days
Fosfomycin	3 g single dose	
Recurrent Bacteriuria or Cystitis		
Cephalexin	250 mg nighttime (or postcoital)	
Nitrofurantoin	50 mg nighttime (or postcoital)	
Amoxicillin	250 mg nighttime (or postcoital)	
Pyelonephritis (Initial IV Therapy)		
Ceftriaxone	1 g daily	
Ampicillin (with gentamicin)	1 g every 6 hours	
Gentamicin	3 mg/kg daily	
Ticarcillin	3.2 g every 8 hours	
Piperacillin	4 g every 8 hours	

Table 44-1 Antibiotic regimens for treatment for urinary tract infections in pregnancy.

Pathogenesis

The majority of stones are formed from calcium oxalate and calcium phosphate. Struvite stones are the next most common, usually when the urinary tract is infected with organisms such as *Proteus* spp. Small proportions of renal stones are formed from uric acid or cystine. As discussed, pregnancy is a physiologic state of relative urinary stasis, as well as of increased calcium and uric acid excretion. The incidence of renal calculi is not increased during pregnancy probably because of the enhanced excretion of inhibitors of stone formation, such as magnesium, citrate, and the glycoprotein nephrocalcin.

Clinical Manifestations

Symptomatic stones during pregnancy are rare, usually presenting in the second or third trimester with acute flank pain radiating to the groin or lower abdomen and hematuria. However, clinical features of renal calculi may be more difficult to interpret in pregnancy because frequent episodes of diffuse, poorly localized abdominal pain and lower urinary tract symptoms are relatively common in normal pregnancy.

From 75% to 85% of stones will pass spontaneously during pregnancy,[19] and some women with calculi will have a concomitant UTI. Pregnant women with renal calculi are at greater risk of superimposed pyelonephritis.

The diagnosis of renal calculi in pregnancy is made more difficult because of the accompanying physiologic hydronephrosis and the risks of radiation to the fetus if investigating the urinary tract with computed tomography (CT). Ultrasound will detect hydronephrosis (usually as part of normal pregnancy) and will often detect calculi within the kidney, but ultrasound rarely finds ureteral stones and is less accurate than CT for these purposes. Transvaginal ultrasound should be performed when transabdominal ultrasound is uninformative, to detect distal ureteral stones if pain persists.[20] If this remains negative, the woman can be treated symptomatically, with pain relief, hydration, and lying on her side, with the symptomatic side up, enabling relief of pressure on the ureter from the gravid uterus. If symptoms persist and further diagnosis is required, magnetic resonance (MR) urography or low-dose CT (in second or third trimester) can be used, although in our experience, this is rarely needed.

Treatment

Initial management of renal calculi is conservative, with appropriate hydration, antiemetics, and analgesia. Stones pass spontaneously (75% to 85%) in part because of the normally dilated urinary tract in pregnant women. Calcium intake should not be limited in pregnancy. However, women in whom calcium oxalate stones form persistently can limit foods high in oxalate, such as spinach, rhubarb, and chocolate. Urine should always be cultured and appropriate antibiotics administered when a UTI is suspected.

Quantitation of urine calcium, uric acid, or other mineral excretion is not necessary in pregnancy, because specific pharmacologic agents to modify excretion (including thiazides and allopurinol) are contraindicated. Investigations can be completed postpartum.

Urine output should be monitored and renal function assessed. Surgical intervention is considered only when stones cause persistent obstruction, deteriorating renal function, intractable pain or infection, or premature labor unresponsive to other treatment.

Cystoscopy with ureteral stenting may be required in pregnancy, and ureteroscopic removal of stones has been reported.[21] Lithotripsy is generally contraindicated during pregnancy because of the presumed adverse effect of the shock waves on the fetus; however, some centers have used ureteroscopic laser lithotripsy in pregnant women.[22] Extracorporeal shock wave lithotripsy has been reported as an inadvertent procedure in six women in the first month of pregnancy, all of whom subsequently delivered normal infants.[23]

Postpartum follow-up is important. In the absence of ongoing symptoms, we perform a CT scan of kidney, ureters, and bladder 3 months later. This delay is necessary to eliminate confusion in interpreting the findings; calyceal and ureteral dilation may persist that long after delivery. Women planning a further pregnancy should be assessed for idiopathic hypercalciuria or other causes of renal calculi after a minimum of 3 months postpartum.

HYPERTENSION IN PREGNANCY

Definitions

There are four major hypertensive disorders related to pregnancy (Fig. 44-1), as follows:

1. Gestational hypertension
2. Preeclampsia-eclampsia
3. Chronic/preexisting hypertension
   - Primary
   - Secondary
   - White coat hypertension
4. Preeclampsia superimposed on chronic/preexisting hypertension

Hypertension in pregnancy is defined as blood pressure of 140/90 mm Hg or higher. Normal pregnancy is characterized by a fall in BP, beginning in the first trimester and reaching a nadir in the second trimester. BP rises toward preconception levels near the end of the third trimester. A BP increment of 30 mm Hg or greater systolic and/or 15 mm Hg diastolic to levels still below 140/90 mm Hg warrants increased frequency of follow-up. By itself, this BP increase does not diagnose gestational hypertension or preeclampsia, but in the presence of proteinuria, this may signify early preeclampsia in some women.

The development of newly elevated BP after 20 weeks' gestation without evidence of maternal organ dysfunction is known as *gestational hypertension.* This should usually resolve by 12 weeks postpartum. If hypertension persists beyond 12 weeks postpartum, the diagnosis is likely chronic/preexisting hypertension that has been masked by the physiologic decrease in BP that occurs in early pregnancy. It is important to note, however, that some women with preeclampsia or gestational hypertension may take longer for their high BP to resolve.

Preeclampsia is also hypertension developing in the second half of pregnancy, but this more serious disorder includes accompanying evidence of maternal renal, cerebral, hepatic, or clotting abnormalities and fetal growth restriction (see later discussion).

Chronic/preexisting hypertension is BP of 140/90 mm Hg or higher that antedates pregnancy or is present before the 20th week of pregnancy (on at least two occasions) or persists beyond 12 weeks postpartum. This should ideally be confirmed by 24-hour ambulatory BP monitoring or home self-initiated BP monitoring, to exclude *white coat hypertension,* which is common in pregnancy.[24]

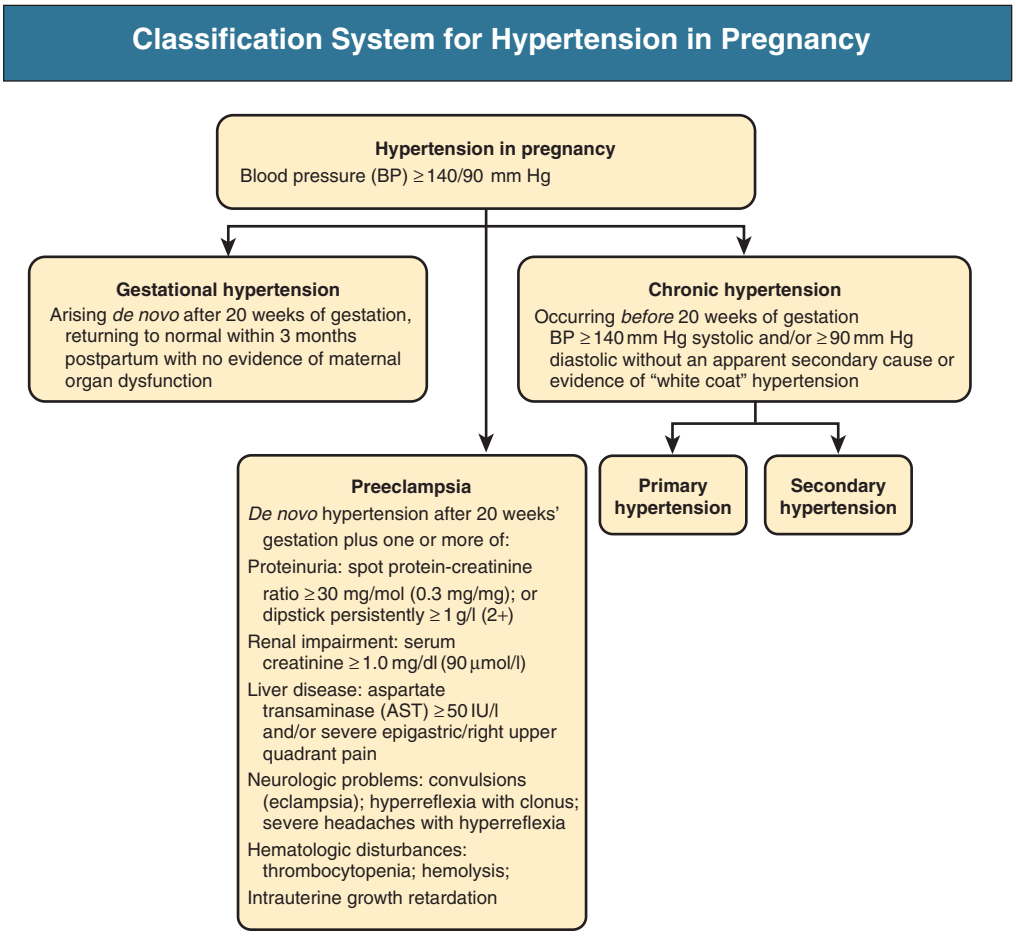

Figure 44-1 Classification of hypertension in pregnancy.

Superimposed preeclampsia is the development of proteinuria or new renal dysfunction, thrombocytopenia, neurologic features, or abnormal liver function after 20 weeks' gestation in a woman with chronic/preexisting hypertension.

The traditional definition of *preeclampsia* has been hypertension with proteinuria and edema developing after 20 weeks' gestation. However, edema accompanies two thirds of both normal and preeclamptic pregnancies and is not a particularly useful sign. The detection of proteinuria in the past has also been quite unreliable, and insisting on the finding of proteinuria for this diagnosis ignores the protean manifestations of preeclampsia, as discussed later. In practice, however, the majority of women with multisystem features of preeclampsia also have proteinuria.

Eclampsia (convulsions) is now uncommon in developed countries, with a prevalence of about 0.3% of hypertensive pregnancies. In underdeveloped countries, eclampsia is much more common, with greater risks of maternal mortality and morbidity as well as perinatal mortality.

Epidemiology

Hypertensive disorders of pregnancy are the second most common cause for maternal death worldwide, after hemorrhage.[25] Hypertension affects 10% to 12% of all pregnancies,[26] and the distribution of causes in a population depends largely on the nature of the obstetric unit assessing that population; tertiary referral units tend to have a higher proportion of severe preeclamptic cases. In general, primary hypertension accounts for about 20%, secondary causes 4%, preeclampsia 35%, and gestational hypertension the remainder of hypertensive disorders in pregnancy. About one in four women with apparent primary hypertension early in pregnancy has white coat hypertension. They present early in pregnancy with apparent chronic hypertension, but their outcomes are better than those with true chronic hypertension. Women with white coat hypertension may be managed without medication through regular home BP monitoring. A small proportion will go on to develop preeclampsia.[27]

PREECLAMPSIA

Epidemiology

Preeclampsia follows no recognized racial patterns, and no specific genotype-phenotype relation has been associated with this disorder.[27] Preeclampsia occurs in 2% to 8% of pregnancies and is a major contributor to maternal mortality worldwide.[31] Box 44-2 lists risk factors for preeclampsia. The risk is highest in those with a past history of preeclampsia, with rates ranging from15% to 65% depending on the gestation at onset of the preeclampsia.[28,29] Risk of preeclampsia is also high in the first pregnancy, possibly because of limited recent exposure to paternal (sperm) antigens, which may play a role in disease pathogenesis.

An intriguing observation is the reduced risk of preeclampsia in subsequent pregnancies, but a return to the risks of the first pregnancy in women who have a new partner for subsequent pregnancies. This observation, combined with an increased likelihood of preeclampsia in women who have used barrier methods of contraception, raised the possibility of an impaired immunologic response to paternal antigens in such pregnancies. However, this may simply be explained by a longer interpregnancy interval rather than a change of partners, with the incidence increasing after about 7 years between pregnancies.[30]

Smoking reduces the risk of preeclampsia by a third, but increases the risk of preterm labor, intrauterine growth restriction (IUGR) and placental abruption.[31] Obesity increases the likelihood of preeclampsia.

Risk Factors for Preeclampsia

Maternal Obstetric Factors
Nulliparity
Multiple-gestation pregnancy
History of previous preeclampsia
Molar pregnancy
Trisomy 13 or fetal hydrops
Gestational diabetes

Obstetric Paternal Factors
Father born from preeclamptic pregnancy

Maternal Comorbid Conditions
Chronic hypertension
Chronic kidney disease
Pregestational diabetes mellitus
Obesity
Antiphospholipid antibody
Systemic lupus erythematosus

Maternal Genetic Factors
Thrombophilias
Preeclampsia in pregnancy of first-degree relative

Other Maternal Factors
Age over 40 years

Box 44-2 Risk factors for the development of preeclampsia. *(Modified from reference 73.)*

Pathogenesis

The pathogenesis of preeclampsia is complex. The placenta likely causes preeclampsia, with other maternal organs (e.g., kidney) amplifying the disease process (Fig. 44-2). This is supported by the observation that preeclampsia can occur in hydatidiform mole, where the fetus is absent, with the condition resolving when the placenta is removed. The following key mechanisms are involved in the progression to the clinical preeclamptic syndrome:

- *The immune response at the placental-maternal interface.* An imbalance in the immunologic milieu can lead to placental failure. The fetal-maternal immunologic interaction at placentation involves maternal killer, immunoglobulin-like receptors and fetal human leukocyte antigen (HLA-C) molecules. This interaction fails in preeclampsia, leading to an abnormal interaction among uterine natural killer cells, trophoblastic cells, and macrophage-derived tumor necrosis factor α (TNF-α).
- *Superficial placentation with insufficient remodeling of spiral arteries and imbalance of angiogenic factors.* Invasive cytotrophoblasts penetrate the walls of the spiral arteries, where they replace maternal endothelium, converting them to capacitance vessels capable of carrying greater blood flow through the placenta and reducing their capacity for vasoconstriction.[32] Factors implicated in the pathogenesis of preeclampsia include placental growth factor (PlGF), vascular endothelial growth factor (VEGF-A), the VEGF receptor soluble fms-like tyrosine kinase 1 (sFlt-1), transforming growth factor β (TGF-β), and soluble endoglin (sEng).[33] In particular, there is an excess of syncytiotrophoblast-derived antiangiogenic factors, such as sEng and sFlt-1. Although still not fully understood, this excess is thought to be triggered by placental

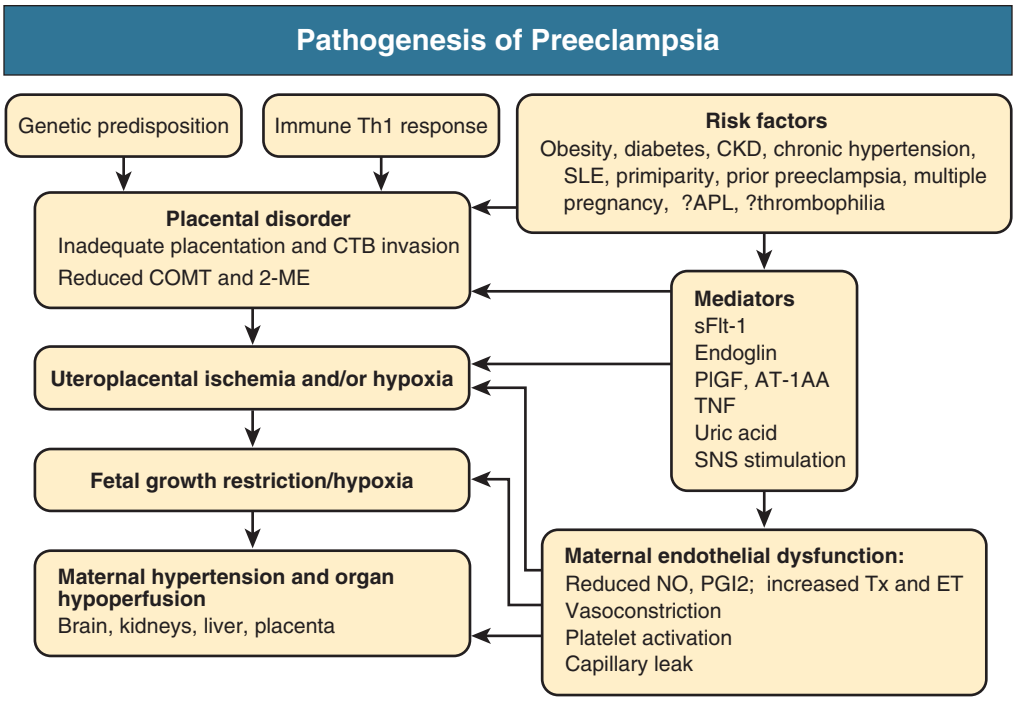

Figure 44-2 Pathogenesis of preeclampsia. *Th1,* T helper cell type 1; *CKD,* chronic kidney disease; *SLE,* systemic lupus erythematosus; *APL,* antiphospholipid syndrome; *CTB,* cytotrophoblast; *COMT,* catechol-*O*-methyltransferase; *2-ME,* 2-methoxyestradiol; *sFlt-1,* soluble fms-like tyrosine kinase 1; *PlGF,* placental growth factor; *AT-1AA,* angiotensin-II type 1 receptor autoantibodies; *TNF,* tumor necrosis factor; *SNS,* sympathetic nervous system; *NO,* nitric oxide; *PGI2,* prostacyclin; *Tx,* thromboxane; *ET,* endothelin.

ischemia or hypoxia. sFlt-1 binds to VEGF and PlGF, preventing its interaction with endothelial receptors on the cell surface, inducing endothelial dysfunction (Fig. 44-3).

- *Oxidative stress that triggers inflammation.* Maternal blood enters into the intervillous space at higher pressure and faster rate because of the impaired arterial remodeling of the spiral arteries. This exposes the placental villi to fluctuating oxygen concentrations, leading to oxidative stress and activation of nuclear factor-κB, a transcription factor central to the inflammatory response.[34] Increase in necrotic trophoblast shedding occurs and may be important in the pathogenesis of preeclampsia through systemic endothelial cell activation by secretion of interleukin-6 (IL-6).[35] Microparticles derived from placental syncytiotrophoblasts in maternal plasma interact with leukocytes and monocytes and stimulate production of proinflammatory cytokines.[36]

In summary, the impaired placentation leads to an imbalance in angiogenic factors and oxidative stress that triggers inflammation. The resulting insufficient placental function, release of placental factors into the maternal circulation, and exaggerated maternal inflammatory response cause a generalized endothelial dysfunction with leukocyte and clotting activation.

Regardless of etiology, preeclampsia is characterized by the following pathophysiologic triad:

1. Vasoconstriction
2. Platelet activation with intravascular coagulation (usually local but occasionally disseminated)
3. Maternal plasma volume contraction

This triad leads to further impairment of blood flow through the placenta as well as through the maternal kidneys, liver, and brain. It is unknown why these organs are most often affected in preeclampsia or why other vascular beds (e.g., gut) are unaffected, even in severe cases.

The clinical presentation of preeclampsia will depend on the extent to which maternal organ systems and the placenta have been affected by this process, but once begun, preeclampsia runs a progressive course until delivery, the only definitive cure.

Renal Abnormalities in Preeclampsia

Several abnormalities of renal function and structure occur in preeclampsia (Fig. 44-4). The kidneys in preeclampsia undergo a series of unique pathologic changes, including diffuse *glomerular endotheliosis,* characterized by swelling and vacuolization of endothelial cells, capillary lumen occlusion, and enlarged glomeruli. The swollen endothelial cytoplasm encroaches upon the lumen of the glomerular capillaries, contributing to the tuft ischemia[37] (Fig. 44-5). Immunofluorescence may reveal fibrin deposits. These changes are infrequently seen in clinical practice because renal biopsy is rarely performed in preeclamptic women.

Proteinuria

The urine sediment is usually bland. Both *tubular* and *glomerular* patterns of proteinuria have been reported in preeclampsia. Glomerular proteinuria is nonselective and may range from a few hundred milligrams per day up to the nephrotic range. In many studies, levels of proteinuria in women with preeclampsia do not seem to correlate with maternal and fetal outcomes.[38] However, there is some evidence for increased risk of adverse maternal and fetal outcomes with a very high level of proteinuria (spot urine protein-creatinine ratio >900 mg/mmol at any age or >500 mg/mmol in women over 35).[39] Preeclamptic women with mild or no proteinuria should be managed with the same caution as those with nephrotic-range proteinuria. Measuring microalbuminuria has not yet proved useful in clinical management of preeclamptic women, or

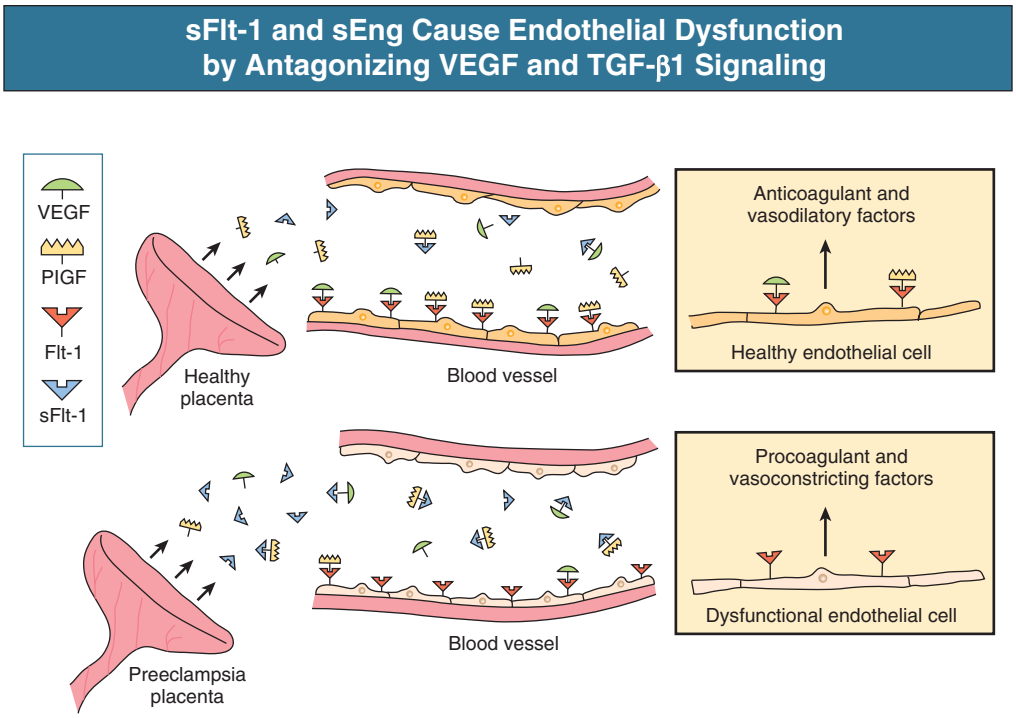

Figure 44-3 Proteins sFlt-1 and sEng cause endothelial dysfunction by antagonizing VEGF and TGF-β1 signaling. There is mounting evidence that vascular endothelial growth factor *(VEGF)* and transforming growth factor β1 *(TGF-β1)* are required to maintain endothelial health in several tissues, including the kidney and perhaps the placenta. During normal pregnancy, vascular homeostasis is maintained by physiologic levels of VEGF and TGF-β1 signaling in the vasculature. In preeclampsia, excess placental secretion of sFlt-1 and sEng (two endogenous circulating antiangiogenic proteins) inhibits VEGF and TGF-β1 signaling, respectively, in the vasculature. This results in endothelial cell dysfunction, including decreased prostacyclin, nitric oxide production, and release of procoagulant proteins. *PlGF,* Placental growth factor; *sFlt-1,* soluble fms-like tyrosine kinase 1; *sEng,* soluble endoglin. *(From reference 74.)*

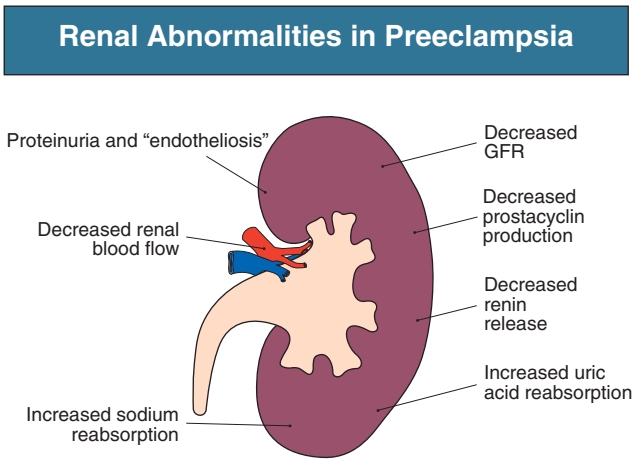

Figure 44-4 Renal abnormalities in preeclampsia. *GFR,* Glomerular filtration rate.

in predicting which women with gestational hypertension will develop preeclampsia.

Proteinuria may be part of the general capillary leak of preeclampsia or may, in part, be a consequence of glomerular endotheliosis.

Decreased Glomerular Filtration Rate

A fall in the glomerular filtration rate (GFR) may be partly caused by the decrease in renal blood flow (in turn caused by vasoconstriction, plasma volume loss, and decreased cardiac output). Other factors may also be involved, however, such as impaired placental production of the vasodilator relaxin, impaired renal prostacyclin or nitric oxide production, or the glomerular morphologic changes themselves.

Acute Tubular Necrosis

Acute tubular necrosis is the most common cause of acute kidney injury (AKI) in preeclampsia. If impaired GFR (serum creatinine >88 μmol/l; >1 mg/dl) is not corrected by BP control and plasma volume restoration, delivery is indicated if renal function continues to deteriorate.

Sodium Retention

Avid sodium retention occurs in preeclampsia, as a renal tubular response to perceived reduction in renal perfusion and perhaps also to increased sympathetic nervous system activity or alterations in expression of epithelial sodium channels. This is a normal renal response to these changes and the resultant oliguria; in the absence of an elevated serum creatinine, oliguria should not itself be an indication for delivery.

Renin

Plasma renin and aldosterone concentrations are reduced in preeclampsia, correlating inversely with the severity of the disorder. This has little direct clinical relevance; however, it may be explained by the recent discovery of a mineralocorticoid receptor mutation, *MRL810,* which allows factors normally antagonistic to aldosterone, such as progesterone, to bind and activate this receptor leading to inappropriate sodium retention, hypertension, and subsequent suppression of renin and aldosterone release.[40] There is a general upregulation of the renin-angiotensin system (RAS) in normal pregnancy and activation of the placental RAS in preeclampsia.[41] However, this

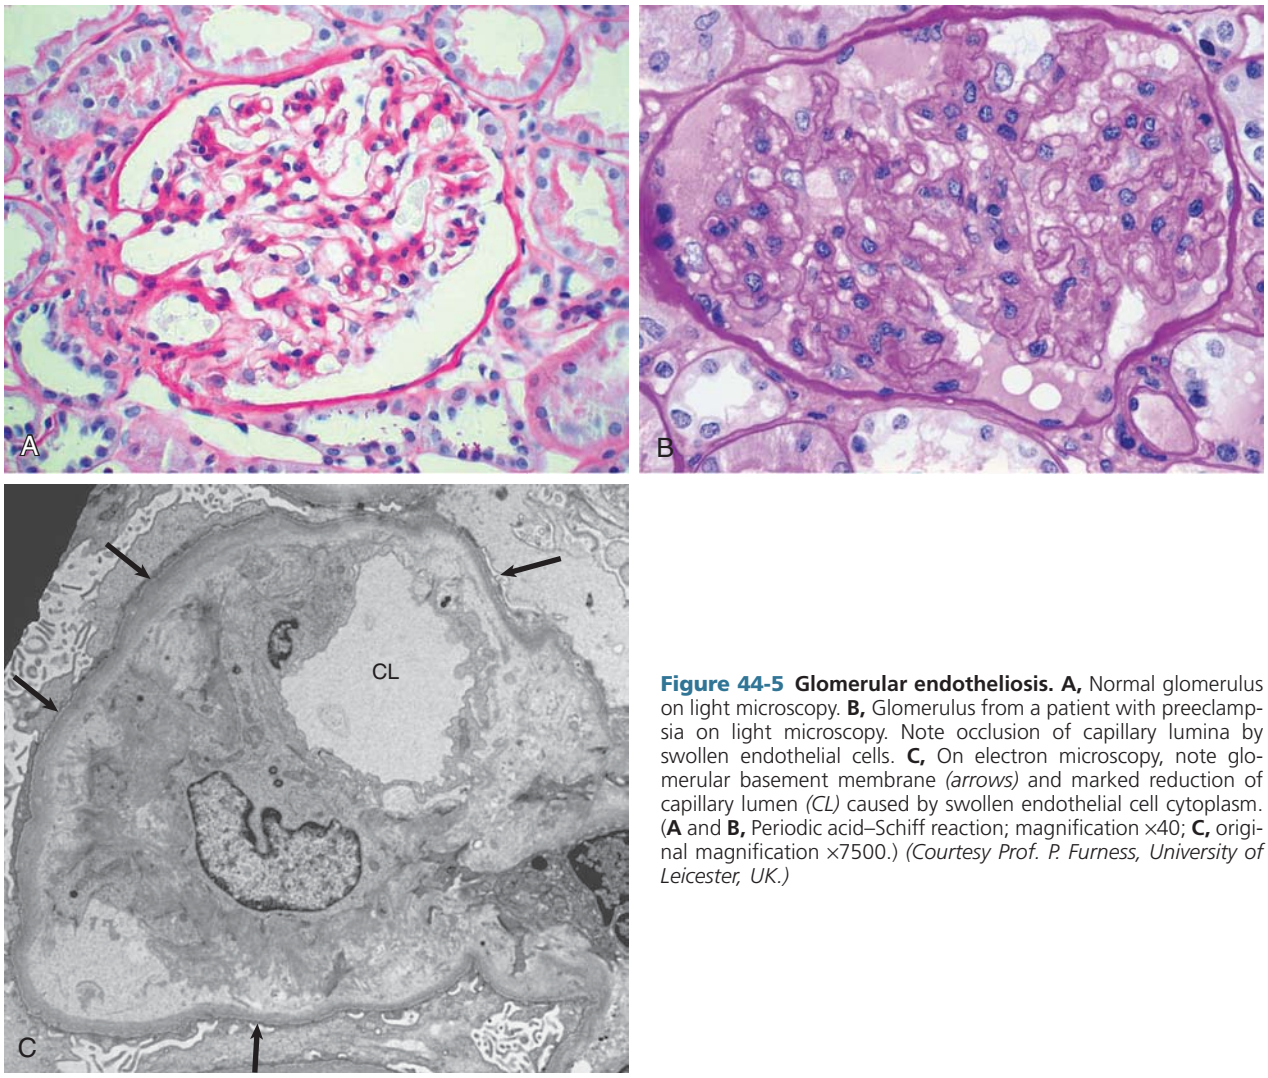

Figure 44-5 Glomerular endotheliosis. A, Normal glomerulus on light microscopy. **B,** Glomerulus from a patient with preeclampsia on light microscopy. delicate balance is lost in preeclampsia, possibly because of development of AT_1 receptor autoantibodies.[42]

Increased Uric Acid Reabsorption

Hyperuricemia in preeclampsia results largely from renal uric acid retention, although there may be some component of increased uric acid production, perhaps by the placenta.[43] Serum uric acid is a useful test in hypertensive pregnant patients because it is generally, but not always, elevated in preeclampsia, and values below 350 µmol/l (5.9 mg/dl) suggest an alternative cause for explanation for hypertension, such as primary hypertension. The degree of hyperuricemia correlates with fetal risk, even in women with gestational hypertension alone, when it should alert clinicians to seek evidence of fetal growth restriction (Table 44-2).[44]

Gestation-Corrected Serum Uric Acid During Pregnancy

Gestational Age	Serum Uric Acid (µmol/l)	Serum Uric Acid (mg/dl)
<32 weeks	>240	>4.0
32-35 weeks	>270	>4.5
36-37 weeks	>290	>4.9
≥38 weeks	>330	>5.6

Table 44-2 Gestation-corrected serum uric acid during pregnancy. Concentrations above these levels should prompt review for associated adverse pregnancy outcomes, even in patients with gestational hypertension alone. Data are from 1610 hypertensive pregnant women. *(From reference 44.)*

Clinical Manifestations

Preeclampsia is initially detected in most women by the onset of hypertension after the 20th week of pregnancy (Box 44-3). It rarely occurs before the 20th week, and such cases are occasionally caused by hydatidiform mole. Symptoms are not always present, but may include severe headaches, convulsions, stroke, repeated visual scotomata (all manifestations of cerebral involvement), severe epigastric or right upper quadrant pain (reflecting hepatic ischemia with possible subcapsular hematoma of the liver or even liver rupture), oliguria, bleeding caused by disseminated intravascular coagulation (DIC), lower abdominal pain caused by placental abruption, or reduced fetal movements.

Routine physical examination should include assessment of fetal growth, fetal heart rate patterns measured by cardiotocography (CTG), and assessment of the maternal reflexes because clonus is a warning sign of impending eclampsia. The following investigations should be performed in all patients:

Clinical Features of Preeclampsia

Primary Manifestation

Hypertension

Renal Involvement

Significant proteinuria: dipstick positive confirmed by spot urine protein-creatinine ratio >30 mg/mmol

Acute kidney injury: serum or plasma creatinine >90 mmol/L

Oliguria

Hematologic Involvement

Thrombocytopenia

Hemolysis

Disseminated intravascular coagulation

Liver Involvement

Raised serum transaminases

Severe epigastric or right upper quadrant pain

Neurologic Involvement

Convulsions (eclampsia)

Hyperreflexia with sustained clonus

Severe headache with hyperreflexia

Persistent visual disturbances (photopsia, scotomata, cortical blindness, retinal vasospasm)

Cerebrovascular accident (stroke)

Other Major Features

Pulmonary edema

Fetal growth restriction

Placental abruption

Box 44-3 Clinical manifestations of preeclampsia.

- Urine dipstick testing for proteinuria, with quantitation by measuring the urinary protein-creatinine ratio if the dipstick is 1+ (30 mg/dl) or higher
- Hemoglobin, platelet count
- Serum creatinine, electrolytes, uric acid
- Liver function tests
- Ultrasound assessment of fetal growth, amniotic fluid volume, and umbilical artery flow

Eclampsia

Eclampsia is defined as the occurrence of tonic-clonic seizures in a woman who is pregnant or has recently delivered that cannot be attributed to other causes. Of these women, 79% have premonitory signs and symptoms present during the week before the first eclamptic seizure: headache (56%), visual disturbances (23%), epigastric pain (17%), hypertension (48%), proteinuria (46%), and concurrent hypertension and proteinuria (38%).[45] Risk of eclampsia is not directly related to BP level. Although some view this as a form of "hypertensive posterior reversible encephalopathy syndrome" (hypertension with headache, confusion or decreased consciousness, visual changes, or seizures, accompanied by MR findings of cerebral white matter edema), eclampsia may occur at relatively low BP levels and has been reported in the absence of proteinuria. Importantly, about half the cases of eclampsia occur after delivery, although rarely more than 5 days postpartum.

HELLP Syndrome

The HELLP syndrome—hemolysis, elevated liver enzymes, and low platelet count—is a variant of preeclampsia. Although sometimes regarded as a separate entity, HELLP simply refers to a severe form of preeclampsia in which the hepatic and platelet abnormalities dominate, with thrombotic microangiopathy. The diagnosis of HELLP syndrome is based on the following laboratory criteria:

- Microangiopathic hemolytic anemia: schistocytes in blood smear, elevated serum bilirubin or lactate dehydrogenase, low haptoglobin
- Increased liver transaminases: aspartate transaminase (AST) greater than 70 U/l
- Platelet count: less than $100 \times 10^3/mm^3$

Maternal mortality from severe HELLP syndrome is about 1% and perinatal mortality between 7% to 34%, largely depending on gestational age.[46] It is best to consider this as a subtype of preeclampsia and continue to seek and manage all the features of preeclampsia as these arise.

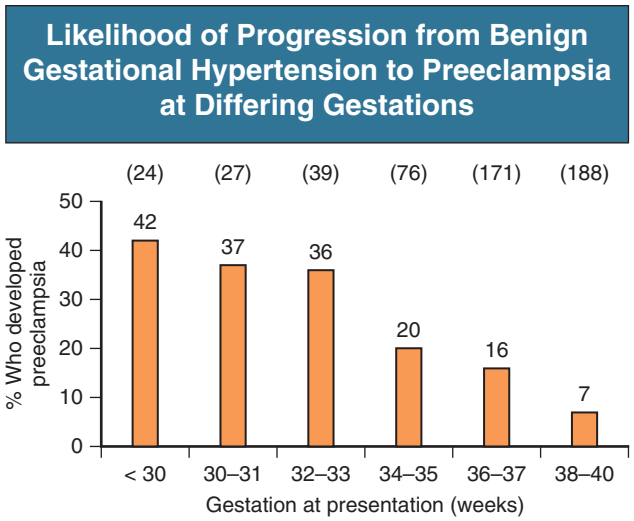

Figure 44-6 Likelihood of hypertension progressing to preeclampsia at various weeks of gestation. The earlier the presentation with gestational hypertension, the greater is the likelihood of progression to preeclampsia. *(Modified from reference 75.)*

Natural History

Women with gestational hypertension have a 10% risk of progressing to develop preeclampsia if they present after 36 weeks of gestation, but a greater than one third risk if they present before 32 weeks (Fig. 44-6).

In general, the prognosis is favorable for women with preeclampsia. Severe preeclampsia is associated with maternal, fetal, or neonatal complications, including abnormal liver function or thrombocytopenia (10% to 20%), pulmonary edema (2% to 5%), AKI (1% to 5%), placental abruption (1% to 4%), fetal growth restriction (10% to 25%), neurologic damage (<1%), and perinatal death.[47] After delivery, all clinical and laboratory derangements of preeclampsia resolve but may be delayed by several days; thus it is critical to remain vigilant until the patient's clinical picture improves. Some patients require antihypertensives for the first time in the postnatal period, which should be commenced when BP exceeds 150/100 mm Hg, although some recommend treatment at 140/90 mm Hg. Hypertension may persist for days, weeks, or months. If there is no underlying medical disorder, resolution will occur.

Prediction and Prevention

Unfortunately, despite numerous studies, no test has been found that can reliably predict the development of preeclampsia. Multiple risk

factors for development of preeclampsia have been described, although most are not highly predictive of the disorder or modifiable. Measurement of angiogenic factors (VEGF, PlGF, sFlt-1, sEng) in blood or urine seems a promising approach, particularly the ratio of sFlt-1/PlGF.[48] However, these tests require further study and are not part of usual clinical practice at present.

The observation that preeclampsia is associated with increased platelet turnover and increased platelet-derived thromboxane levels led to trials investigating the effect of aspirin in prevention of preeclampsia. It has been shown to reduce the risk of developing preeclampsia, with 19 high-risk women (one or more of previous severe preeclampsia, diabetes, chronic hypertension, renal disease, or autoimmune disease) and 119 moderate-risk women being treated to prevent one case of preeclampsia.[49] Treatment with aspirin should begin at 12 to 14 weeks' gestation because the pathophysiologic features of preeclampsia develop at this time, weeks before clinical disease is apparent. Aspirin is ideally discontinued 10 days before expected delivery, but bleeding is not significantly increased, even for women in labor while taking aspirin.[50] Women who have already developed preeclampsia do not benefit from aspirin in preventing progression to more severe disease.[51]

Oral calcium supplementation appears to halve the risk of preeclampsia in women at high risk and in communities with low dietary calcium levels.[52] Nutritional supplements, including magnesium, folic acid, fish oils, antioxidants, and garlic, have been extensively studied and do not seem to be effective in preventing preeclampsia.[53] In particular, combined use of vitamins C and E has been associated with worse maternal and fetal outcomes. Currently, anticoagulation is not recommended for reducing the risk of preeclampsia. Maternal obesity is associated with an increased risk of preeclampsia and weight loss has been shown to reduce the risk of preeclampsia.[54]

Antihypertensive drugs do not reduce the risk of preeclampsia, but do reduce the incidence of severe hypertension with its associated maternal risks.

Treatment

The only definitive treatment for preeclampsia is delivery of the placenta. Because the disorder may occur in the absence of the fetus (e.g., hydatidiform mole), it is removal of the placenta that is important. Therefore, preeclampsia that continues to worsen several days postpartum should prompt consideration of retained placental products.

Indications for delivery are generally as follows:

- Progressive evidence of maternal organ dysfunction: worsening renal or hepatic function, worsening thrombocytopenia, and development of neurologic symptoms or signs
- Inability to control blood pressure
- Inadequate fetal growth or nonreassuring fetal status
- Gestational age beyond 37 weeks

Timing of delivery should be based on optimizing perinatal outcomes while avoiding maternal risks. This requires assessment of fetal well-being with ultrasound and CTG, and an assessment of the likely gains to be made with further intrauterine time. Antenatal corticosteroids for fetal lung maturation should be given to all women at risk of delivery at less than 34 weeks' gestation; many obstetricians will also give steroids at later gestation if cesarean birth is likely.

There is consensus after the HYPITAT trial that women with preeclampsia at later than 37 weeks' gestation should be delivered.[55] The optimum management for women with preeclampsia between 34 to 37 weeks' gestation is uncertain because no randomized trials have been performed. These patients are usually managed expectantly to enable further fetal growth and maturation, with delivery if any of the previously listed indications arise. At earlier than 34 weeks' gestation, expectant management of preeclampsia is recommended, testing repeatedly for one of the indications for delivery.

General Management

All women with preeclampsia should be admitted at the initial diagnosis. If the condition appears stable, outpatient care is reasonable provided appropriate resources and expertise are available. Reviews should include once- or twice-weekly laboratory evaluation of platelet count, serum creatinine, and AST as well as CTG. Repeated quantification of proteinuria is not required once protein-creatinine ratio has risen to 30 mg/mmol, because the amount or rate of increase of proteinuria is not associated with maternal or perinatal outcome. Ultrasound estimation of fetal weight, looking for growth restriction and oligohydramnios, along with umbilical artery Doppler flow should be done at diagnosis and every 2 to 3 weeks if initially normal.

Blood Pressure Management

The major indication for antihypertensive therapy in preeclampsia is prevention of maternal cerebrovascular accident (stroke) and other sequelae of severe hypertension. Treatment does not affect the course of preeclampsia because the primary pathogenic process is related to the maternal response to abnormal placental vasculature. However, lowering BP removes one maternal indication for delivery and therefore allows pregnancy to be prolonged, with further fetal maturation and possibly fetal growth.

Antihypertensive medications are always recommended if systolic BP is 160 and/or diastolic is 100 mm Hg or higher, although the BP level at which treatment is required remains controversial. Treatment of hypertension in the range 140 to 160 systolic and 90 to 100 diastolic is a reasonable approach and will reflect local practice. For such chronic treatment, the first-line agents oxprenolol, labetalol, and methyldopa are used (Table 44-3). When additional treatment is required, hydralazine, nifedipine, or prazosin may be added. ACE inhibitors and ARBs should be avoided, because they cause fetal renal abnormalities in the latter half of pregnancy and fetal cardiac or other abnormalities with first-trimester exposure. Diuretics should be avoided because they reduce an already-impaired maternal blood volume, although there are no convincing data about harm of diuretics in pregnancy.

Target blood pressure is controversial, with a lack of clinical trial data; our practice is to target BP between 110 to 140/80 to 90 mm Hg, balancing between reducing maternal stroke risk, and ensuring adequate pressure to support placental perfusion.

Blood pressure of 170/110 mm Hg or higher always requires acute treatment, to prevent maternal stroke and eclampsia. In this patient, oral nifedipine (short-acting tablets), IV hydralazine, or labetalol is typically used.

Magnesium sulfate (4 g over 10 to 15 minutes) followed by an infusion (1 to 2 g/h) is used as seizure prophylaxis, and after a seizure, it should be continued for at least 24 hours. Magnesium sulfate is renally excreted, so particular caution is required in women with oliguria or renal failure. Serum magnesium concentrations can be monitored in conjunction with electrocardiogram (ECG), respiratory rate, and reflexes. The recurrence rate of seizures despite appropriate magnesium therapy is 10% to 15%.[56] In our view, convulsion prophylaxis should usually be reserved for preeclamptic women with clinical evidence of cerebral involvement, such as hyperreflexia with clonus, severe headaches, or visual scotomata. Withholding convulsion prophylaxis in the remainder is associated with an extremely

Medications in Treatment of Hypertension in Preeclampsia	
Drug	**Treatment Regimen**
Acute Hypertension	
Hydralazine	5-mg IV bolus every 20-30 minutes, to maximum of 20 mg, then infusion at 5-10 mg/h
Labetalol	50 mg IV every 20 minutes, to maximum 300 mg
Nifedipine	10 mg oral (tablets, not capsules)
Chronic Hypertension	
First-Line Choice	
Methyldopa	500-2000 mg/day PO
Clonidine	0.2-0.8 mg/day PO
Oxprenolol	80-480 mg/day PO
Labetalol	200-1200 mg/day PO
Second-Line Choice	
Hydralazine	25-200 mg/day PO
Prazosin	1-15 mg/day PO
Nifedipine SR	40-120 mg/day PO

Table 44-3 Medications typically used in the treatment of hypertension in women with preeclampsia. Diuretics and propranolol are not recommended. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are contraindicated. *PO,* Orally; *SR,* sustained release.

Management of Preeclampsia	
Clinical Problem	**Management**
Assess indications for delivery	Always review whether an indication for delivery is present by clinical and laboratory monitoring
Control blood pressure (BP)	Acute treatment if BP ≥170/110 mm Hg Chronic treatment if BP ≥140/90 mm Hg
Eclampsia prophylaxis or treatment	Magnesium sulfate for eclampsia or persistent neurologic signs (also indication for delivery): 4 g intravenously over 20 minutes, then 1.5 g/h for 48 hours
Supportive therapies (sometimes required)	Platelet infusion if count <20-40 × 10^9/l Fresh-frozen plasma for microangiopathy or for reduced clotting factors Dialysis for established acute kidney injury
Progressive decline in renal, hepatic, or clotting function or fetal growth	Delivery

Table 44-4 Summary of management of preeclampsia.

Long-term Consequences of Preeclampsia
Following preeclampsia, there is long-term increased likelihood of:
Fatal and nonfatal coronary heart disease
Cerebrovascular accident (stroke)
Hypertension
Thromboembolism
End-stage renal disease (ESRD)
Diabetes
Cognitive dysfunction and white matter lesions on cerebral CT scan
Death from any cause

Box 44-4 Long-term consequences of preeclampsia. *CT,* Computed tomography.

low likelihood of fits and avoids the potential for drug toxicity in a large number of pregnant women.[57] However, in developing countries, we recommend routine magnesium prophylaxis because the rate of eclampsia is higher and the cost benefit much greater.[58]

Although preeclampsia is a volume-contracted state, the increased capillary permeability makes IV volume expansion a potentially harmful procedure, with the ever-present risk of pulmonary edema. Therefore, volume expansion should be used only in select patients, such as before parenteral treatment of acute severe hypertension (when rapid vasodilation may occur) and as initial treatment in the persistently oliguric woman. No more than 1 liter of crystalloid or colloid should be given in such women, usually over 4 to 6 hours. This will restore the average plasma volume deficit in most preeclamptic women, but careful clinical observation is required for the possibility of pulmonary edema, particularly if oliguria persists.

Platelet transfusion is generally given when the platelet count falls below 20 × 10^9/l, but in some cases at higher levels (e.g., 20 to 40 × 10^9/l) if hypertension is difficult to control and the risk of intracerebral hemorrhage is therefore high. Fresh-frozen plasma is only indicated if there is accompanying microangiopathy and thrombocytopenia, when it may be difficult to differentiate preeclampsia from hemolytic uremic syndrome (HUS), or when hepatic disease leads to impaired coagulation in preeclamptic women. We do not recommend plasma exchange or corticosteroids for HELLP syndrome. Adsorption of sFlt-1 by dextran column pheresis has been in trials and will be the subject of ongoing study, although it is not part of standard practice at present.[59] Table 44-4 summarizes management of preeclampsia.

Postpartum Management

Recovery should be anticipated over 5 to 7 days in most women after delivery. In many women, the condition may worsen in the first 3 days after delivery, and they should be monitored and treated just as aggressively then as antepartum. Some patients may require up to 3 months for all the features to resolve, and a few patients will have proteinuria that takes up to 1 year to disappear completely.

Assessment of the preeclamptic woman several months postpartum is mandatory. BP should have returned to normal within 3 months in most women, and if not, this should prompt a search for underlying primary or secondary hypertension. Urinalysis and urine microscopy should be normal, certainly by 12 months postpartum, and if not, a primary underlying renal disease should be sought.

Women with recurrent preeclampsia, or severe early-onset disease (in whom recurrence is more likely) warrant special consideration and should be tested for underlying connective tissue, renal, thrombophilic and antiphospholipid disorders.

As a general rule, preeclampsia and the more benign gestational hypertension will recur in only about 15% of women in a subsequent pregnancy. Women who have presented at or before 28 weeks of gestation have at least a 25% risk of recurrence.

There are now well-recognized long-term implications of preeclampsia, particularly if it occurs before 37 weeks, including an increased risk of primary hypertension, coronary heart disease, stroke, venous thromboembolism, and end-stage renal disease (ESRD) (Box 44-4). The mechanism behind these increased risks appears to be a tendency to metabolic syndrome.[60] It is appropriate

to counsel women who develop hypertension in pregnancy on cardiovascular risk factor lifestyle modifications, along with periodic BP, serum lipid, and blood glucose checks. All such women should also receive counseling before embarking on another pregnancy.

ACUTE FATTY LIVER OF PREGNANCY

Acute fatty liver of pregnancy (AFLP) presents in the third trimester with fever, malaise, epigastric pain, nausea, vomiting, and jaundice. The incidence of AFLP is 1 per 7000 to 20,000 pregnancies,[61] but many milder cases may go undiagnosed. AKI is a common complication of AFLP, although the exact incidence is unclear, with a small case series describing rates that vary from 20% to 100%.[62]

Pathogenesis and Pathology

The disease is frequently associated with an autosomal recessive genetic error that causes a defect on long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD), an enzyme involved in mitochondrial fatty acid β-oxidation. This causes excessive fetal fatty acid accumulation to be released into the maternal circulation, which deposits in liver tissue and leads to maternal hepatic dysfunction. The hallmark of the hepatic pathology is lipid microvesicle infiltration of the hepatocytes without inflammation or necrosis.

The renal lesion in AFLP is nonspecific, and the pathophysiology is unclear. It may be caused by hemodynamic changes similar to those seen in the hepatorenal syndrome or by a thrombotic microangiopathy. Coexisting preeclampsia may also contribute to the renal injury. Renal biopsy and autopsy studies have shown mild glomerular hypercellularity with thick, narrow capillary loops and tubular free fatty acid accumulation, suggesting that abnormal fatty acid oxidation may also contribute to renal dysfunction.

Clinical Manifestations

The severity of liver involvement in women with AFLP is highly variable, ranging from a moderate isolated increase in transaminases to fulminant hepatic failure with encephalopathy and coagulopathy. Characteristic laboratory abnormalities include hyperbilirubinemia, increased transaminases, hypoglycemia, leukocytosis, and evidence of coagulopathy (hypofibrinogenemia, prolonged prothrombin time, depressed antithrombin III levels) with thrombocytopenia.

Differential Diagnosis

Viral hepatitis and biliary obstruction should be excluded before confirming the diagnosis of AFLP. Distinguishing AFLP from severe preeclampsia can be challenging; up to 50% of women with AFLP have concomitant preeclampsia with hypertension and proteinuria. Because the two disorders share many pathophysiologic and clinical features, some suspect that these are part of the same spectrum of disease. Nevertheless, distinguishing between preeclampsia and AFLP is important to guide whether offspring should be assessed for LCHAD mutation.

Treatment and Outcome

Early diagnosis, supportive care, and prompt delivery are critical in the management of AFLP. In most women, there is complete liver and kidney recovery after delivery. However, AFLP is associated with maternal and perinatal mortality of 10% to 20%. Renal recovery typically follows delivery, but dialysis may be needed.

THROMBOTIC MICROANGIOPATHY

Pregnancy-associated thrombotic microangiopathy (TMA) is defined by the presence of fibrin and platelet thrombi in the microcirculation of multiple organs, microangiopathic hemolysis, and thrombocytopenia. Manifestations of pregnancy-associated TMA include the HELLP syndrome, HUS, and thrombotic thrombocytopenic purpura (TTP). Pregnancy-associated TMA is also discussed in Chapter 29.

Clinical Manifestations and Differential Diagnosis

Women with HUS typically present with AKI (often with hypertension) in the postpartum period, although injury can occur at any time during pregnancy, even as early as the first trimester. TTP presents antepartum, usually before 28 weeks' gestation. Coagulation studies and liver function tests are usually normal in HUS and TTP, unlike cases of severe preeclampsia or AFLP. One study suggests that a high lactate dehydrogenase (LDH)–AST ratio (25:1) indicates that HUS is a more likely diagnosis than preeclampsia/HELLP in the third trimester.

In practice, it may be difficult to distinguish HUS and TTP from preeclampsia without renal biopsy, which often must be delayed until thrombocytopenia is resolving. If renal failure is progressive, biopsy becomes more important to guide ongoing therapy, including plasma exchange.

Natural History

The maternal mortality in pregnancy-associated TMA has declined in recent years and is now between 10% and 20%. However, perinatal mortality is high (30% to 80%), mainly from growth restriction and placental infarction caused by thrombosis of decidua arterioles.[63] The long-term renal outcome is poor, with 76% of patients with AKI from HUS developing ESRD.[64]

ACUTE KIDNEY INJURY

Definition

The diagnosis of AKI in pregnancy is based on the serum creatinine increase. The usual formulas for estimating GFR are not validated in pregnancy, nor are systems for defining AKI (e.g., AKIN; see Chapter 71). Creatinine clearance by 24-hour urine collection remains the gold standard method for estimating GFR in pregnancy, but this is impractical in most women with AKI. Unfortunately, there is still no agreed definition of AKI in pregnancy, but in general, a serum creatinine greater than 88 μmol/l (>1 mg/dl), or an increase within 48 hours of 44 μmol/l (0.5 mg/dl) above baseline, should be investigated.

Epidemiology

Acute kidney injury necessitating dialysis now occurs in developed countries in only about 1 of 20,000 pregnancies, so a typical obstetric unit (with 2000 to 3000 unselected deliveries per year) will only see one case every 6 to 10 years; the incidence will be greater in tertiary referral centers but is still very low. The development of AKI in pregnancy follows a bimodal distribution with two incidence peaks: the first and third trimesters. Pre-renal causes are more common in the first trimester because of hyperemesis gravidarum or acute

tubular necrosis in the context of septic abortion. Common causes in the later stages of pregnancy are preeclampsia, HUS, or AFLP. Obstructive uropathy is an uncommon cause of AKI in pregnancy.

Pathogenesis

Common to many of the disorders causing AKI in pregnancy are the pre-renal elements of volume contraction and vasoconstriction, as well as intravascular coagulation, each abnormality tending to reduce renal perfusion and setting the scene for renal ischemia (Table 44-5). It is generally believed that a pregnant woman is more likely to develop AKI than a nonpregnant woman exposed to the same set of conditions that threaten renal perfusion, although there are no confirmatory data for this view. The best explanation for this would be that many of the renal "protective" mechanisms (e.g., increased prostacyclin production to enhance renal blood flow) are already activated maximally in normal pregnancy and may not be augmented in the setting of a pre-renal problem.

It is also a common view that subsequent bilateral renal cortical necrosis is more likely than if AKI had developed outside of pregnancy. The risk of cortical necrosis is estimated at 20% when AKI follows septic abortion. This contrasts with a lower incidence of cortical necrosis (~2%) after other causes of AKI in pregnancy.[65] Irreversible renal damage follows 10% to 25% of such cases of cortical necrosis, mostly after preeclampsia or antepartum hemorrhage.[66] Since septic abortion is now an uncommon problem in developed countries, cortical necrosis is a less common complication of obstetric AKI than in the past, although this risk remains higher in developing countries where opportunities to prevent AKI are fewer.

Antepartum Hemorrhage, Prolonged Intrauterine Fetal Death, or Amniotic Fluid Embolism

In these conditions, primary DIC and severe renal ischemia (leading to endothelial damage and secondary fibrin deposition) are the initiating events. Local release of nitric oxide (NO) normally minimizes the degree of thrombus formation by diminishing platelet aggregation, but if endothelial injury is too great, NO release is impaired, accelerating the tendency to thrombosis. Renal cortical necrosis or acute tubular necrosis (in less severe cases) may then occur, manifesting as abrupt onset oliguria or anuria with gross hematuria, flank pain, and often hypotension caused by the initiating disorder.

Causes of Acute Kidney Injury in Pregnancy

Category	Specific Causes*
Pre-renal	Antepartum or postpartum hemorrhage Hyperemesis gravidarum Sepsis Congestive heart failure (rare)
Renal	Acute tubular necrosis Pyelonephritis Renal cortical necrosis Thrombotic microangiopathy Preeclampsia/HELLP syndrome Acute fatty liver of pregnancy glomerulonephritis Medication toxicity
Post-renal	Urinary tract obstruction Gravid uterus (rare) Calculi

Table 44-5 Causes of acute kidney injury (AKI) in pregnancy. *Although all the usual causes of AKI apply, these causes are more specific to pregnancy.

Sepsis

In septic conditions in pregnancy, AKI is probably the result of cytokine-induced changes in vascular permeability and a loss of effective renal plasma flow, sometimes with accompanying hemolysis or DIC or acute pyelonephritis.

Clinical Manifestations and Differential Diagnosis

Most cases of AKI in pregnancy are associated with oliguria, and the clinical manifestations in the mother are the same as for AKI in general (see Chapter 71). However, there is the added concern of fetal death; the fetus does not survive in an environment of prolonged uremia. Clinical features that should be considered in the differential diagnosis of AKI in pregnancy include preeclampsia and obstructive uropathy.

Preeclampsia

Oliguria in the context of preeclampsia is a worrying sign but of itself may represent a normal renal response to volume contraction. The rise in serum creatinine can sometimes be prevented by good BP control and judicious volume expansion in these patients. AKI is more likely to develop in the HELLP syndrome. Table 44-6 outlines the differential clinical features of preeclampsia/HELLP syndrome, HUS, and AFLP.

Obstructive Uropathy

Obstructive uropathy is uncommon in pregnancy. Usually, there are no specific clinical features; renal failure is discovered when serum creatinine is measured because a pregnant woman is progressively unwell or she is oliguric. Ureteral dilation, more common on the right, may reach up to 8 cm of renal pelvic dilation as part of normal pregnancy. Therefore, ultrasound diagnosis of obstructive uropathy is difficult. If urinary tract obstruction is the suspected cause of AKI

Table 44-6 Comparison of clinical and laboratory characteristics of syndromes causing AKI in pregnancy. *HUS,* Hemolytic uremic syndrome; *TTP,* thrombotic thrombocytopenic purpura; *HELLP,* syndrome of hemolysis, elevated liver enzymes, and low platelet count; *AFLP,* acute fatty liver of pregnancy; *CNS,* central nervous system; *AST,* aspartate transaminase.

in pregnancy, a thorough search should be made first for other disorders causing the AKI. If no other cause is found, if renal failure is progressive, and if delivery cannot be initiated immediately, percutaneous nephrostomy may rarely be required. The diagnosis is confirmed if serum creatinine falls.

Natural History

The likelihood of AKI in pregnancy progressing to a dialysis-dependent patient has not been studied systematically. Recovery from dialysis-dependent AKI is much more likely in preeclamptic women or those with AFLP or antepartum hemorrhage, because the pathophysiologic changes of these disorders resolve quickly after delivery. Recovery is much slower after HUS, and CKD is more likely.

Maternal and Fetal Mortality

Maternal mortality varies between 6% and 30% depending on the study.[67] Fetal mortality rates are much higher but vary enormously depending on the availability of perinatal care.[68]

Treatment

The key issue in treatment of AKI in the pregnant patient is restoration of fluid volume deficits, and in later pregnancy, delivery of the baby and placenta, because this is likely to remove the stimulus for AKI as quickly as possible. This is relatively easy when AKI develops late in pregnancy, but when fetal viability is uncertain and the maternal condition stable, dialysis and specific treatment of the underlying condition are begun.

Dialysis

The indications for dialysis are the same as for the general population with severe AKI: uremic symptoms (encephalopathy or pericarditis), volume overload, hyperkalemia, and metabolic acidosis unresponsive to initial medical treatment. However, it is generally recommended to start dialysis earlier, when the urea rises above 15 mmol/l (equivalent to BUN of 42 mg/dl) despite volume restoration, because the uremic environment has a negative effect on fetal survival. Both peritoneal dialysis and hemodialysis have been used in pregnancy with success. Peritoneal dialysis requires dialysis catheter insertion under direct vision and has the potential advantage of maintaining fairly constant maternal hemodynamics without threatening uteroplacental blood flow, but it does carry the risk of peritonitis. Hemodialysis is required more frequently than usual and has the risk of impairing uteroplacental perfusion if sudden fluid shifts occur. Neither method is superior, and there is only limited experience with continuous renal replacement therapy in pregnancy. Dialysis in pregnancy is discussed in more detail in Chapter 45.

OVARIAN HYPERSTIMULATION SYNDROME

Definition and Epidemiology

Ovarian hyperstimulation syndrome (OHSS) is an exaggerated response to ovulation induction associated with *in vitro* fertilization (IVF) therapy. OHSS manifests as increased capillary permeability and fluid retention, with inflammatory mediators (e.g., VEGF). Fortunately, it is self-limiting. Severe OHSS is reported to occur in 0.5% to 5% of stimulated ovarian cycles.[69] Risk factors include polycystic ovarian syndrome, retrieval of more than 200 oocytes, relative youth (<35 years), atopy, previous OHSS, and pregnancy. Mortality rates may be as high as 1 in 50,000 patients, usually from multiorgan failure caused by volume depletion and hemoconcentration.[70]

Pathogenesis

In spontaneous ovulatory cycles, hypothalamic-pituitary-ovarian negative feedback mechanisms usually limit recruitment and development to a single follicle. Ovulation induction generally involves administration of a pharmacologic dose of exogenous gonadotropin that overrides normal feedback mechanisms. This results in recruitment of a large number of follicles. When human chrorionic gonadotropin (hCG) or a gonadotropin-releasing hormone (GnRH) agonist is administered to trigger ovulation in the setting of multiple follicles, or if pregnancy ensues, massive follicular luteinization occurs, which can lead to excessive release of factors, including VEGF, cytokines, prostaglandins, histamine, and angiotensin. These factors increase vascular permeability, causing massive fluid shifts and abdominal ascites, pleural and pericardial effusions, and edema. The hemoconcentration, hypovolemia, and elevated estrogen increase susceptibility to thromboembolic events. Hypovolemia and hypotension decrease renal perfusion and stimulate the RAS and sympathetic nervous system, along with antidiuretic hormone release, which then leads to oliguria, hyperkalemia, hyponatremia, and acidosis. A state of relative immunodeficiency results from loss of serum immunoglobulins into the peritoneal cavity, leading to greater infection risk. Eighty-three percent of patients with severe OHSS will have at least one febrile episode over 24 hours, with only one third of these associated with infection, usually UTI.[71]

Prevention

Modifications to the IVF protocol, such as delaying the administration of hCG until estradiol levels plateau or decrease, using a lower dose of hCG in high-risk patients, or using GnRH antagonists without hCG, have all been used to minimize the risk of OHSS. A meta-analysis of five randomized controlled trials (RCTs) demonstrated that prophylactic albumin significantly reduced the risk of developing OHSS, with albumin infusion preventing one case of severe OHSS for every 18 women at risk who are treated.[72]

Clinical Manifestations and Investigations

The clinical presentation of OHSS can be categorized into mild or severe (Table 44-7). OHSS has also been classified by time of onset.

Clinical Features of Ovarian Hyperstimulation Syndrome

Severity	Symptoms and Signs
Mild to moderate	Ovaries enlarged up to 12 × 12 cm with: Abdominal discomfort Nausea, vomiting, diarrhea Sudden increase in weight of >3 kg
Severe	Ovaries enlarged, abdominal pain, and one or more of following: Rapid weight gain Ascites, pleural or pericardial effusion Hypovolemia, hemoconcentration Oliguria, acute kidney injury Abnormal liver function Hypoalbuminemia Hyponatremia or hyperkalemia

Table 44-7 Clinical features of ovarian hyperstimulation syndrome (OHSS). OHSS is a cause of acute kidney injury.

Early-onset OHSS occurs 3 to 7 days after the administration of the ovulatory dose of hCG and is caused by excessive preovulatory ovarian response to stimulation. Late-onset OHSS occurs later than 1 week after hCG administration and is thought to be caused by pregnancy-related increase in hCG level. Pregnancy-related OHSS is usually clinically severe and more prolonged. Patients should be investigated with full blood count and hematocrit, serum creatinine, electrolytes, liver function tests (albumin), β-hCG, and coagulation studies. An abdominal ultrasound will help confirm the diagnosis. Abdominal pain must be investigated thoroughly because the enlarged, fragile ovaries are prone to torsion and rupture. Intra-abdominal infection and ectopic pregnancy must also be considered.

Management

Ovarian hyperstimulation syndrome is self-limiting, on average 7 days in nonpregnant patients and 10 to 20 days in pregnant patients. Treatment is mainly supportive. In the woman with moderate to severe OHSS, hospital admission is required for correcting volume depletion, monitoring and correcting electrolyte abnormalities (particularly hyperkalemia), providing analgesia, offering nutrition and psychological support, preventing deep vein thrombosis, and supporting respiratory function. The ideal fluid replacement is not clear. Our practice is to give only 2 liters of crystalloid over 24 hours to correct intravascular volume depletion, recognizing that some of this will be lost into third-space fluid. Paracentesis may be necessary to improve symptoms and respiratory function in the short term. It can also improve hemodynamic status, renal blood flow, creatinine clearance, and urinary output by decreasing intra-abdominal pressure. Simultaneous albumin infusion is given to avoid protein depletion, hypotension, and rapid reaccumulation of fluid within the pleural and peritoneal spaces. Diuretics are contraindicated because these will not reduce third-space fluid and may worsen hypovolemia and hemoconcentration and precipitate AKI. Prophylactic anticoagulation with heparin is required due to the risk of thromboembolism.

CHAPTER 45

Pregnancy with Preexisting Kidney Disease

Mark A. Brown

Historically, renal disease was considered a contraindication to pregnancy, but now many pregnant women with chronic kidney disease (CKD) have successful outcomes. Accordingly, nephrologists and obstetricians need to be skilled in the management and counseling of such women. This chapter details the outcomes and management of such pregnancies. More recently, information indicates that even women with the earliest stages of CKD and those with previously treated lupus nephritis carry increased pregnancy risks, and that fetal survival continues to improve in well-dialyzed pregnant women.

CHRONIC KIDNEY DISEASE: ADVERSE EFFECTS ON PREGNANCY

Up to 3% to 10% of women of childbearing age have CKD stages 3 to 5.[1] Available data on pregnancy outcomes are mainly from studies published 10 to 20 years ago and probably overestimate risk compared to outcomes achieved with modern care, particularly with improvements in neonatal intensive care. This is changing, with more recent emphasis on assessing pregnancy outcome according to pre-pregnancy estimated glomerular filtration rate (eGFR) when possible, but there are still fewer data for pregnancy outcomes assessed by this method than by pre-pregnancy serum creatinine alone. The key pre-pregnancy factors predicting outcome include the following:

- Degree of renal impairment
- Control of hypertension
- Degree of proteinuria

In most circumstances, these features are more important in predicting outcome than the mother's specific renal disease.

The traditional view was that most women with mild renal impairment (serum creatinine <1.5 mg/dl; 130 µmol/l) and controlled hypertension have a successful pregnancy outcome, with preexisting hypertension the main predictor of pregnancy outcome in women with mild renal impairment. However, more recent studies challenge this. Perinatal mortality, preterm delivery, small-for-gestational age rates, and development of superimposed preeclampsia appear high even in women with creatinine less than 125 µmol/l before conception, but more than 100 µmol/l in early pregnancy, and indeed, even in women with normal GFR but dipstick proteinuria and one or more other risk factors for preeclampsia.[2] Those with moderate (serum creatinine 1.5 to 2.5 mg/dl; 130 to 220 µmol/l) to severe (>2.5 mg/dl; 220 µmol/l) renal impairment, particularly when accompanied by hypertension and heavy proteinuria, have a lower chance of live birth and a greater risk for maternal complications, including progression of their renal disease (Box 45-1).

Control of Hypertension

A retrospective analysis of 358 pregnant women with CKD in the United Kingdom found an association between diastolic blood pressure (BP) above 90 mm Hg (treated or untreated) and neonatal death. This relatively mild degree of hypertension also compounded the risk of preterm birth resulting from renal impairment alone.[3]

Progression of Chronic Kidney Disease

The risk of progression of renal disease during the pregnancy likewise depends less on the specific renal disorder and more on baseline serum creatinine, control of hypertension, and increasing proteinuria or onset of superimposed preeclampsia. The natural history of most mild CKD is that accelerated deterioration during a pregnancy is unlikely; the main exception is lupus nephritis, which can flare, leading to worsening renal disease during the pregnancy. However, 50% of women with moderate baseline renal impairment (serum creatinine >1.5 mg/dl; 130 µmol/l) have a significant rise in serum creatinine in the third trimester or early postpartum. If this occurs, almost one in five progress to end-stage renal disease (ESRD) within 6 months after delivery.

Prematurity or Fetal Growth Restriction

Prematurity, fetal growth restriction, and stillbirth are the major concerns for pregnancies of women with renal impairment, particularly if superimposed preeclampsia develops. Uncontrolled hypertension at conception is a poor prognostic feature for fetal outcome (Box 45-2). A new reason to avoid prematurity, besides the immediate effects on the baby, is the association with higher mortality in young adulthood.[4]

Fertility

Fertility rate is reduced in women with moderate to severe CKD, but the only estimates are imprecise. Even women receiving dialysis may become pregnant, so all women should be advised to use contraception unless planning a pregnancy.

MANAGEMENT COMMON TO ALL PREGNANCY WITH PREEXISTING KIDNEY DISEASE

Box 45-3 summarizes the general principles of management of pregnancy in women with CKD.

Pre-pregnancy Counseling

It has long been known that any woman with CKD stage 3 to 5 should receive pre-pregnancy counseling. We now know that this should also apply to women with CKD stage 1 or 2, particularly if they have hypertension, significant proteinuria, a poor obstetric history, recurrent urinary tract infection (UTI), inheritable renal

Maternal Renal Outcomes According to Pre-pregnancy Serum Creatinine

Creatinine <1.5 mg/dl (130 μmol/l)
- Permanent loss of GFR in <10% of women
- Greatest risk if GFR <40 ml/min and proteinuria >1 g/day
- Major determinant of ESRD progression is hypertension
- 40% risk of preeclampsia if baseline proteinuria >500 mg/day

Creatinine 1.5-2.5 mg/dl (130-220 μmol/l)
- Decline or permanent loss of GFR in 30% of women
- Increased to 50% if uncontrolled hypertension
- 10% ESRD soon after pregnancy

Creatinine >2.5 mg/dl (220 μmol/l)
- Progression to ESRD highly likely during or soon after pregnancy

Box 45-1 Maternal renal outcomes according to pre-pregnancy serum creatinine. Note that MDRD or CKD-EPI formulas for estimation of glomerular filtration rate *(GFR)* are *not* valid for pregnancy; *ESRD,* end-stage renal disease.

Fetal Outcomes According to Maternal Pre-pregnancy Serum Creatinine

Outcomes after accounting for first-trimester miscarriage:

Creatinine <1.5 mg/dl (130 μmol/l)
- Live births in >90% of women
- Up to 50% preterm delivery, 60% small for gestational age if baseline proteinuria >500 mg/day

Creatinine 1.5-2.5 mg/dl (130-220 μmol/l)
- Live births in about 85% of women unless uncontrolled hypertension (MAP >105) at conception
- 60% prematurity, mainly iatrogenic (preeclampsia/fetal growth restriction)

Creatinine >2.5 mg/dl (220 μmol/l)
- Fetal loss high; estimates uncertain

Box 45-2 Fetal outcomes according to maternal serum creatinine before pregnancy. Note that MDRD and CKD-EPI formulas for estimating glomerular filtration rate are *not* valid for pregnancy; *MAP,* mean arterial pressure.

disease, or other disease (e.g., SLE) likely to worsen during pregnancy. Studies from Italy have found that preterm delivery, cesarean rates, and need for neonatal intensive care were higher than in the general population, even in women with stage 1 CKD; this was particularly true if baseline proteinuria was more than 1 g/day.[5,6] Another meta-analysis included older studies but also a large number of women in stage 1 CKD; both maternal and fetal outcomes were worse in women with any form of CKD.[7] A study from Arabian Gulf countries examined outcomes of women with stage 1 and 2 CKD and also showed unexpectedly high rates of preterm delivery, fetal growth restriction, and fetal death in women with eGFR as high as 60 to 89 ml/min.[8] Although this may not be a worldwide experience, it now seems prudent to follow all women with any CKD more closely during pregnancy, not just those with impaired GFR or proteinuria above 1 g/day. This is more relevant because CKD stage 1 or 2 affects 3% of women of childbearing age, whereas CKD stage 3 to 5 affects about 1 in 150 of these women.[9] Box 45-4 summarizes issues that should be covered in counseling.

Principles of Antenatal Care with Preexisting Chronic Kidney Disease

- Management of hypertension aiming for BP 110-140/80-90 mm Hg
- Aspirin (75-150 mg daily) if serum creatinine ≥1.5 mg/dl (130 μmol/l) *or* 0.9-1.5 mg/dl (100-130 μmol/l) and proteinuria >1 g/day
- Regular medications review: discontinue statins, ACE inhibitors, ARBs
- Correct interpretation of changes in serum creatinine
- Clinical assessment and maintenance of volume homeostasis
- Interpretation and management of proteinuria including nephrotic syndrome
- Identification of superimposed preeclampsia
- Identification and management of urinary tract infection
- Consideration of the primary renal disease
- Assessment for fetal well-being and consider if delivery is indicated (see Box 45-5)

Pre-pregnancy Counseling for Women with Chronic Kidney Disease

Maternal Risks
- Accelerated decline in glomerular filtration rate, sometimes precipitating dialysis during pregnancy or soon after
- Severe maternal hypertension with risk of stroke
- Superimposed preeclampsia with renal, hepatic, thrombotic, or bleeding and neurologic risks
- Nephrotic syndrome with risks of thrombosis or sepsis and iron or vitamin D deficiency

Fetal Risks
- Fetal growth restriction or intrauterine fetal death from placental insufficiency
- Prematurity, with both short-term and long-term consequences
- Complications of drug therapy for renal disease during pregnancy
- Inheritance of a renal disorder

Box 45-4 Pre-pregnancy counseling for women with chronic kidney disease.

Excretory Renal Function

During normal pregnancy, GFR rises by about 50%, typically apparent by the end of the first trimester (see Chapter 43). Serum creatinine greater than 1 mg/dL (88 μmol/l) in a pregnant woman generally indicates reduced GFR. The Modification of Diet in Renal Disease (MDRD) or Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equations or other formulas that estimate GFR are not valid for pregnancy; whereas it is reasonable to assess pregnancy risks based on pre-pregnancy eGFR, these formulas should not be applied in pregnancy. Measurement of creatinine clearance is the only clinical way of truly assessing GFR in pregnancy but requires 24-hour urine collection, which is cumbersome, and even when conducted diligently, may be inaccurate because of

ureteral dilation, which results in pooling of urine and an incomplete collection. Serum cystatin C is being evaluated but also appears inaccurate. Serum creatinine remains the clinical standard for assessing GFR during pregnancy.

Blood Urea Nitrogen

Increments in blood urea nitrogen (BUN) and creatinine may indicate deteriorating GFR and the need for initiation of dialysis if the pregnancy is to succeed (see Dialysis in Pregnancy). However, a rising BUN, particularly when accompanied by rising hemoglobin or hematocrit, may represent intravascular contraction, typically seen in preeclampsia. The main role for BUN in pregnancy is for monitoring the effectiveness of dialysis.

Serum Electrolytes, Albumin, and Volume Homeostasis

Serum sodium and bicarbonate are slightly reduced, potassium is at the lower end of the normal range, and albumin and uric acid are lower than in the nonpregnant state. Increases in serum sodium to those of nonpregnant women should suggest (reversible) pregnancy-specific diabetes insipidus (from excess placental vasopressinase). In general, this is a mild disorder, but DDAVP should be given if serum sodium rises above 150 mmol/l with low urine osmolality.

Adequate intravascular volume is essential to preservation of GFR and good pregnancy outcome for mother and baby. Clinically, it is difficult to assess maternal volume homeostasis. Edema is an unhelpful sign in pregnancy, so hematocrit should be measured in women with underlying CKD at the initial first trimester visit, along with serum albumin. Both measures should fall slightly as pregnancy progresses. A rise in either value strongly suggests intravascular volume contraction, although there is no absolute discriminant value. Conversely, a significant fall in either value does not by itself diagnose excessive volume expansion, because the hematocrit depends on other factors, and serum albumin may fall in patients with nephrotic syndrome, who in turn may have reduced intravascular volume.

In practice, provided there is no respiratory compromise and BP can be controlled, volume excess is more favorable for maternal renal function and fetal growth than volume depletion. When there is concern about fetal growth or deteriorating GFR in women with CKD, and reduced intravascular volume is suggested by the change in hematocrit and albumin from baseline, a trial of intravenous normal saline (no more than 1 liter) under observation in hospital is a reasonable clinical approach.

Urinalysis

A dipstick test showing negative or trace protein in most (but not all) cases excludes true proteinuria. Any woman with 1+ (0.3 g/L) proteinuria or above should have formal quantification of protein excretion either with a spot urine protein-creatinine (PC) ratio or 24-hour urine collection. Glycosuria may be normal and is not itself diagnostic of diabetes mellitus, but when glycosuria is detected in early pregnancy in a woman with CKD, a 75-g oral glucose tolerance test should be performed. Dipstick hematuria during pregnancy is common and often resolves after delivery. Provided there is no UTI, urine sediment is inactive, and serum creatinine normal, this is not associated with adverse maternal or fetal outcomes during pregnancy and can be investigated if persistent postpartum.[10] Pregnancy may be the woman's first urinalysis, so previously undetected renal disorders are diagnosed at this point.

Proteinuria and Nephrotic Syndrome

The upper limit of normal protein excretion during pregnancy is defined as 300 mg/day. In a midstream specimen of urine, a PC ratio greater than 30 mg/mmol (0.27 mg/mg) correlates with more than 300 mg/day proteinuria.[11]

New-Onset Proteinuria

Isolated non-nephrotic proteinuria may develop *de novo* during pregnancy.[12] In these women, with normal GFR, one of the following three scenarios usually unfolds:

1. Preeclampsia is subsequently evident.
2. No pregnancy complications occur, and the proteinuria disappears postpartum.
3. Intrinsic glomerular disease has developed and remains postpartum.

In my experience, the third scenario is an uncommon event.

Preexisting Proteinuria

Although the spot urine PC ratio in pregnancy is a reasonably reliable method of determining whether protein excretion is abnormal, serial measurements of urine PC ratio are not recommended for reliably predicting *changes* in proteinuria. When a true increase in protein excretion occurs during pregnancy in women with underlying renal disease, few therapeutic options exist besides ensuring BP control (see later discussion).

Nephrotic Syndrome

The one situation in which 24-hour urinary protein excretion should be measured in these women is to diagnose nephrotic syndrome. Serum albumin falls in most pregnancies as a result of volume expansion and is often below 30 g/l, so this is not a reliable indicator of nephrotic syndrome. A spot urine PC ratio greater than 230 mg/mmol indicates protein excretion above 3 g/day,[13] which should be confirmed by 24-hour urinary protein measurement. These women will generally have edema, but this is unhelpful because it occurs in two thirds of normal pregnancies. Although increased serum cholesterol is typical of nephrotic syndrome, this frequently occurs during normal pregnancy.

Confirmation of true nephrotic syndrome has important implications in pregnancy. There will be urinary loss of vitamin D–binding protein, transferrin, immunoglobulins, and antithrombin III (accompanied by increased hepatic synthesis of clotting factors) and a propensity for intravascular volume contraction. These changes can result in calcium deficiency, iron deficiency, increased likelihood of infection, thrombosis, and reduced uteroplacental blood flow with fetal growth restriction or death; some patients have reduced renal blood flow with worsening renal function. Adequate fetal growth and amniotic fluid should be evaluated by serial ultrasound. Treatment requires oral calcium, vitamin D and iron supplementation and subcutaneous heparin for thrombosis prophylaxis, and reassessment of maternal serum creatinine on a regular basis. If nephrotic syndrome occurs early in pregnancy, I add vitamin D for prophylaxis against osteoporosis, although there are no controlled trials to test this practice.

Hypertension

Hypertension in pregnancy is defined as blood pressure above 140/90 mm Hg, and this is generally the threshold for treatment, with an acceptable range on treatment of 110 to 140 systolic and 80 to 90 mm Hg diastolic. This range is not based on solid pregnancy outcome data but is thought to be the range that reduces maternal risk from severe hypertension while providing sufficient systemic BP

to maintain placental perfusion. Although the target BP for nonpregnant women with CKD is also less than140/90 mm Hg, it is probably lower (≤125/75 mm Hg) if proteinuria is more than 1 g/day; therefore a pregnant woman with proteinuric CKD may have about 40 weeks when BP is above usual target, which may contribute to progressive renal impairment postpartum. Nevertheless, if a pregnant woman develops BP below 110/80 mm Hg, my practice is to reduce antihypertensive drugs and avoid the risk of fetal hypoperfusion.

Most pregnant women with CKD will not exhibit the usual first-trimester fall in BP, and in many, BP increases as the pregnancy progresses. The reason is not clear. Normal pregnancy is accompanied by significant volume expansion, which does not usually induce hypertension. In CKD, however, there is often inability to excrete a sodium load with accompanying hypertension, and this mechanism likely contributes in pregnancy. Other factors almost certainly playing a role in this hypertension include stimulation of the renin-angiotensin and sympathetic nervous systems, alterations in endothelial factors such as prostacyclin, nitric oxide, and endothelin, and particularly in transplant patients, the drugs used, such as calcineurin inhibitors and corticosteroids. Regardless of its cause, persistence of hypertension is an adverse factor in pregnancy outcome.[14] Concern about using antihypertensives in pregnancy has been associated with poorer pregnancy outcomes, at least in women with renal transplant.[15]

Blood pressure will often rise significantly soon after delivery. Therefore, BP measurement and treatment should be undertaken diligently in the early postpartum period.

Control of BP is imperative to successful pregnancy outcome in women with underlying renal disease. Diuretics are not recommended during pregnancy because any reduction in maternal plasma volume may have adverse effects on uteroplacental or renal perfusion. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) must be discontinued, preferably before pregnancy but certainly as soon as pregnancy is diagnosed, because of increased risks of fetal growth restriction, oligohydramnios, neonatal renal failure, and probably cardiac and neurologic developmental abnormalities. Aldosterone antagonists should also be avoided, and atenolol has been associated with fetal growth restriction. Suitable antihypertensives include methyldopa, labetalol, oxprenolol, hydralazine, prazosin, and nifedipine, and all may be used in conventional doses. Diltiazem may also have a small benefit on reducing proteinuria, but this has not been addressed specifically for pregnancy.

Superimposed Preeclampsia

Preeclampsia is a placental disorder of unknown etiology that has several predisposing risk factors, one of which is CKD (see Chapter 44). The maternal renal effects of preeclampsia include a reduction in renal blood flow, increased sodium and uric acid reabsorption, reduced circulating renin and aldosterone concentrations, proteinuria, and impaired GFR. Superimposed preeclampsia in a woman with underlying renal impairment will lead to worsening renal function, exaggerated hypertension and proteinuria with risks of nephrotic syndrome, short-term and long-term risks to maternal renal function, as well as increased risks for fetal growth restriction, prematurity, and perinatal mortality.

However, it is difficult to diagnose superimposed preeclampsia in a woman who begins her pregnancy with renal impairment or proteinuria. An increase in BP, decline in GFR, increased plasma uric acid, or increasing protein excretion can all be caused by progression of the underlying renal disorder rather than superimposed preeclampsia, and no definitive diagnostic test yet exists. However, when these features are accompanied by neurologic symptoms, such as hyperreflexia with clonus, or by abnormal liver transaminases or new-onset thrombocytopenia (except in SLE), it is highly likely that superimposed preeclampsia has developed. Typically, these changes occur after 20 weeks' gestation. It has been proposed that an increased ratio of soluble fms-like tyrosine kinase 1 (sFlt-1) to placental growth factor (PlGF) is diagnostic of preeclampsia and distinguishes this condition from pregnant women with CKD.[16] Although promising, incorporated this into routine clinical practice is not yet recommended.

Indications for Delivery in Women with Preeclampsia or CKD

- Inability to control blood pressure
- Deteriorating glomerular filtration rate
- Neurologic abnormalities, such as eclampsia, headaches with accompanying clonus and hyperreflexia, or repeated visual scotomata
- Worsening thrombocytopenia
- Increasing liver transaminase levels
- Failure of fetal growth
- Reversed or absent end-diastolic flow on cardiotocography

Box 45-5 Indications for delivery in women with preeclampsia or chronic kidney disease (CKD). The decision to deliver is based on a global clinical assessment rather than on specific thresholds for each parameter.

Diagnosing superimposed preeclampsia in women with CKD is somewhat unnecessary. Clinicians managing the woman with underlying renal disease should be vigilant for changes in maternal and fetal condition in all cases, and the indications for delivery in women with preeclampsia are broadly the same as those in women with progressive underlying renal disease (Box 45-5). On the other hand, it is now well recognized that preeclampsia is associated with long-term cardiovascular, metabolic, and renal risks for the mother so it is practical to error on the side of caution and "overdiagnose" this disorder because this may prompt better long-term follow-up.[17]

Limited studies suggest that aspirin is of benefit in reducing superimposed preeclampsia and perinatal death in women with underlying renal disease. A review found that the number needed to treat was 9 to 57 women for prevention of preeclampsia and 42 to 357 to prevent perinatal death.[18] The PARIS study also found that aspirin reduced superimposed preeclampsia in women with underlying renal disease, but only 450 women were included in this analysis.[19] My practice is to use low-dose aspirin (100 to 150 mg/day) for all women with CKD and creatinine greater than 1.5 mg/dl (130 µmol/l) or for those with lower creatinine who have had early-onset or severe preeclampsia or fetal loss in a previous pregnancy. The effects of this dose of aspirin on renal function are minimal, and generally this is a safe approach. I also use calcium (1200 mg/day) as prophylaxis against preeclampsia when there is no concern about hypercalcemia. Data for calcium as prophylaxis are less convincing than for aspirin, but when used carefully, calcium has minimal effects and may have benefit.

RENAL BIOPSY IN PREGNANCY

It is rare to require renal biopsy in pregnancy. After 32 weeks' gestation, if the renal state has changed so much that biopsy is considered necessary to guide treatment, it is better to deliver and manage the renal disease outside of pregnancy. Biopsy may provide information that could significantly impact on the pregnancy outcome for mother and infant in the following settings:

1. *De novo* onset of nephrotic-range proteinuria or unexplained impaired GFR with abnormal urine sediment before fetal viability (i.e., <24 weeks' gestation). Nephrotic syndrome after this stage can generally be managed conservatively until delivery, usually at about 32 weeks. Most such cases are caused by preeclampsia.
2. Situations prior to 32 weeks' gestation in which clinician and patient have agreed that immunosuppression and/or plasma exchange will be used, if necessary, while prolonging the pregnancy to about 32 weeks:
   - Rapidly declining GFR without any apparent reversible cause in women with underlying primary glomerulonephritis
   - Acute kidney injury with active urine sediment
   - Declining GFR or increasing proteinuria in a woman with lupus nephritis or lupus without previously known nephritis
3. Deteriorating GFR before 32 weeks' gestation without obvious cause in a woman with a kidney transplant, to exclude acute rejection

Complication rates of renal biopsy in pregnancy are similar to those in general nephrology practice.[20]

ASSESSMENT OF FETAL WELL-BEING

An early pregnancy ultrasound is invaluable in accurately dating the expected birth. The next usual assessment is a fetal morphology scan at 18 to 20 weeks' gestation to confirm gestational age, screen for fetal anomaly, assess fetal well-being, and check placental position. In women with CKD stage 3 to 5, this is followed by regular ultrasounds every 2 to 4 weeks to assess fetal growth and the volume of amniotic fluid, as well as Doppler studies of umbilical artery blood flow. More recently, the combination of tests at 12 weeks' gestation for pregnancy-associated plasma protein A (PAPP-A), inhibin, human chorionic gonadotropin (hCG), and α-fetoprotein, with measurement of uterine artery pulsatility index at 20 weeks' gestation has provided a good negative predictive test for fetal outcome in women with high-risk pregnancies, although these studies are not specific for women with underlying renal disease. An important caveat is that hCG levels are often elevated in women with ESRD and may overestimate the risk of a fetal abnormality when used as part of the 12-week testing.[21] It is important that women are counseled about this in advance of the testing.

Asymmetric intrauterine growth restriction (IUGR), in which abdominal measurements are more decreased than the fetal head and femur measurements, is characteristic of IUGR related to maternal CKD. Amniotic fluid volume correlates well with perinatal outcome, and a low amniotic fluid index helps distinguish babies who are small because of IUGR from those constitutionally small. Second-trimester severe oligohydramnios is associated with very poor outcome, indicating nonfunctioning fetal kidneys, and usually also leads to pulmonary hypoplasia and limb contractures. Absent end-diastolic flow on umbilical artery velocimetry is usually an indication for delivery, depending on gestational age. The development of reversed end-diastolic flow indicates a high risk of fetal hypoxia, acidosis, and death. Fetoplacental assessment by ultrasound for growth and Doppler blood flow should be carried out regularly throughout pregnancy, particularly in the third trimester.

TIMING DELIVERY

In women with stable CKD and no evidence of fetal compromise, pregnancies should be continued to term and spontaneous labor awaited. The method of delivery (vaginal or cesarean) is normally determined by other issues (e.g., previous cesarean section, poor obstetric history) rather than the presence of CKD. Box 45-5 lists the usual indications for delivery.

The goal is to time delivery such that the risks of delivery (to both mother and fetus) are less than the risks of the pregnancy continuing. This is often a difficult and individual decision requiring consultation among nephrologist or obstetric medicine physician, obstetrician, midwife, and neonatologist. The following issues need to be considered:

1. Gestational age is the most important determinant of pregnancy outcome. Decisions are difficult to make at the borderlines of viability (23 to 25 weeks' gestation). Although outcome data vary among countries, approximate survival rates increase from 30% at 23 weeks to 65% at 25 weeks to 95% at 30 weeks of gestation. Babies born at less than 30 weeks' gestation have significant risks of long-term morbidity, including chronic lung disease and cerebral palsy.
2. The most common problem faced by preterm infants is respiratory distress syndrome. Maternally administered antenatal corticosteroids, generally intramuscular betamethasone (11.4 mg, two doses 12 hours apart), have been shown to reduce respiratory distress syndrome by 50%. For best effect, the corticosteroids need to be administered at least 24 hours before delivery.
3. There is less neonatal morbidity and mortality if babies are born in hospitals where there is appropriate neonatal care rather than being transferred after delivery. Thus, if preterm delivery is likely, transfer of the mother to an appropriate unit before delivery should be considered.

Although these pregnancies are certainly high risk compared with normal pregnancy, clinicians and midwives need to remember that the final pregnancy outcome in most cases is successful for both mother and baby, but with long-term implications for both. Clinicians can take a positive approach, at all times emphasizing the need for diligence and assessment for potential complications, while highlighting that the end result in most cases will be good, in turn helping to relieve some of the stress that accompanies pregnancy for these women.

MANAGEMENT OF SPECIFIC RENAL DISORDERS DURING PREGNANCY

The most common chronic kidney diseases predating pregnancy are primary glomerulonephritis (usually IgA nephropathy or focal segmental glomerulosclerosis), diabetic nephropathy, lupus nephritis, and reflux nephropathy.

IgA Nephropathy

Long-term follow-up of childhood IgA nephropathy showed that later pregnancy was complicated by hypertension in half the cases and prematurity in one third,[22] but these outcomes are not peculiar to this renal disease. It seems unlikely that pregnancy in IgA nephropathy of itself causes accelerated renal dysfunction, at least in those with early-stage CKD (1 or 2), but proteinuria may increase in the third trimester.[23] Rare cases are familial, and the pregnant woman should be advised to have her child screened by urinalysis in the first few years of life. Macrohematuria is not more likely during pregnancy unless there is concurrent upper respiratory or gastrointestinal tract infection. IgA nephropathy should be managed as for other CKD during pregnancy.

Diabetic Nephropathy

Studies in the United Kingdom found that 8% of pregnant women with type 1 diabetes and 5% of those with type 2 diabetes had nephropathy. Diabetes increases risks for preterm birth, cesarean section, and perinatal mortality. The presence of overt nephropathy more than doubles the risk of fetal death after 20 weeks. There is an added risk for congenital abnormalities if blood sugar was not adequately controlled at conception.

The Diabetes Control and Complications Trial and EURODIAB trial both concluded that pregnancy does not increase the progression of diabetes to early diabetic nephropathy (microalbuminuria).[24,25] Microalbuminuria alone did not correlate with increased perinatal risk, but both prematurity and superimposed preeclampsia rates were higher than in type 1 diabetic patients without microalbuminuria.

The outcome of established diabetic nephropathy during pregnancy depends on the usual factors of preexisting renal impairment and control of hypertension. Meticulous control is required of blood glucose and BP during pregnancy in women with early or overt diabetic nephropathy. One study showed that failure to achieve mean arterial pressure below 100 mm Hg was associated with increased risk of early delivery, even after adjusting for glucose control.[26] Ideally, ACE inhibitors should be introduced soon after delivery for prevention of progression of diabetic nephropathy, with at least captopril being safe during breastfeeding.

Recent data suggest that having gestational diabetes mellitus (GDM) without developing overt diabetes after the pregnancy, is still associated with about a 10% risk for microalbuminuria by age 50, an intermediate risk between that of nondiabetic and diabetic women.[27] This means that women with a history of GDM, not just those with type 1 or 2 diabetes, should be followed up after pregnancy, assessing renal function and urine albumin excretion, because of their risk of developing later diabetes (see also Chapters 30 to 32).

Lupus Nephritis

Women with lupus nephritis should have quiescent disease at conception to offer the best chance of a successful pregnancy outcome. Those with active disease at conception have a higher likelihood of developing acute lupus nephritis during pregnancy, which is then associated with high fetal risk; about 20% have miscarriage, stillbirth, or neonatal death.[28] Ideally, women with lupus should be in remission for at least 6 months[29,30] before conception and receiving maintenance corticosteroids in doses less than prednisolone 20 mg/day, with or without azathioprine; all should receive aspirin and hydroxychloroquine.[29] In these women, the prior histologic class of lupus nephritis has no influence on pregnancy outcome. Predictors of poor pregnancy outcome are baseline creatinine greater than 100 µmol/l, proteinuria more than 0.5 g/24 h, antiphospholipid syndrome, and hypertension.[31]

New onset or a flare of lupus nephritis, evidenced by increasing proteinuria, active urine sediment, and rising serum creatinine, are a major concern, and some cases have been associated with maternal death. Treatment includes increasing doses of prednisolone with the early introduction of azathioprine. Some prefer to undertake renal biopsy at this point to confirm the histologic changes before introducing immunosuppression. Either approach is reasonable, but my approach is to introduce steroids and azathioprine and reserve biopsy for after delivery.

Other women with known lupus nephritis in remission before conception should continue receiving low-dose prednisolone and azathioprine throughout pregnancy and should also take low-dose aspirin.[32] Cyclophosphamide and mycophenolate mofetil are contraindicated in pregnancy because of teratogenicity, including for mycophenolate microtia, auditory canal atresia, cleft lip and palate, and micrognathia.[33] Although cyclophosphamide has been used successfully in a few patients with lupus nephritis, its use is not recommended.

Lupus nephritis may flare during pregnancy in about 30% or in about 15% postpartum,[31] but prophylactic steroid therapy is not indicated for those not experiencing a flare during pregnancy. The major cause of maternal death in lupus nephritis is sepsis, and immunosuppression should be used with care in pregnant women.[34]

When counseling about future pregnancies, women should be advised that even if their lupus nephritis has been well treated, they appear to have a greater risk of maternal complications and lupus flare in their next pregnancy than do women with SLE who have never had nephritis; this appears only partly explained by increased activity of the SLE at conception. Fortunately, fetal outcomes are not affected adversely in this group,[35] and postpartum renal function appeared unaffected.[36] This means that such women need more surveillance during pregnancy than usual, to detect a renal flare or preeclampsia, their two greatest maternal risks.

Reflux Nephropathy

The outcome of pregnancies in women with reflux nephropathy depends on the preexisting renal function and BP control rather than the disorder itself, as for other renal disorders. Approximately one in four women with reflux nephropathy develop preeclampsia, and about 40% of offspring have vesicoureteral reflux. These women are more predisposed to UTI throughout pregnancy, as are women who have had surgically corrected reflux in childhood.[37] About 20% of women with reflux nephropathy will develop UTI in pregnancy, with about 6% caused by acute pyelonephritis. UTI can be associated with premature labor or spontaneous rupture of membranes. Regular urine culture should be obtained throughout pregnancy in women with underlying reflux nephropathy.

Inherited Renal Disorders

Inherited renal disorders are likely to have been diagnosed before the pregnancy and the specific implications for the offspring discussed. The most common inherited disorder is autosomal dominant polycystic kidney disease. Others include Alport syndrome and familial hyperuricemic nephropathy, the latter having been described in one pregnancy with good renal adaptation but inheritance of the *UMOD* mutation.[38]

The pregnant woman needs to be aware that reflux nephropathy is not inherited by specific mendelian traits but tends to cosegregate within families.

Fetal renal anomalies are usually identified at routine ultrasound screening or during evaluation of a fetus from a family with a known hereditary renal disorder. Invasive procedures such as chorionic villus sampling for DNA analysis is rarely informative and should be undertaken only after advice from a clinical geneticist.

ACUTE AND RECURRENT URINARY TRACT INFECTION

The diagnosis and general management of asymptomatic bacteruria and UTI during pregnancy, including choice of antibiotic regimens, are discussed in Chapter 44.

Standard antenatal care should include culture of a midstream specimen of urine early in the pregnancy. In women with abnormal

urinary tract structure, a history of recurrent UTI, CKD, or diabetes, further regular cultures are required. Women with a history of recurrent UTI should have monthly urine cultures. For those with a predictable history of postcoital cystitis, postcoital single-dose cephalexin (250 mg) or nitrofurantoin (50 mg) can significantly reduce the likelihood of infection. For others with recurrent UTI pre-pregnancy, low-dose cephalexin (or another first-generation cephalosporin) at night may help suppress further infections. Any woman who has recurrent UTI before pregnancy should undergo ultrasound of the urinary tract before conception or in early pregnancy to exclude structural pathology.

RENAL CALCULI IN PREGNANCY

Women with a history of metabolic abnormalities causing stone formation prior to pregnancy need their treatment modified during pregnancy. I advocate adherence to a fluid intake of 2.5 to 3 liters per day and recommend that thiazides (for hypercalciuria), allopurinol (for hyperuricosuria), or captopril or penicillamine (for cystinuria) be discontinued. Fortunately, normal pregnancy is accompanied by increased urine pH, which may help reduce uric acid or cystine stone formation.

Despite relative hypercalciuria and urinary stasis in pregnancy, pregnant women may be protected against renal calculi by the simultaneous increase in endogenous inhibitors of stone formation, such as urinary thiosulfate, which parallels hypercalciuria during gestation and returns to normal postpartum.

Because of concerns about radiation from computed tomography (CT) scanning (~8 mSv) and the uncertain utility of magnetic resonance imaging (MRI) in this setting, ultrasound is the preferred investigation for renal colic in pregnancy, despite its poor sensitivity and specificity for stone diagnosis (30% to 60%). Abdominal radiography provides radiation of about 1.5 mSv.

Definitive management of a calculus is usually best left until after delivery. Because ultrasound will almost always show pelviureteral dilation, which is a feature of normal pregnancy, systemic infection or acute kidney injury are the only indications for urgent decompression of an obstructed system by percutaneous nephrostomy. Conservative therapy with analgesia and hydration will result in spontaneous passage of a stone in the majority of cases. Extracorporeal shock wave lithotripsy is contraindicated because it can be deleterious to fetal hearing. If a surgical procedure is necessary, ureteroscopy with yttrium-aluminum-garnet (YAG) laser lithotripsy has been used and is considered relatively safe in pregnancy.

Perhaps the most important recent finding is that women with renal calculi in pregnancy are more likely to be obese and have higher rates of preeclampsia (also related to obesity), GDM, and recurrent miscarriage. Overall, however, fetal outcomes remain good, with no increase in prematurity or perinatal mortality.[39] Thus, the treatment of women with renal calculi in pregnancy should be expanded to include not only the specific treatment of the calculus disorder, but also increased surveillance for preeclampsia and GDM.

DIALYSIS IN PREGNANCY

There has been significant improvement in the outcome of pregnant women with renal disease requiring dialysis during pregnancy over the past two decades, as well as a reduction in therapeutic terminations, as clinicians and pregnant women come to understand that these pregnancies can have a successful outcome.[21] An analysis of 52 pregnant women, about half starting dialysis after conception and most receiving aspirin and calcium as preeclampsia prophylaxis, demonstrated extremely good outcomes with 85% fetal survival; the development of preeclampsia was the major issue that affected the outcome of these pregnancies. Dialysis included short, daily dialysis, although the dialysis prescription was increased from baseline in all women, accounting for residual function in dialysis of those starting after conception. Not all reports have such good outcomes, but such pregnancies (mostly in women already receiving dialysis) now have one-half to two-thirds chance of fetal survival,[40] although with about 80% chance of prematurity.[41] These improved outcomes have been associated with more intensive dialysis regimens, and advances in neonatal care also allow survival for more premature and growth-restricted infants. Table 45-1 provides recommendations for managing hemodialysis during pregnancy.

Managing Hemodialysis During Pregnancy

Pre-pregnancy	
Discuss risks of pregnancy (miscarriage, fetal death, fetal growth restriction, prematurity, preeclampsia). Ensure all medications safe in pregnancy. Aspirin: 75-150 mg daily Folic acid: 5 mg daily	
During Pregnancy:	
Dialysis	20 h/wk in four or more sessions Aim for predialysis BUN >40 mg/dl (serum urea 15 mmol/l). Heparin requirement may increase because of hypercoagulability of pregnancy.
Anemia	Intravenous iron to maintain iron stores Dose ESA to achieve hemoglobin of 10-11 g/dl.
Bicarbonate	Adjust oral and dialysate bicarbonate to achieve normal serum bicarbonate for pregnancy (18-22 mmol/l).
Nutrition	Dietician advice to ensure adequate protein and nutrient intake Supplement oral or dialysate phosphate to maintain post-dialysis serum phosphate in normal range.
Calcium	Maintain normal serum calcium with additional oral calcium and vitamin D, as well as increased dialysate calcium. Hypercalcemia occasionally provoked by placental PTHrP and vitamin D–like substances.
Phosphate	Supplement oral or dialysate phosphate to maintain postdialysis serum phosphate in normal range.
After Pregnancy	
Return to usual dialysis schedule immediately. Readjust dry weight and antihypertensives weekly for 6 weeks.	

Table 45-1 Managing hemodialysis during pregnancy. *ACE,* Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *BUN,* blood urea nitrogen; *ESA,* erythropoiesis-stimulating agent; *PTHrP,* parathyroid hormone–related peptide.

Initiating Dialysis for Progressive Chronic Kidney Disease

A key question is when to initiate dialysis in women who have advanced CKD but are not yet receiving dialysis at the time of conception. It is generally recommended to commence dialysis at eGFR below 20 ml/min or BUN 50 mg/dl (serum urea >17 mmol/l) and aim for predialysis blood urea below 15 mmol/l (BUN 45 mg/dl).[42,43] The available data suggest that dialysis initiated during pregnancy is

associated with greater likelihood of successful pregnancy than with continuation of maintenance dialysis, probably because of the benefits of residual renal function.

Women Already Needing Regular Dialysis

Women of childbearing age undergoing dialysis have about a 1 in 20 chance of conceiving throughout their dialysis therapy.[44] Women of childbearing age receiving maintenance dialysis therefore need to be counseled about adequate contraception, particularly in view of the fairly poor outcomes of these pregnancies.

Dialysis Regimens in Pregnancy

Reports of successful pregnancy outcomes, although with high rates of preterm delivery and polyhydramnios, generally include intensified hemodialysis or peritoneal dialysis schedules. Daily hemodialysis may be necessary to achieve the biochemical goal of predialysis BUN of 15 mmol/l or less. Nocturnal hemodialysis may allow improved dialysis clearances with greater hemodynamic stability, improved fertility rates,[21] and good pregnancy outcomes in early reports.[45]

More intensive dialysis improves phosphate control. Phosphate binders become unnecessary, and additional oral phosphate or increased dialysate phosphate may be needed because of the intensified dialysis and the fetal requirements for phosphate.

Minimal data exist on specific requirements of women receiving peritoneal dialysis (PD) during pregnancy. There is no need to switch from PD to hemodialysis, even as the uterus enlarges. Dialysis adequacy can be maintained throughout pregnancy, although a major risk is that PD peritonitis may provoke premature labor or premature rupture of membranes. Other management necessary for a successful pregnancy outcome includes the following:

- Control of maternal BP, generally to 110 to 140/80 to 90 mm Hg. This is difficult to achieve in many women. First, despite little or no endogenous renal function, there still appears to be volume expansion in women on maintenance hemodialysis who become pregnant, as evidenced by anemia and fall in serum albumin. To date, no data recommend assessing volume status in dialysis patients during pregnancy by measurements such as ultrasound of inferior vena cava diameter or bioimpedance.
- Active management of anemia with iron and erythropoiesis-stimulating agents. Target hemoglobin value should be 10 to 11 g/dl.
- Detection and early treatment of sepsis, which may precipitate premature labor or premature rupture of membranes. For those with residual renal function, repeated urine cultures are required to detect and treat asymptomatic bacteriuria.

At least weekly surveillance of pregnant women receiving dialysis is required to optimize outcome. Dialysis intensity should be increased as much as practically possible, ensuring the biochemical goals are achieved. Fetal monitoring should include at least ultrasound scans every 2 to 4 weeks from the time of fetal viability, about 24 weeks' gestation.

RENAL TRANSPLANTATION AND PREGNANCY

Successful renal transplantation is an excellent way of restoring fertility in women with ESRD. It is therefore surprising that the pregnancy rate among female transplant recipients decreased by more than 50% between 1990 and 2003, unexplained by a change in age of women receiving transplant.[46] Women with transplants appear more likely to conceive if they are not diabetic or they have been receiving dialysis 3 or more years before transplant.

The key questions in relation to managing women with a renal transplant in pregnancy are whether the pregnancy will affect graft survival and whether fetal side effects will result from the transplant or the immunosuppressive drugs. Women should be advised to wait 12 months after a successful renal transplant before planning pregnancy, to ensure stable transplant function and maintenance immunosuppression. This interval is not based on solid data; indeed, one small study suggested that pregnancies even within 12 months of transplantation are as successful as those performed later.[47] One year seems a practical time for ensuring clinical stability, with optimal BP control and stable immunosuppression.

Immunosuppressive drugs considered safe in the transplant patient include prednisolone, azathioprine, and cyclosporine. Tacrolimus has been associated with neonatal hyperkalemia, but recent data support its safety. Mycophenolate is associated with embryotoxic effects and should be avoided in pregnancy, as should sirolimus.

A favorable view of pregnancy in women who have undergone successful renal transplantation was supported early on by observations in more than 3000 pregnancies from 2000 women mostly receiving azathioprine and prednisone.[48] About 15% of these pregnancies miscarried spontaneously, and of those continuing past the first trimester, pregnancy was successful in more than 90% of women, provided that hypertension or a decline in renal function had not occurred before 28 weeks' gestation, in which case successful pregnancy outcome was reduced to about 70%. Women with preconception serum creatinine less than 125 µmol/l had 96% pregnancy success, whereas those with higher serum creatinine had a 75% success rate. In keeping with the data for all women with CKD, long-term decline in renal function occurred significantly more often (27%) in those with preconception serum creatinine more than 125 µmol/l.

Hypertension, either accelerated from preexisting hypertension or *de novo* during pregnancy, is present in 58% to 72% of pregnant women. Even with these relatively good outcomes, 30% to 70% of women will have hypertension requiring treatment as the pregnancy progresses, sometimes with superimposed preeclampsia. Fetal growth restriction occurs in 40% to 50% and preterm delivery in as many as two thirds, with attendant long-term risks of prematurity.[49] Cesarean birth is necessary in approximately half of these women.

The United States National Transplantation Pregnancy Registry (NTPR) reported in 2008 on the outcomes of 1208 pregnancies from 781 women who had received kidney alone transplants.[50] This is a voluntary registry, so there is potential for reporting bias. The majority of women were taking cyclosporine or tacrolimus. The mean preconception serum creatinine level was 125 µmol/l. Overall live birth rates were about 75%, 30% had preeclampsia, and babies of these women were smaller, although mean birth weight was about 2500 g. Acute rejection occurred in 2% to 4% of pregnancies, and 5% of infants had a birth defect, comparable to that of the general population. Graft loss within 2 years ranged from 4% to 13%, and 20% to 30% of women had one or more of the following complications: death within 5 years of pregnancy, acute rejection during pregnancy or within 3 months postpartum, loss of graft function within 2 years postpartum, infant with a birth defect, or delivery very preterm (<33 weeks) or of very low birth weight (<1500 g). Box 45-6 summarizes maternal and fetal risks for pregnancy in women with a renal transplant.

There were higher risks in a study of 530 pregnancies in 483 women using U.S. Renal Data System (USRDS) Medicare data.[46]

Maternal and Fetal Outcomes in Renal Transplant Pregnancies

Maternal

- Long-term decline in glomerular filtration rate if preconception serum creatinine <1.4 mg/dl (125 μmol/l); rate of decline is not usually different from transplant women without pregnancy
- Graft loss in 5%-10% at 2 years postpartum
- Hypertension in about two thirds
- Rejection risk in 2%-4%
- Infection in 20%-35%
- Gestational diabetes mellitus in 10%

Fetal

- Overall live birth rate: 75%-80%
- Spontaneous miscarriage: 15%
- Prematurity: 50%
- Fetal growth restriction: 50%
- Birth defects in about 5%, probably no more than in the general population
- Long-term consequences of prematurity, although most infants have normal postnatal growth and development

Box 45-6 Maternal and fetal outcomes in renal transplant pregnancies.

Fetal loss was 45%, with spontaneous abortion rates between 20% and 35% and a stillbirth rate of 1.5%, higher rates than observed in UK or Australian analyses.[51,52] Overall, it seems that there is a high risk of miscarriage, but once past the first trimester, the pregnancy outcomes are quite good. Graft and patient survival are similar in those with and without any pregnancy over follow-up as long as 15 to 20 years, as observed with 577 pregnant women in the Australian and New Zealand data registry, most of whom had glomerulonephritis or reflux nephropathy as their primary diagnosis.[52]

An increase in serum creatinine after pregnancy has been associated with cyclosporine use, possibly because cyclosporine doses were increased during pregnancy as blood levels fell, presumably from the plasma volume expansion of pregnancy. However, it remains controversial whether cyclosporine or tacrolimus doses should be increased during pregnancy. It is not my practice to make dose adjustments unless there are marked deviations from the baseline blood level during pregnancy.

Acute transplant rejection is uncommon, reported in less than 1 in 20 cases. Presentation as acute graft dysfunction is no different in pregnancy; renal biopsy is required to confirm the diagnosis. There is an increased risk of infection (20% to 35%), particularly UTI but also cytomegalovirus infection, with attendant maternal and fetal risks. The consequences of any infection can include premature labor and preterm rupture of membranes. GDM occurs in 3% to 12% of these pregnancies, no more common in tacrolimus-treated women than in those receiving cyclosporine.

Recommendations remain uncertain regarding breastfeeding for women taking immunosuppressive agents. The decision to breastfeed must be an individual one, informing the woman that effects on the baby remain largely unknown but that breastfeeding may have considerable advantages, particularly in premature and growth-restricted babies. Box 45-7 summarizes recommendations for management of pregnancy in women with a renal transplant.

Outcomes of pregnancies fathered by male transplant recipients showed mean gestational age and mean birth weight similar to those of the general population.

General Management of Renal Transplant Patients During Pregnancy

Pre-pregnancy

- Stable graft function at least 1 year after transplantation.
- Discuss risks with transplant recipient and her partner.
- Best pregnancy outcome will occur if:
  - Pre-pregnancy serum creatinine <1 mg/dl (125 μmol/l)
  - Proteinuria <500 mg/day
  - Blood pressure <140/90 mm Hg
- Aspirin (75-150 mg/day) if creatinine ≥1.5 mg/dl (130 μmol/l) *or* 0.9-1.5 mg/dl (100-130 μmol/l) and proteinuria >1 g/day.
- Replace all medications that are not safe in pregnancy.
- Eradicate UTI before pregnancy; prophylactic antibiotics indicated if there has been recurrent UTI since transplant.
- Stable cyclosporine or tacrolimus blood levels.
- Test for and control diabetes.

During Pregnancy

- Visits every 2 weeks until 24 weeks' gestation (alternating between obstetrician and nephrologist), then weekly.
- Assess fetal growth by ultrasound at least every 4 weeks from 24 weeks' gestation.
- Do not adjust CNI dose during pregnancy unless there are extreme variations from stable pre-pregnancy levels.
- Screen for gestational diabetes at 28 weeks' gestation with 1-hour 50-g glucose challenge test.
- At each visit, assess BP (goal 110-140/80-90 mm Hg), proteinuria (dipstick, then PC ratio if dipstick result is positive), urine culture (if history of recurrent UTI, otherwise at 24, 28, and 32 weeks of gestation), electrolytes, creatinine, full blood count, CNI level, and fetal growth.
- Reassess at each visit whether there is an impending indication for delivery (see Box 45-5).

During Delivery

- Vaginal delivery is usually possible despite pelvic kidney.
- Prophylactic antibiotics are not required routinely.

Postpartum

- Monitor CNI and serum creatinine levels daily in hospital.
- Breastfeeding appears safe with CNI drugs, azathioprine, and corticosteroids, but discuss individual case with neonatologist.
- Review weekly or every other week for the first 3 months.

PREGNANCY IN THE KIDNEY DONOR

It is usually stated that being a kidney donor does not adversely affect future pregnancy outcomes in terms of fetal birth weight, stillbirth, or prematurity. However, recent studies suggest there may be an increased risk of preeclampsia in pregnancy after organ donation,[53] and that fetal outcomes may also be slightly worse.[54,55] These studies have some limitations, and pregnancy should not be discouraged in women who have been kidney donors. Rather, the key message is that all such women should be treated as "at-risk" pregnancies and should have a higher number of clinical reviews, focusing on maternal BP and urinalysis and fetal growth, than in normal, low-risk pregnancies.

COURSE OF CHRONIC KIDNEY DISEASE AFTER PREGNANCY

In a review of 49 women with stage 3 to 5 CKD before conception and whose pregnancy proceeded beyond 20 weeks, GFR was lower after pregnancy than before conception. This decrease was predicted by the combination of preconception GFR less than 40 ml/min and proteinuria more than 1 g/day, but not by GFR alone.[1]

The course of renal disease postpartum is unpredictable. Even some women with stable renal function throughout their pregnancy develop an acute deterioration postpartum. About 50% of women with moderate renal impairment (serum creatinine >1.5 mg/dl; 130 µmol/l) have a significant rise in serum creatinine in the third trimester or early postpartum, and if this occurs, almost one in five progress to ESRD within 6 months after delivery. Surveillance by the nephrologist therefore needs be just as diligent in the first 3 to 6 months postpartum as during pregnancy. ACE inhibitors or ARBs should be commenced soon after delivery for their antiproteinuric effect if GFR is stable.

Women with biopsy-proven kidney disease in Norway had slightly faster progression to ESRD if they were delivered preterm, but not if they had preeclampsia.[56] A neglected issue is the association between preterm birth/low birth weight and cardiovascular/renal disease later in life.[57] Many women with CKD are delivered prematurely, which in turn passes on risks of later renal disease to their offspring even if the renal disease is not hereditary. On balance, it is prudent to consider both preeclampsia and preterm delivery as risk factors for later kidney disease.

SUMMARY

Box 45-8 summarizes factors to consider in managing a pregnant woman with renal disease. Attention to these issues, from preconception through postpartum, can result in good pregnancy outcomes with preservation of maternal health. These women and often their offspring require lifelong assessment for progressive renal and cardiovascular disease.

Managing Women with Preexisting Renal Disease During Pregnancy

1. Women with chronic kidney disease should be managed by a team comprising obstetrician, nephrologist, and experienced midwife, preferable in a high-risk pregnancy clinic
2. Main determinants of pregnancy outcome are pre-pregnancy GFR, proteinuria, and blood pressure. These should be the focus in counseling
3. GFR should be estimated using serum creatinine and proteinuria using changes in spot urine PC ratio after calculation of initial ratio on 24-hour urine collection
4. Low-dose aspirin should be given to reduce risk of preeclampsia or perinatal death. Subcutaneous heparin if nephrotic syndrome develops
5. Primary issues during pregnancy are control of blood pressure, watching for emerging preeclampsia, and regular assessment of fetal well-being
6. An appropriate schedule of visits is every 2 weeks until 24 weeks' gestation (alternating between obstetrician and nephrologist) then weekly until delivery
7. Appropriate laboratory evaluations are:
   - Initial visit at 12 weeks' gestation: full blood count, serum creatinine and electrolytes, liver function, 24-hour urine PC ratio if proteinuria on dipstick testing
   - If baseline GFR normal, repeat at 24 weeks' gestation
   - If baseline GFR abnormal, repeat every 4 weeks
   - Midstream urine culture at 24, 28, and 32-34 weeks' gestation (monthly throughout pregnancy if woman has history of UTI)
8. Fetal assessment by ultrasound, in those with impaired GFR, or with heavy proteinuria
   - At 20 weeks: uterine artery pulsatility index b
   - Monthly from 24 weeks: fetal growth, blood flow, amniotic fluid index
9. Obstetric review at 6 weeks' postpartum, nephrology review within the first 4 weeks because impairment of renal function can occur after delivery. Transplant patients should be seen more often

SECTION VIII

Hereditary and Congenital Diseases of the Kidney

CHAPTER 46

Autosomal Dominant Polycystic Kidney Disease

Vicente E. Torres and Peter C. Harris

DEFINITION

Autosomal dominant polycystic kidney disease is a multisystem disorder characterized by multiple, bilateral renal cysts associated with cysts in other organs, such as liver, pancreas, and arachnoid membranes.[1] It is a genetic disorder caused by mutations in one of two different genes and is expressed in an autosomal dominant pattern, with variable expression. Although benign renal cysts are common, multiple bilateral cysts are not. Therefore, an underlying inherited disease should be considered in patients with normal renal function and multiple bilateral renal cysts.

ETIOLOGY AND PATHOGENESIS

The autosomal dominant polycystic kidney disease (ADPKD) proteins now known as polycystin-1 and polycystin-2 play a critical role in the normal function of the primary cilium that is essential to maintaining the differentiated phenotype of tubular epithelium.[2,3]

Genetic Mechanisms

Autosomal dominant polycystic kidney disease (ADPKD) is genetically heterogeneous with two genes identified (Fig. 46-1), *PKD1* (chromosome 16p13.3) and *PKD2* (4q21). Autosomal dominant polycystic liver disease (ADPLD) also exists as an independent entity and is genetically heterogeneous; the first two genes identified (*PRKCSH* in chromosome 19 and *SEC63* in chromosome 6) account for about one third of isolated ADPLD cases.

Evidence from animal models of ADPKD and analysis of cystic epithelia have shown that renal cysts may develop from loss of functional polycystin with somatic inactivation of the normal allele. However, cysts can develop even if the protein is not completely lost, as demonstrated by animal models expressing incompletely penetrant alleles.[4] Furthermore, transgenic rodents overexpressing *Pkd1* or *Pkd2* develop renal cystic disease, which suggests that multiple genetic mechanisms causing an imbalance in expression of polycystins can lead to the development of cysts.[2,3]

Polycystic Kidney Disease Proteins

Polycystin-1 (PC1) and polycystin-2 (PC2) belong to a subfamily of transient receptor potential (TRP) channels. PC1 (TRPP1; ~460 kd) has the structure of a receptor or adhesion molecule and contains a large extracellular N region, 11 transmembrane regions, and a short intracellular C region (Fig. 46-1). PC1 interacts with PC2 through a coiled-coil domain in the C-terminal portion and with multiple other proteins at different extracellular and intracellular sites. PC1 is found in the primary cilia, cytoplasmic vesicles, plasma membrane at focal adhesions, desmosomes, adherens junctions, and possibly endoplasmic reticulum and nuclei. PC1 may regulate the mechanical strength of adhesion between cells by controlling the formation of stabilized, actin-associated adherens junctions. PC2 (TRPP2; ~110 kd) contains a short N-terminal cytoplasmic region, six transmembrane domains, and a short C-terminal portion. PC2 is localized predominantly to the endoplasmic reticulum but also to the plasma membrane, primary cilium, centrosome, and mitotic spindles in dividing cells.[2,3] PC1 and PC2 are also found at high concentrations in exosomes, which are shed into the urine and physically interact with primary cilia, possibly exerting a urocrine function of cell-cell communication.[5]

Mechanisms of Cyst Formation

Experimental data indicate that the timing of ciliary loss or *Pkd1* inactivation determines the rate of development of cystic disease. Inactivation in the developing kidney results in rapid progression.[6] Cysts also develop rapidly in the corticomedullary region (pars recta and thick ascending limbs of Henle loop) of adult mouse kidneys subjected to ischemic injury to stimulate cell proliferation.[7]

The polycystins are involved in the detection of extracellular cues at primary cilia, cell-cell contacts, and cell-matrix contacts and are essential to maintain the differentiated phenotype of the tubular epithelium. Reduction in one of the polycystins below a critical threshold results in inability to maintain planar polarity, increased rates of proliferation and apoptosis, expression of a secretory phenotype, and remodeling of the extracellular matrix.[2,3] PC1 and PC2 in the primary cilium are required for a calcium transient in response to ciliary bending.[8] PC2 is a TRP channel (TRPP2), and functions as a calcium release channel in the endoplasmic reticulum.[9] PC1 interacts with and modulates the function of PC2. PC1 and PC2 also interact with additional calcium channel proteins. Precisely how intracellular calcium homeostasis is altered in ADPKD remains uncertain, but many studies show reduced resting intracellular calcium, endoplasmic reticulum calcium stores, and store-operated calcium entry in primary cell cultures or microdissected samples from human and rodent polycystic tissues[2-3] (Fig. 46-2).

A common finding in animal models of PKD is increased levels of cyclic adenosine monophosphate (cAMP), not only in the kidney but also in the liver and vascular smooth muscle.[10] Tissue levels of cAMP are determined by the activities of membrane-bound and soluble adenylyl cyclases (ACs) and cAMP phosphodiesterases (PDEs), themselves subject to complex regulatory mechanisms. Reduced intracellular calcium in PKD may activate calcium inhibitable AC6, directly inhibit calcium/calmodulin-dependent PDE1, and indirectly inhibit cGMP inhibitable PDE3, therefore accounting for the accumulation of cAMP and activation of protein kinase A (PKA),

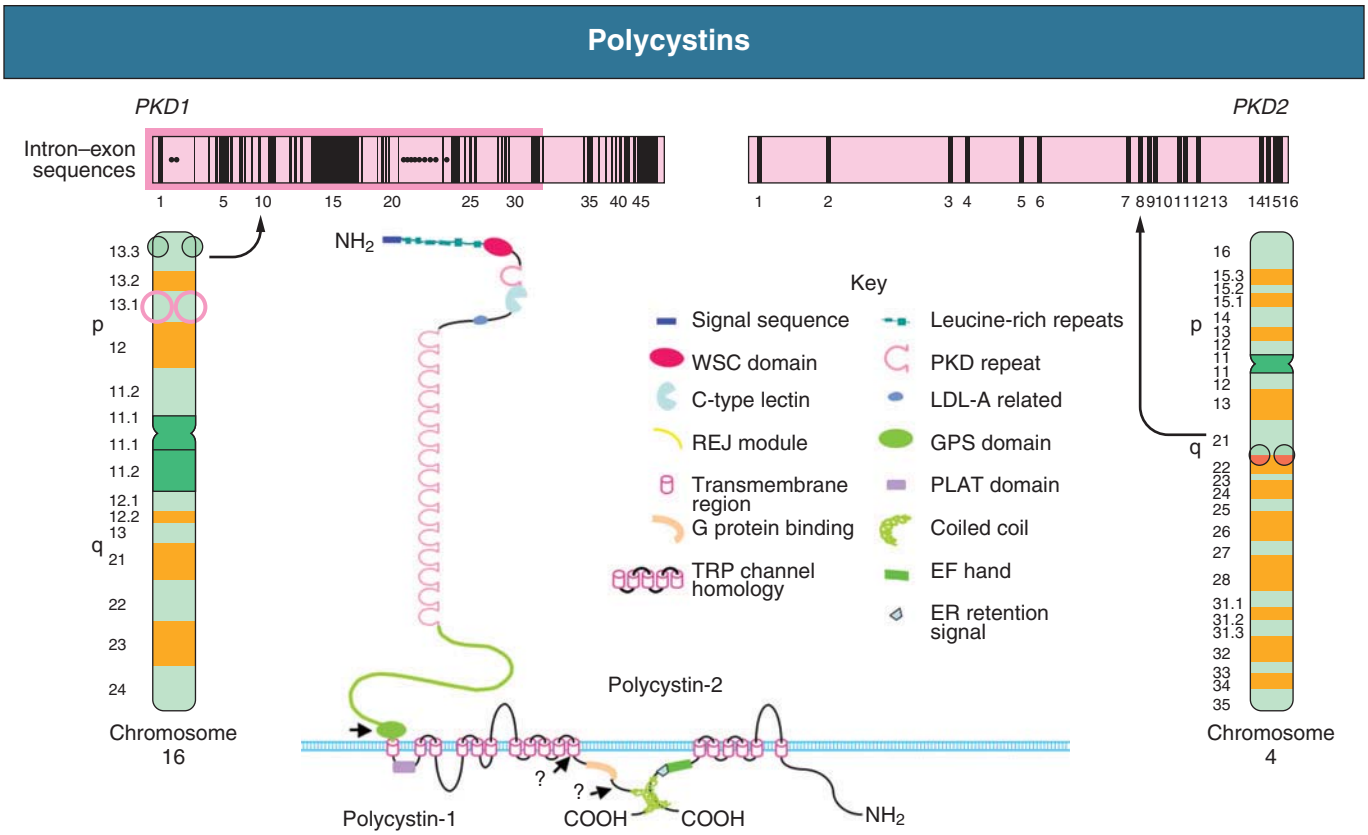

Figure 46-1 Polycystins: genes, messenger RNAs, and proteins. Diagrammatic representation of chromosome 16 *(left)* and chromosome 4 *(right)*. Intron-exon sequences of *PKD1 (upper left)* and *PKD2 (upper right)*. Diagram of proposed structural features of the polycystin-1 and polycystin-2 proteins *(center)*.

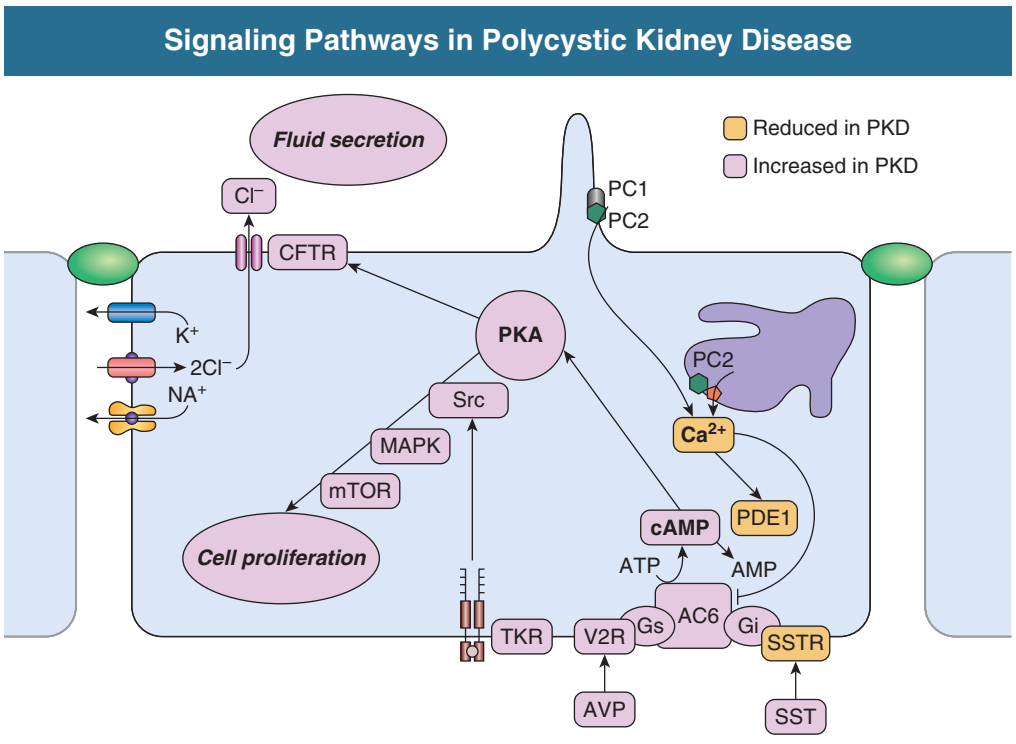

Figure 46-2 Signaling pathways in polycystic kidney disease (PKD). Pathways that are upregulated or downregulated in polycystic kidney disease and rationale for potential therapies. Dysregulation of intracellular calcium homeostasis leads to intracellular accumulation of cyclic adenosine monophosphate *(cAMP)*, activation of protein kinase A *(PKA)*, cystic fibrosis transmembrane conductance regulator *(CFTR)* phosphorylation, and stimulation of chloride-driven fluid secretion. In the setting of reduced intracellular calcium, PKA activates Src, mitogen-activated protein kinase *(MAPK)*/extracellular signal–regulated kinase (ERK), and mammalian target of rapamycin *(mTOR)* signaling. Activation of tyrosine kinase receptors *(TKR)* for several growth factors contributes to the activation of Src and downstream pro-proliferative pathways. Therapies currently under clinical investigation target G protein–coupled receptors (modulating activity of adenylyl cyclase 6 *[AC6]* and generation of cAMP), Src, mTOR, and TKRs. *AVP,* Arginine vasopressin; *PDE1*, phosphodiesterase-1; *SST,* somatostatin; *SSTR,* somatostatin receptor.

which in turn contributes to the development and progression of PKD by stimulating CFTR-driven chloride and fluid secretion and cell proliferation (Fig. 46-2).

Chloride enters across basolateral Na-K-2Cl cotransporters, driven by the sodium gradient generated by basolateral Na^+,K^+-ATPase, and exits across apical PKA–stimulated cystic fibrosis transmembrane conductance regulator (CFTR). Basolateral recycling of potassium occurs through the KCa3.1 channel.

Cyclic AMP exerts opposite effects on cell proliferation in different cell types. Cyclic AMP and PKA signaling enhance several pro-proliferative pathways (extracellular signal–regulated kinase, ERK) in cells derived from polycystic kidneys, while inhibiting proliferation in cells derived from normal human kidney cortex.[11,12] Treatment of normal human kidney or murine collecting duct cells with calcium channel blockers replicates the proliferative response of the ADPKD cells to cAMP, thus linking this response to the reduction in intracellular calcium that results from disrupting the polycystin pathway.[13] Conversely, treatment of ADPKD cyst derived cells with calcium channel activators or calcium ionophores restores the normal antimitogenic response to cAMP (Fig. 46-2). Activation of mTOR signaling downstream from PKA through ERK-mediated phosphorylation of tuberin has been linked to transcriptional activation of aerobic glycolysis, increased levels of adenosine triphosphate (ATP), and, together with ERK-dependent inhibition of liver kinase B1 (LKB1) and inhibition of AMP kinase (AMPK).[14-16]

Liver Cyst Development

Liver cysts arise by excessive proliferation and dilation of biliary ductules and peribiliary glands. Estrogen receptors, insulin-like growth factor 1 (IGF-1), IGF-1 receptors, and growth hormone receptor are expressed in the epithelium lining the hepatic cysts, and estrogens and IGF-1 stimulate hepatic cyst–derived cell proliferation.[17] Cyst growth is also promoted by growth factors and cytokines secreted into the cyst fluid.

Hypertension

Hypertension is a major clinical manifestation and predictor of outcome in ADPKD (see Clinical Manifestations). Several factors contribute to the development of hypertension in ADPKD. Activation of the intrarenal renin-angiotensin system (RAS) likely plays an important role, but controversy surrounds whether the circulating RAS is inappropriately activated.[18] The expression of PC1 and PC2 in vascular smooth muscle and endothelium, along with enhanced vascular smooth muscle contractility and impaired endothelium-dependent vasorelaxation in ADPKD, suggest that disruption of polycystin function directly contributes to hypertension. Other factors include increased sympathetic nerve activity and plasma endothelin-1 levels and insulin resistance.[19]

Endothelial vasodilation and constitutive nitric oxide synthase (NOS) activity are reduced in subcutaneous resistance vessels from patients with ADPKD and normal glomerular filtration rate (GFR). Flow-induced vasodilation of the brachial artery is inconsistently impaired, whereas pulse wave reflection is amplified, suggesting a predominant involvement of small resistance vessels. Reduced coronary flow velocity reserve and increased carotid intima-media thickness in normotensive patients with normal GFR suggest that atherosclerosis starts early in the course of ADPKD.[20]

Reduced nitric oxide (NO) endothelium-dependent vasorelaxation in ADPKD may be caused by increased plasma levels of asymmetric dimethylarginine, a mechanism common to all hypertension associated with kidney disease (see Chapter 82).

EPIDEMIOLOGY

Autosomal dominant PKD occurs worldwide and in all races, with a prevalence of genetically affected individuals at birth estimated at 1:400 to 1:1000.[1] In most patients, however, the diagnosis is made decades later, and some patients are never diagnosed. Therefore, at any point in time, only a fraction of genetically affected individuals are aware of having the disease. The percentage of end-stage renal disease (ESRD) caused by ADPKD is less among African Americans than among Caucasians because of a higher incidence of other causes of ESRD. Yearly incidence rates for ESRD caused by ADPKD in men and women, respectively, are 8.7 and 6.9 per 1 million (1998 to 2001, United States), 7.8 and 6.0 per million (1998 and 1999, Europe), and 5.6 and 4.0 per million (1999 and 2000, Japan). Age-adjusted gender ratios greater than unity (1.2 to 1.3) suggest more progressive disease in men than in women. In recent studies, the age of patients with ESRD has increased in both genders; the age-adjusted male-female ratio for onset of ESRD has trended toward unity; and all-cause mortality has decreased, possibly because of improved detection and control of hypertension.[21,22]

PHENOTYPIC VARIABILITY

Genic, allelic, and gene-modifier effects contribute to the high phenotypic variability of ADPKD. *PKD1*-associated disease is more severe than *PKD2*-associated disease (age at ESRD, 54 years vs. 74 years for *PKD1* and *PKD2,* respectively). The greater severity of *PKD1* is caused by development of more cysts at an early age, not faster cyst growth.[23] Both *PKD1* and *PKD2* can be associated with severe polycystic liver disease and vascular abnormalities. Because of the lesser severity of the renal involvement, the prevalence of *PKD2*-associated disease has likely been underestimated in clinical studies.

Mutations in *PKD1* and *PKD2* are highly variable and usually "private" (unique to a kindred). The ADPKD Mutation Database (http://pkdb.mayo.edu) lists 868 truncating *PKD1* mutations identified in 1243 families with a total of 2322 variants, including missense mutations and silent polymorphisms. Also, 162 *PKD2* truncating mutations are listed in 278 families, with a total of 374 different variants.

Allelic factors (mutation type or location) have an effect on the severity of ADPKD. Patients with mutations in the 5′ region of *PKD1* were found to have more severe disease than patients with 3′ mutations. More recent studies in larger cohorts have shown that the type of *PKD1* mutation, but not its position, correlates strongly with renal survival. The median age at onset of ESRD was 55 years for carriers of a truncating mutation and 67 years for carriers of a nontruncating mutation.[24] Hypomorphic or incompletely penetrant *PKD1* or *PKD2* alleles have been described.[25] These alleles alone may result in mild cystic disease; two such alleles cause typical to severe disease and in combination with an inactivating allele, may be associated with early-onset disease that mimics ARPKD.[26]

The large intrafamilial variability of ADPKD highlights a role for genetic background in disease presentation. Age at clinical manifestations in ADPKD is less variable within than between families, which suggests a common familial modifying background for early and severe disease expression (e.g., mutations or variants in genes encoding other cystoproteins). The contiguous deletion of the adjacent *PKD1* and *TSC2* is characterized by childhood PKD with additional clinical signs of tuberous sclerosis complex. Other modifying loci are likely to account for more common and subtle intrafamilial variability.

DIAGNOSIS

Only individuals who have been properly informed about the advantages and disadvantages of screening should be offered presymptomatic screening. If ADPKD is diagnosed, the patient should receive appropriate genetic counseling, and risk factors such as hypertension can be identified and treated early. If ADPKD is absent, the patient can be reassured. Disadvantages of presymptomatic screening relate to insurability and employability. Presymptomatic screening of children is not recommended, but this advice will likely change when more effective therapy for the disease becomes available.

Renal Ultrasound

Renal ultrasound is used for presymptomatic testing because of cost and safety. Revised criteria have been proposed to improve the diagnostic performance of ultrasound in ADPKD (Table 46-1). At least three (unilateral or bilateral) renal cysts and two cysts in each kidney are sufficient for diagnosis of at-risk individuals age 15 to 39 and 40 to 59 years, respectively.[27] For at-risk individuals age 60 and older, four or more cysts in each kidney are required.

Whereas the overall specificity and positive predictive value (PPV) of ultrasound are high by use of these criteria, their sensitivity and negative predictive value (NPV) when applied to *PKD2* patients age 15 to 59 are low. This is a problem in the evaluation of potential kidney donors, in which exclusion of the diagnosis is important.[17] Different criteria have therefore been proposed to exclude a diagnosis of ADPKD in an individual at risk from a family with an unknown genotype. An ultrasound finding of normal kidneys or one renal cyst in an individual age 40 or older has an NPV of 100%. The absence of any renal cyst provides near certainty that ADPKD is absent in at-risk individuals age 30 to 39, with a false-negative rate of 0.7% and NPV of 98.7%. A normal or indeterminate ultrasound scan does not exclude ADPKD with certainty in an at-risk individual younger than 30; normal magnetic resonance imaging (MRI) or contrast-enhanced computed tomography (CT) provides further assurance, but data are insufficient to quantify its predictive accuracy.

Ultrasound Criteria for the Diagnosis of ADPKD

Age (years)	Criteria	PPV	NPV
Original Ravine's PKD1 Diagnostic Criteria			
15-29	≥2 cysts, unilateral or bilateral	99	88
30-39	≥2 cysts in each kidney	100	88
40-59	≥2 cysts in each kidney	100	95
≥60	≥4 cysts in each kidney	100	100
Revised Unified Diagnostic Criteria			
15-29	≥3 cysts, unilateral or bilateral	100	86
30-39	≥3 cysts, unilateral or bilateral	100	86
40-59	≥2 cysts in each kidney	100	95
≥60	≥4 cysts in each kidney	100	100
Revised Criteria for Exclusion of Diagnosis			
15-29	≥1 cyst	97	91
30-39	≥1 cyst	94	98
40-59	≥2 cysts	97	100
≥60	≥3 cysts in each kidney	100	100

Genetic Testing

Genetic testing can be performed when a precise diagnosis is needed and the results of imaging are indeterminate. However, there are limitations to genetic testing, by either linkage or mutation analysis. Linkage analysis requires accurate diagnosis and the availability and willingness of sufficient affected family members to be tested; it is feasible in less than 50% of families. *De novo* mutations can also complicate interpretation of results. Molecular testing by direct DNA sequencing is now informative in about 90% of patients.[28] However, because most mutations are unique and up to one third of *PKD1* changes are missense, the pathogenicity of some changes is difficult to prove.

In preimplantation genetic diagnosis, genetic analysis is performed on single blastomeres from preimplantation embryo biopsy specimens obtained after *in vitro* fertilization (IVF), and only embryos unaffected by the disease are selected for transfer. Preimplantation genetic diagnosis for ADPKD is complicated by the genetic heterogeneity of the disease and by the large size and complex structure of the *PKD1* gene. Demand is limited in this late-onset disorder, and it has been performed in very few cases.

DIFFERENTIAL DIAGNOSIS

Renal cystic disease can be a manifestation of many other systemic diseases. Conditions to consider when renal cystic disease is detected but presentation is not typical of ADPKD include autosomal recessive PKD, tuberous sclerosis complex, von Hippel–Lindau disease, renal cysts and diabetes (RCAD) from *HNF1β* mutations, and oro-faciodigital syndrome type I, as well as medullary sponge kidney and simple renal cysts. These are discussed further, including differential diagnosis, in Chapter 47. If the patient has ESRD, acquired cystic disease should also be considered (see Chapter 89).

CLINICAL MANIFESTATIONS

Autosomal dominant PKD is a multisystem disorder. Multiple renal and extrarenal manifestations of ADPKD have been described that cause significant complications.

Renal Manifestations

A number of clinical features that result from renal damage can be identified (Box 46-1). Reduction in urinary concentrating capacity and glomerular hyperfiltration are early functional abnormalities that can be observed in some children and adolescents with ADPKD.

Renal Size

Renal size increases with age, and renal enlargement eventually occurs in 100% of patients with ADPKD. The severity of the structural abnormality correlates with the manifestations of ADPKD, such as pain, hematuria, hypertension, and renal impairment.[29] Massive renal enlargement can lead to compression of local structures, resulting in such complications as inferior vena cava (IVC) compression and digestive symptoms. Most manifestations are directly related to the development and enlargement of renal cysts. The Consortium for Radiologic Imaging Studies of Polycystic Kidney Disease (CRISP), a prospective study of 241 patients by annual MRI,

Renal Manifestations of Autosomal Dominant Polycystic Kidney Disease

Functional Manifestations
Concentrating defect
Reduced renal blood flow

Hypertension → Target Organ Damage
Cardiac
Cerebrovascular
Arteriolosclerosis and glomerulosclerosis
Peripheral vascular disease

Pain, Caused by
Cyst hemorrhage
Gross hematuria
Nephrolithiasis
Infection
Renal enlargement

Renal Failure, Possibly Caused by
Interstitial inflammation
Apoptosis of tubular epithelial cells
Hypertensive glomerulosclerosis
Compression atrophy

Box 46-1 Renal manifestations of autosomal dominant polycystic kidney disease (ADPKD).

has shown that total kidney volume and cyst volumes increased exponentially.[30] Rates of growth were relatively constant, averaging 5.3% per year, but highly variable from patient to patient. Baseline total kidney volume predicted the subsequent rate of increase in renal volume and decline in GFR.[31]

Pain

Episodes of acute renal pain are seen frequently; causes include cyst hemorrhage, infection, stone, and rarely tumor, and these must be investigated thoroughly. A few ADPKD patients with renal enlargement and structural distortion develop chronic flank pain without specifically identifiable etiology.

Hematuria and Cyst Hemorrhage

Visible hematuria may be the initial presenting symptom and occurs in up to 40% of ADPKD patients over the course of the disease. Many have recurrent episodes. Differential diagnosis includes cyst hemorrhage, stone, infection, and tumor. Cyst hemorrhage is a frequent complication and produces gross hematuria when the cyst communicates with the collecting system. Frequently, the cyst does not communicate with the collecting system, and flank pain without hematuria occurs. It can present with fever, raising the possibility of cyst infection. On occasion, a hemorrhagic cyst will rupture, resulting in a retroperitoneal bleed that can be significant, potentially requiring transfusion. In most patients, cyst hemorrhage is self-limited, resolving within 2 to 7 days. If symptoms of hematuria or flank pain last longer than 1 week or if the initial episode of hematuria occurs after age 50 years, investigation to exclude neoplasm should be undertaken.

Urinary Tract Infection and Cyst Infection

Urinary tract infection (UTI) is common in ADPKD, but its incidence may have been overestimated because sterile pyuria is common in these patients. UTI presents as cystitis, acute pyelonephritis, cyst infection, and perinephric abscesses. As in the general population, women are affected more frequently than men. Most infections are caused by *Escherichia coli, Klebsiella* and *Proteus* species, and other Enterobacteriaceae. The route of infection in acute pyelonephritis and cyst infection is usually retrograde from the bladder; therefore, cystitis should be promptly treated to prevent complicated infections.

Both CT and MRI are sensitive to detect complicated cysts and to provide anatomic definition, but the findings are not specific for infection. Nuclear imaging, especially indium-labeled white blood cell scanning, is useful, but false-negative and false-positive results are possible. ^{18}F-labeled fluorodeoxyglucose (FDG) positron emission tomography (PET) has recently been used for detection of infected cysts.[32] FDG is taken up by inflammatory cells because of their high metabolic rate but is filtered by the kidneys, is not reabsorbed, and appears in the collecting system, which may limit its use in diagnosis of renal cyst infections; its present role is for diagnosis of infected liver cysts. FDG PET is expensive and not yet widely available, but it provides rapid imaging with high spatial resolution, high target-background ratio, low radiation burden, and high interobserver agreement.

When there is fever and flank pain with suggestive diagnostic imaging but blood and urine cultures are negative, cyst aspiration under ultrasound or CT guidance should be undertaken to culture the organism and to assist in selection of antimicrobial therapy.

Nephrolithiasis

Renal stone disease occurs in about 20% of patients with ADPKD. Most stones are composed of uric acid, calcium oxalate, or both. Uric acid stones are more common in ADPKD than in stone formers without ADPKD. Urinary stasis secondary to distorted renal anatomy may play a role in the pathogenesis of nephrolithiasis. Predisposing metabolic factors include decreased ammonia excretion, low urinary pH, and low urinary citrate concentration.[1]

Stones can be difficult to diagnose on imaging in ADPKD because of cyst wall and parenchymal calcification. The distorted anatomy can cause difficulty in localizing stones to the collecting system on plain films. Intravenous (IV) urography has the advantage of specifically localizing stone material to the collecting system and may provide clues to stone composition. IV urography can also detect pericalyceal tubular ectasia, found in 15% of ADPKD patients. CT scanning is more sensitive in detecting small or radiolucent stones and for differentiating stones from tumor, clot, and cyst wall or parenchymal calcification. Dual-energy CT is increasingly used to distinguish between calcium and uric acid stones.

Hypertension

Hypertension is the most common manifestation of ADPKD and a major contributor to renal disease progression and cardiovascular morbidity and mortality (Fig. 46-3). Microalbuminuria, proteinuria, and hematuria, which are independent risk factors for renal functional decline, are more common in hypertensive patients with ADPKD. Hypertension may also increase morbidity from valvular heart disease and intracranial aneurysms, which are common in ADPKD.

Ambulatory blood pressure (BP) monitoring of children or young adults without diagnosed hypertension often reveals elevated BP, attenuated nocturnal BP dipping, and exaggerated BP response during exercise. A study stratified 65 children by BP into three cohorts: hypertensive (≥95th percentile), borderline hypertensive (75th to 95th percentile), and normotensive (≤75th percentile).[33] Both the hypertensive and the borderline hypertensive children had

significantly higher left ventricular mass indices than the normotensive children. Among normotensive children, indices were significantly higher in those within the upper quartile of normal BP. These observations suggest that target organ damage develops early in ADPKD and that antihypertensive treatment may be indicated in children with ADPKD and borderline hypertension.

End-Stage Renal Disease

In most patients, renal function is maintained within the normal range, despite relentless growth of cysts, until the fourth to sixth decade of life. By the time renal function starts declining, the kidneys usually are greatly enlarged and distorted with little recognizable parenchyma on imaging studies. At this stage, the average rate of GFR decline is 4.4 to 5.9 ml/min per year. Nevertheless, ESRD is not inevitable in ADPKD. Up to 77% of patients are alive with preserved renal function at age 50 years, and 52% at age 73. Men tend to progress to renal failure more rapidly and require renal replacement therapy at a younger age than women. Other risk factors for renal failure include black race, diagnosis of ADPKD before age 30, first episode of hematuria before age 30, onset of hypertension before age 35, hyperlipidemia, low level of high-density lipoprotein cholesterol, and sickle cell trait.

Several mechanisms account for renal function decline. The CRISP study has confirmed that kidney and cyst volumes are the strongest predictors of renal functional decline.[31] CRISP also found that renal blood flow (or vascular resistance) is an independent predictor.[34] This points to the importance of vascular remodeling in the progression of the disease and may account for cases in which the decline of renal function seems disproportionate to the severity of the cystic disease. Other factors, such as heavy use of analgesics, may contribute to chronic kidney disease progression in some patients.

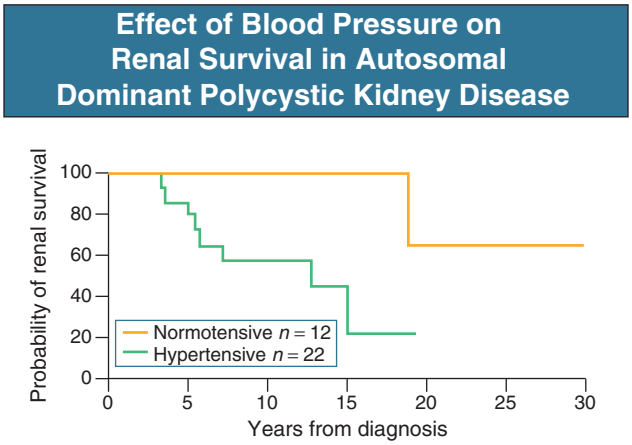

Figure 46-3 Patients with polycystic kidney disease and hypertension at diagnosis have less probability of renal survival than those with normal blood pressure. *(From reference 62.)*

Extrarenal Manifestations

Polycystic Liver Disease

Polycystic liver disease (PLD) is the most common extrarenal manifestation of ADPKD. PLD is associated with both *PKD1* and *PKD2* genotypes. In addition, PLD also occurs as a genetically distinct disease in the absence of renal cysts. Most simple hepatic cysts are solitary, and PLD should be suspected when four or more cysts are present in the hepatic parenchyma. The liver in PLD contains multiple microscopic or macroscopic cysts that result in hepatomegaly (Fig. 46-4), but typically there is preservation of normal hepatic parenchyma and liver function.

Hepatic cysts are exceedingly rare in children with ADPKD. Their frequency increases with age and may have been underestimated by ultrasound and CT studies. Their prevalence by MRI in the CRISP study was 58%, 85%, and 94%, respectively, in participants age 15 to 24, 25 to 34, and 35 to 46 years.[35] Women develop more cysts at an earlier age than men. Women who have multiple pregnancies or who have used oral contraceptives (OCs) or estrogen replacement therapy (ERT) in the postmenopausal period have worse disease.

Typically, PLD is asymptomatic, but reported symptoms have become more frequent as the life span of ADPKD patients is prolonged with dialysis and transplantation. Symptoms result from mass effect or from complications related to the cysts themselves.[36] Symptoms typically caused by massive enlargement of the liver or by mass effect from a single or a limited number of dominant cysts include dyspnea, orthopnea, early satiety, gastroesophageal reflux, mechanical low back pain, uterine prolapse, and even rib fracture. Other complications caused directly by mass effect include hepatic venous outflow obstruction, IVC compression, portal vein compression, and bile duct compression presenting as obstructive jaundice. Hepatic venous outflow obstruction is an uncommon condition caused by severe extrinsic compression of the intrahepatic IVC and hepatic veins by cysts, rarely with superimposed thrombosis. Symptomatic cyst complications include cyst hemorrhage, which occurs less frequently than renal cyst hemorrhage; cyst infection; and the rare occurrence of torsion or rupture of cysts. Hepatic cyst infection can be a serious complication and typically presents with localized pain, fever, leukocytosis, elevated sedimentation rate, and often elevated

alkaline phosphatase. Enterobacteriaceae are the most common microorganisms causing cyst infection. The same imaging techniques discussed for the investigation of renal cyst infections may be useful for the localization of infected cysts in the liver.

Congenital hepatic fibrosis (CHF), always found in association with autosomal recessive PKD, can rarely coexist with autosomal dominant PKD.[37] Contrary to PKD, which affects members of several generations in these families, CHF is seen in only one generation and is not transmitted vertically, suggesting the importance of modifier genes. These patients present with manifestations of portal hypertension, but hepatocellular function is normal.

Intracranial Aneurysms

Intracranial aneurysms occur in about 8% of patients with ADPKD. There is some familial clustering; intracranial aneurysms occur in 6% of patients with a negative family history and 16% of those with a positive family history.[38] Most are asymptomatic. Focal findings, such as cranial nerve palsy and seizure, may result from compression of local structures by an enlarging aneurysm (Fig. 46-5). Yearly rupture rates increase with size, ranging from less than 0.5% for aneurysms smaller than 5 mm in diameter to 4% for aneurysms larger than 10 mm. Rupture carries a 35% to 55% risk for combined severe morbidity and mortality. The mean age at rupture in ADPKD is 39 years (vs. 51 years in general population), with a range of 15 to 69 years. Most patients have normal renal function, and up to 29% have normal BP at rupture.

Screening is not indicated for all patients with ADPKD because most intracranial aneurysms found by presymptomatic screening are small, have a low risk for rupture, and require no treatment because the risks of intervention exceed any risk of rupture.[39] Indications for screening in patients with a good life expectancy include family history of intracranial aneurysm or subarachnoid hemorrhage, previous aneurysmal rupture, preparation for elective surgery with potential hemodynamic instability, high-risk occupations (e.g., airline pilots), and significant patient anxiety despite adequate information about the risks. MR angiography is the diagnostic imaging modality of choice for presymptomatic screening because it is noninvasive and does not require IV contrast administration. CT angiography is a satisfactory alternative if there is no contraindication to IV contrast.

Other Vascular Abnormalities

In addition to intracranial aneurysms, ADPKD has been associated with other vascular abnormalities, such as thoracic aortic and cervicocephalic arterial dissections, coronary artery aneurysms, and retinal artery and vein occlusions (Fig. 46-6). Thoracic aortic dissection is seven times more common in ADPKD than in the general population in autopsy series, but reported cases are rare. Rare patients with coronary aneurysms can present with cardiac ischemia and thrombus in the aneurysm in the absence of atherosclerotic disease. Several case reports describe abdominal aortic aneurysms in ADPKD. However, a prospective ultrasound study showed neither a wider aortic diameter nor a higher prevalence of abdominal aortic aneurysms in ADPKD patients compared with unaffected kindred in any age group.

Valvular Heart Disease and Other Cardiac Manifestations

Mitral valve prolapse is the most common valvular abnormality and has been demonstrated in up to 25% of ADPKD patients by echocardiography. Mitral regurgitation, tricuspid regurgitation, and tricuspid prolapse also occur more frequently in ADPKD than in unaffected kindred. Aortic regurgitation may be associated with

dilation of the aortic root. On histologic examination, valvular tissue shows myxoid degeneration with disruption of collagen, as seen in Marfan and Ehlers-Danlos syndromes. Although the lesions may progress with time, they rarely require valve replacement. Screening echocardiography is not indicated unless a murmur is detected on physical examination. Small, hemodynamically insignificant pericardial effusion can be detected by CT scanning in up to 35% of ADPKD patients.[1]

Other Associated Conditions

Cyst formation has been described in such diverse organs as the pancreas, seminal vesicles, and arachnoid membrane (Fig. 46-7). Seminal vesicle cysts, usually multiple and bilateral, are found in 40% of ADPKD compared with 2% of nonaffected males. Ovarian cysts are not associated with ADPKD. Pancreas and arachnoid membrane cysts are present in 5% and 8% of patients, respectively. Pancreatic cysts are almost always asymptomatic, with rare occurrences of recurrent pancreatitis and possibly chance associations of intraductal papillary mucinous tumor or carcinoma. Epididymal and prostate cysts may also occur with increased frequency. Sperm abnormalities with defective motility are common in ADPKD and rarely may be a cause of male infertility. Spinal meningeal diverticula may occur with increased frequency and rarely present with intracranial hypotension (orthostatic headache, diplopia, hearing loss, ataxia) caused by cerebrospinal fluid (CSF) leak. The prevalence of colonic and duodenal diverticula may also be increased.[1]

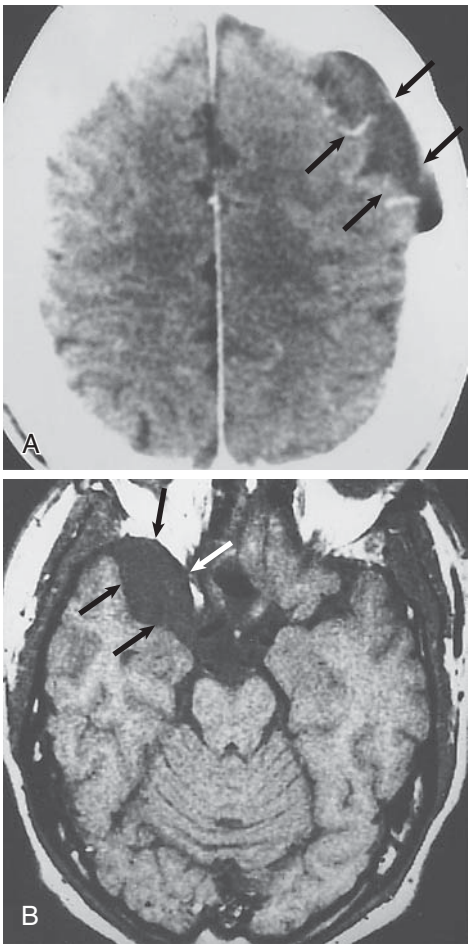

Figure 46-7 Extrarenal manifestations of autosomal dominant polycystic kidney disease. Computed tomography (**A**) and magnetic resonance imaging (**B**) scans demonstrate cysts in the arachnoid membrane *(arrows)* in ADPKD.

PATHOLOGY

Polycystic kidneys are diffusely cystic and enlarged (Fig. 46-8). Size varies from normal to weighing more than 4 kg. The outer and cut surfaces show numerous spherical cysts of varying size, which are distributed evenly between cortex and medulla. The collecting system typically is distorted. The epithelium lining the cysts is characterized by hyperplastic changes, including flat nonpolypoid hyperplasia, polypoid hyperplasia, and microscopic adenomas (Fig. 46-9),

Figure 46-8 Polycystic kidneys. Greatly enlarged polycystic kidneys from a patient with ADPKD compared with a normal kidney *(middle)*.

A, Effects on relief of pain. **B,** Rate of decline of renal function. *Orange lines* indicate the course of renal function in individual patients who underwent cyst fenestration at month 0. *(From reference 63.)*

as well as increased rates of cell proliferation and apoptosis. Despite the frequency of hyperplastic lesions and microscopic adenomas, the incidence of renal cell carcinoma is not increased.

Cysts arise from all segments of the nephron and collecting ducts. As they grow, cysts dissociate from the parent tubule and eventually become isolated, fluid-filled sacs. There is no agreement on whether the cysts originate preferentially from particular tubular segments. Most studies indicate that cysts are predominantly of distal nephron and collecting duct origin. Studies in advanced renal disease showing proximal tubular cysts may be confounded by the effects of obstruction and acquired renal cystic disease.

Polycystic kidneys demonstrate advanced sclerosis of preglomerular vessels, interstitial fibrosis, and tubular epithelial hyperplasia, even in patients with normal renal function or early renal failure. Sclerosis involves both afferent arterioles and interlobular arteries. Interstitial fibrosis is also prominent, even in early disease. It is associated with an interstitial infiltrate of macrophages and lymphocytes.

TREATMENT

Current therapy is directed toward the renal and extrarenal complications of ADPKD in an effort to limit morbidity and mortality. Advances in the understanding of the genetics of ADPKD and mechanisms of cyst development and growth have raised hopes for treatments specifically directed toward limiting the development and progression of the disease, and some of these treatments are now being evaluated in clinical trials (see Novel Therapies).

Flank Pain

Causes of flank pain that may require intervention, such as infection, stone, and tumor, should be excluded. Care should be taken to avoid long-term administration of nephrotoxic agents, such as combination analgesics and nonsteroidal anti-inflammatory drugs. Narcotic analgesics should be reserved for the management of acute pain. Patients with chronic kidney pain are at risk for narcotic and analgesic dependence, and a psychological evaluation and a supportive attitude by the physician are essential. Reassurance, lifestyle modification, and avoidance of aggravating activities may be helpful. Tricyclic antidepressants are helpful as in other chronic pain syndromes, with a generally well-tolerated side effect profile. Splanchnic nerve blockade with local anesthesia or corticosteroids results in pain relief prolonged beyond the duration of the local anesthetic.

When distortion of the kidneys by large cysts is deemed responsible for the pain and conservative measures fail, cyst decompression should be considered. Cyst aspiration, under ultrasound or CT guidance, is a relatively simple procedure. To prevent the reaccumulation of cyst fluid, sclerosing agents such as 95% ethanol or acidic solutions of minocycline may be used. Minor complications include microhematuria, localized pain, transient fever, and systemic absorption of the alcohol. More serious complications, such as pneumothorax, perirenal hematoma, arteriovenous fistula, urinoma, and infection, are rare. Complications from aspiration of centrally located cysts are more common, and the morbidity of the procedure is proportional to the number of cysts treated.

If multiple cysts are contributing to pain, laparoscopic or surgical cyst fenestration may be of benefit. Surgical decompression is effective in 80% to 90% of patients at 1 year, and 62% to 77% have sustained pain relief for more than 2 years (Fig. 46-10, *A*). Surgical intervention does not accelerate the decline in renal function, as once thought, but does not appear to preserve declining renal function either (Fig. 46-10, *B*). Laparoscopic fenestration is as effective as open surgical fenestration in short-term follow-up in patients with limited disease, and there is a shorter, less complicated recovery period compared with open surgery. Previous abdominal surgery with possible adhesion formation is a relative contraindication to the procedure.

There are a number of other interventions for the management of pain in ADPKD whose roles have not been fully defined. Laparoscopic renal denervation has been used in combination with cyst fenestration and may be considered, particularly in polycystic kidneys without large cysts. A nonrandomized, open-label, uncontrolled trial of video thoracoscopic sympatho-splanchnicectomy is under way (www.clinicaltrials.gov, NCT00571909). Laparoscopic and retroperitoneoscopic nephrectomy and arterial embolization have been used to treat symptomatic polycystic kidneys in ADPKD patients with ESRD.

Cyst Hemorrhage

Episodes of cyst hemorrhage are self-limited, and patients respond well to conservative management with bed rest, analgesics, and adequate fluid intake to prevent obstructing clots. Rarely, bleeding is more severe, with extensive subcapsular or retroperitoneal hematoma causing significant decrease in hematocrit and hemodynamic instability. This requires hospitalization and transfusion. The antifibrinolytic agent tranexamic acid has been successfully used in some patients, but no controlled studies have been performed.[40] The dose needs to be reduced in the presence of renal impairment. Potential adverse effects of tranexamic acid therapy include glomerular thrombosis and ureteral obstruction from clots. In patients with unusually severe or persistent hemorrhage, segmental arterial

embolization can be successful. If not, surgery may be required to control bleeding.

Urinary Tract and Cyst Infection

Because most renal cyst infections begin as cystitis, prompt treatment of symptomatic cystitis and asymptomatic bacteriuria is indicated to prevent retrograde seeding of the renal parenchyma. Antibiotics that require glomerular filtration, such as highly polar aminoglycosides, are not effective for upper UTI in severe renal impairment. Cyst infection is often difficult to treat despite prolonged therapy with an antibiotic to which the organism is susceptible. Treatment failure occurs if antibiotics do not penetrate the cyst epithelium and achieve therapeutic concentrations within the cysts. Lipophilic agents have been shown to penetrate cysts reliably and have a pK_a that allows favorable electrochemical gradients into acidic cyst fluid. Therapeutic agents of choice include trimethoprim-sulfamethoxazole and fluoroquinolones, both of which have favorable intracystic therapeutic concentration gradients at physiologic pH in gradient and nongradient cysts.

If fever persists after 1 to 2 weeks of appropriate antimicrobial therapy, percutaneous or surgical drainage of infected cysts should be undertaken. In the case of end-stage polycystic kidneys, nephrectomy should be considered. If fever recurs after stopping antibiotics, complicating features such as obstruction, perinephric abscess, and stone should be excluded. If no such complicating features are identified, the antibiotic course should be extended and may require several months to fully eradicate infection.

Nephrolithiasis

Treatment of nephrolithiasis in patients with ADPKD is the same as that in patients without ADPKD. Potassium citrate is the treatment of choice in the three stone-forming conditions associated with ADPKD: uric acid lithiasis, hypocitraturic calcium oxalate nephrolithiasis, and distal acidification defects. Extracorporeal shock wave lithotripsy and percutaneous nephrostolithotomy are reported to be 82% and 80% successful, respectively, without increased complications compared to patients without ADPKD.[41] Flexible ureterorenoscopy with laser fragmentation has also been used safely and effectively and cannot cause traumatic nephron loss.[42,43]

Hypertension

Control of hypertension is essential because uncontrolled hypertension accelerates the decline in renal function and aggravates extrarenal complications. Antihypertensive agents of choice and optimal blood pressure targets in ADPKD have not been established. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) increase renal blood flow in ADPKD, have a low side effect profile, and may have renoprotective properties that go beyond BP control. Although studies have failed to demonstrate a beneficial effect of ACE inhibitors on the progression of ADPKD, these studies have been limited by the use of low drug dosages, small numbers of patients, short duration of follow-up, and inclusion of patients with widely different renal function. An ongoing study (HALT PKD) is designed to determine whether combined therapy with an ACE inhibitor and an ARB is superior to an ACE inhibitor alone in delaying the progression of the cystic disease in patients with preserved renal function or in slowing the decline of renal function in patients with chronic kidney disease (CKD) stage 3. HALT PKD will also determine whether a low BP target is superior to a standard BP target in patients with preserved renal function.[44] Although these definitive studies are needed, on available evidence, we recommend tight BP control to 125/75 mm Hg with a regimen that includes ACE inhibitors or ARBs.

Progressive Renal Failure

General strategies to delay progression of CKD are discussed in Chapter 80. A subgroup analysis of the Modification of Diet in Renal Disease (MDRD) study showed no beneficial effect on renal function in ADPKD of strict versus standard BP control and marginal benefit of a very-low-protein diet. A long-term follow-up of participants in this study, however, showed that individuals with ADPKD randomized to a low BP target (mean arterial pressure [MAP] <92 mm Hg) experienced significantly less ESRD and combined ESRD/death than those randomized to the usual BP target (MAP <107 mm Hg).[45]

Based on evidence suggesting that increased vasopressin effect on the kidney and cAMP levels are involved in cyst progression and on preclinical studies, the ingestion of supplemental water sufficient to achieve a low urinary osmolality below 250 mOsm/kg H_2O has been recommended for ADPKD patients with an estimated GFR greater than 30 ml/min, although there are no randomized controlled trials (RCTs) to support the value of this approach.[46,47] Exclusions would include severe protein or sodium restriction, volume contraction, or reduced effective intravascular volume, taking diuretics or drugs enhancing the release of arginine vasopressin (AVP), or presenting abnormal voiding or urologic problems. Serum sodium concentration should be monitored.

Patients with ADPKD have reduced morbidity and mortality on dialysis compared to patients with ESRD from other causes. Women appear to do better than men. The good outcome in ADPKD may result from higher endogenous erythropoietin production and better maintenance of hemoglobin, or lower comorbidity. Rarely, hemodialysis can be complicated by intradialytic hypotension if there is IVC compression by a medially located renal cyst. Despite renal size, peritoneal dialysis can usually be performed in ADPKD, although there is increased risk for inguinal and umbilical hernias, which require surgical repair.

Polycystic Liver Disease

Usually asymptomatic, PLD requires no treatment. When symptomatic, therapy is directed toward reducing cyst volume and hepatic size. Noninvasive measures include avoiding ethanol, other hepatotoxins, and possibly cAMP agonists (e.g., caffeine), which have been shown to stimulate cyst fluid secretion *in vitro*. Histamine H_2 blockers and somatostatin have been suggested to reduce secretion of secretin and secretory activity of cyst walls. Estrogens are likely to contribute to cyst growth, but the use of OCs and postmenopausal ERT are contraindicated only if the liver is significantly enlarged and the risk for further hepatic cyst growth outweighs the benefits of estrogen therapy. Rarely, symptomatic PLD may require invasive measures to reduce cyst volume and hepatic size. Options include percutaneous cyst aspiration and sclerosis, laparoscopic fenestration, and open surgical fenestration.[48] Cyst aspiration is the procedure of choice if symptoms are caused by one or a few dominant cysts or by cysts that are easily accessible to percutaneous intervention. To prevent the reaccumulation of cyst fluid, sclerosis with minocycline or 95% ethanol is often successful. Laparoscopic fenestration can be considered for large cysts that are more likely to recur after ethanol sclerosis, or if several cysts are present that would require multiple percutaneous passes to be treated adequately. Partial hepatectomy with cyst fenestration is an option because PLD often spares a part of the liver with adequate preservation of hepatic parenchyma and

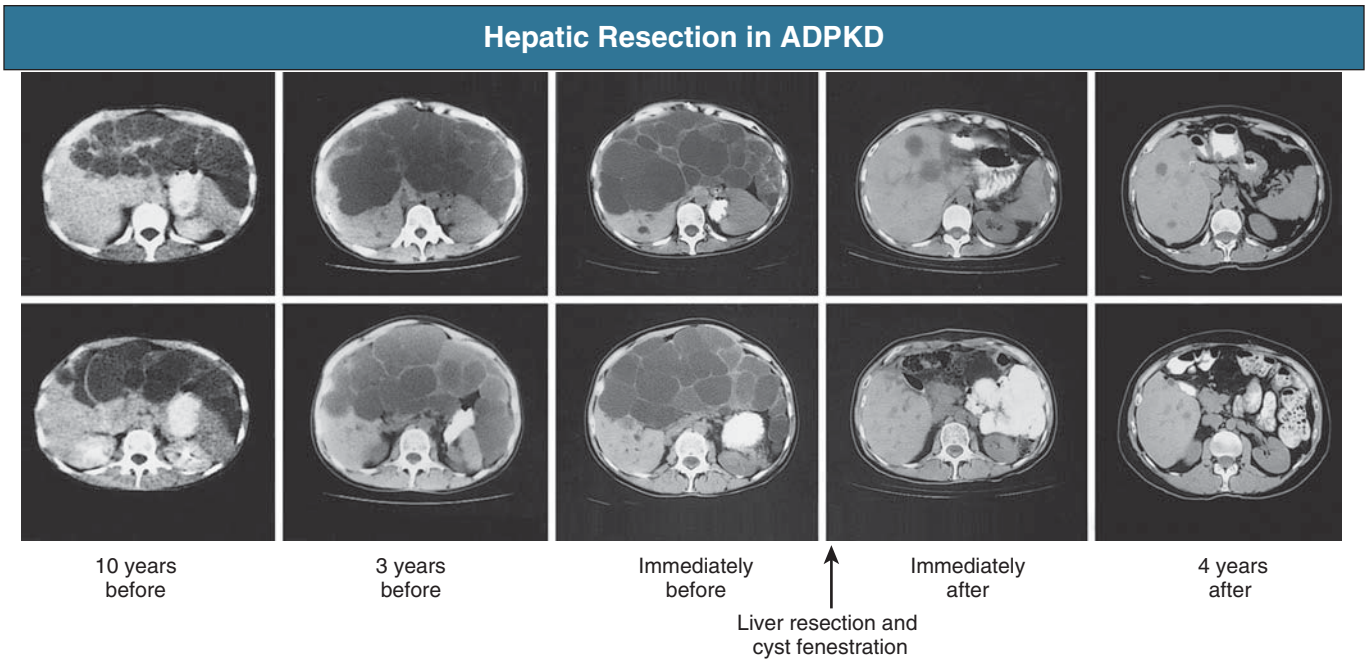

Figure 46-11 Hepatic resection in autosomal dominant polycystic kidney disease. CT scans of the abdomen 10 years before (column 1), 3 years before (column 2), immediately before (column 3), immediately after (column 4), and 4 years after (column 5) liver resection and cyst fenestration, demonstrating long-term, sustained reduction in liver size after the procedure. *(From reference 64.)*

liver function (Fig. 46-11). In the rare case in which no segments are spared, liver transplantation may be necessary.

When a hepatic cyst infection is suspected, any cyst with unusual appearance on an imaging study should be aspirated for diagnostic purposes. The best management is percutaneous cyst drainage in combination with antibiotic therapy. Long-term oral antibiotic suppression or prophylaxis should be reserved for relapsing or recurrent cases. Antibiotics of choice are trimethoprim-sulfamethoxazole and the fluoroquinolones, which are effective against the typical infecting organisms and concentrate in the biliary tree and cysts.

Intracranial Aneurysm

Ruptured or symptomatic intracranial aneurysm requires surgical clipping of the neck of the aneurysm. Asymptomatic aneurysms measuring less than 5 mm, diagnosed by presymptomatic screening, can be observed with repeated MR angiography at 6 months, then annually and less frequently after stability of the aneurysm has been established. If the size increases, surgery is indicated. Definitive management of aneurysms between 6 and 9 mm remains controversial. Surgical intervention is usually indicated for all unruptured aneurysms 10 mm in diameter or larger. For patients with high surgical risk or with technically difficult lesions, endovascular treatment with detachable platinum coils may be indicated.[39]

NOVEL THERAPIES

A better understanding of the pathophysiology and the availability of animal models have facilitated the development of promising candidate drugs for clinical trials (see Fig. 46-2).

Vasopressin Antagonists

The effect of vasopressin, through V_2 receptors, on cAMP levels in the collecting duct, the major site of cyst development in ADPKD, and the role of cAMP in cystogenesis provided the rationale for successful preclinical trials of vasopressin V_2 receptor antagonists.[2,3] High water intake by itself also exerted a protective effect on the development of PKD in PCK rats, probably because of suppression of vasopressin. Genetic elimination of AVP in these rats yielded animals born with normal kidneys that remained relatively free of cysts unless an exogenous V_2 receptor agonist was administered.[49]

In a large, Phase III parallel-arm RCT in ADPKD patients with estimated creatinine clearance above 60 ml/min, a split daily dose of *tolvaptan* administered over 3 years slowed the increase in kidney volume and decline in kidney function and lowered the frequency of ADPKD-related adverse events (kidney pain, hematuria, UTI).[50] However, tolvaptan was associated with a higher frequency of aquaresis-related adverse events (polyuria, thirst, urinary frequency) that led to drug discontinuation in 8.3% of tolvaptan-treated patients. More important, clinically significant increases in liver enzymes (>2.5 times the upper limit of normal) were seen in 4.9% of tolvaptan-treated versus 1.2% of placebo-treated patients and led to discontinuation of the drug in 1.8% of patients taking tolvaptan and 0.2% of the placebo group. Moderate increases in serum sodium and uric acid levels were also seen more frequently in the patients taking tolvaptan. At present, tolvaptan is not approved for ADPKD therapy and should not be used outside of an approved research study. The value of tolvaptan as a long-term treatment in ADPKD patients will depend on the balance between benefits and risks. Patients taking tolvaptan should have easy access to and be able to tolerate water. Liver function should be monitored closely during therapy. Serum sodium and uric acid require monitoring. Efficacy in more advanced stages of disease has not yet been thoroughly ascertained.

Somatostatin Analogues

Somatostatin acting on somatostatin receptors inhibits cAMP accumulation not only in the kidney but also in the liver. Somatostatin has a half-life of approximately 3 minutes, so more stable synthetic

peptides (octreotide, lanreotide, pasireotide) have been developed for clinical use, which vary in stability and receptor affinity. In preclinical studies, these drugs reduced cAMP levels and proliferation of cholangiocytes *in vitro,* expansion of liver cysts in three-dimensional collagen culture, and development of kidney and liver cysts and fibrosis in animal models orthologous to ARPKD and ADPKD. Three small RCTs of octreotide or lanreotide have been completed.[51-54] Two have been extended as open-label, uncontrolled studies.[55-57] The published studies have shown similar results. Kidney growth is halted during the first year of treatment and then resumes, possibly at a lower rate than without treatment. Liver volume decreases by 4% to 6% during the first year of treatment, and this reduction is sustained during the second year. Observation periods have been too short to assess an effect on renal function. Another study has shown that the addition of everolimus to treatment with octreotide does not provide added benefit.[57] Additional clinical trials of somatostatin analogues for ADPKD and for PLD are currently active. Octreotide and lanreotide are generally well tolerated. Self-resolving abdominal cramps and loose stools are common in the first few days following the injections. Other adverse effects include injection site granuloma and pain, cholelithiasis, steatorrhea, weight loss, and rarely hair loss.

mTOR Inhibitors

The mammalian target of rapamycin (mTOR) is activated in animal models of PKD. Patients with the contiguous *PKD1/TSC2* gene syndrome exhibit a more severe form of PKD than those with ADPKD alone. This observation suggests a convergence of signaling pathways downstream from PC1 and the TSC proteins tuberin and hamartin that control the activity of mTOR. Studies in three rodent models of PKD have shown that the mTOR inhibitors sirolimus and everolimus significantly impair cyst expansion and protect renal function. Small retrospective studies of ADPKD patients after transplantation have shown a significant reduction in the volume of the polycystic kidneys or polycystic liver in patients treated with sirolimus compared with patients treated with calcineurin inhibitors. However, two large randomized trials using everolimus and sirolimus for 18 to 24 months have not consistently delayed the increase in kidney size or slowed the decline in progressive renal impairment.[58,59]

Other Investigational Therapies

Other strategies targeting molecular mechanisms that are altered in PKD have shown promising results in animal studies. A Phase II, multicenter, double-blind RCT of the Src inhibitor bosutinib and a Phase I and II clinical trial of the multikinase inhibitor KD019 are ongoing. Other possible therapies not yet assessed in clinical studies include AMP-activated protein kinase (metformin), PPARγ agonists, and inhibitors of channels required for chloride secretion (CFTR inhibitors, KCa3.1 inhibitor), tumor necrosis factor receptor antagonist, and inhibitors of MEK or cyclin-dependent kinases (see Fig. 46-2).

TRANSPLANTATION

Transplantation is the treatment of choice for ESRD in patients with ADPKD. There is no difference in patient or graft survival between ADPKD patients and other ESRD populations. Living donor transplants also have graft survival no different from that of non-ADPKD populations. However, living related transplantation has only recently been widely practiced in the ADPKD population. In 1999, 30% of kidney transplants for ADPKD patients were from living donors in the United States, compared with 12% in 1990.

Complications after transplantation are no greater in the ADPKD population than in the general population, and specific complications directly related to ADPKD are rare. Cyst infection is not increased after transplantation, and there is no significant increase in the incidence of symptomatic mitral valve prolapse or hepatic cyst infection. One study showed an increased rate of diverticulosis and bowel perforation in ADPKD. Whether ADPKD increases the risk for development of new-onset diabetes mellitus after transplantation is controversial.

Although practiced routinely in the past, pretransplantation nephrectomy has fallen out of favor. By 1 and 3 years after renal transplantation, kidney volumes decrease by 37.7% and 40.6%, whereas liver volumes increase by 8.6% and 21.4%, respectively.[60] Indications for nephrectomy include a history of infected cysts, frequent bleeding, severe hypertension, and massive renal enlargement with extension into the pelvis. No evidence shows an increased risk for development of renal cell carcinoma in native ADPKD kidneys after transplantation. When nephrectomy is indicated, hand-assisted laparoscopic nephrectomy is associated with less intraoperative blood loss, less postoperative pain, and faster recovery compared with open nephrectomy and is increasingly being used.

CHAPTER 47

Other Cystic Kidney Diseases

Lisa M. Guay-Woodford

In addition to autosomal dominant polycystic kidney disease (ADPKD), numerous other disorders share renal cysts as a common feature[1,2] (Table 47-1). These disorders may be inherited or acquired; their manifestations may be confined to the kidney or expressed systemically. They may present at a wide range of ages, from the perinatal period to old age (Fig. 47-1). The renal cysts may be single or multiple, and the associated renal morbidity may range from clinical insignificance to progressive parenchymal destruction with resultant renal impairment.

The clinical context often helps distinguish these renal cystic disorders from one another. Echogenic, enlarged kidneys in a neonate or infant should suggest autosomal recessive polycystic kidney disease (ARPKD), ADPKD, tuberous sclerosis complex (TSC), or one of the many congenital syndromes associated with renal cystic disease. Renal impairment in an adolescent suggests juvenile nephronophthisis–medullary cystic disease complex or ARPKD as possible etiologies. The finding of a solitary cyst in a 5-year-old child may indicate a calyceal diverticulum, whereas this finding in a 50-year-old patient is most compatible with a simple renal cyst. Renal stones occur in ADPKD and medullary sponge kidneys. For disorders with systemic manifestations, such as ADPKD, TSC, and von Hippel–Lindau disease, the associated extrarenal features may provide other important differential diagnostic clues.

For an increasing number of the single-gene disorders, genetic testing is available in expert laboratories around the world. Genetic testing resources are listed at Gene Tests (http://www.genetests.org) and the U.S. National Institutes of Health (NIH) Genetic Testing Registry (http://www.ncbi.nlm.nih.gov/gtr).

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

Definition

Autosomal recessive polycystic kidney disease (ARPKD) is a severe, typically early-onset form of cystic disease that primarily involves the kidneys and biliary tract. Affected patients have a spectrum of clinical phenotypes that depend in part on the age at presentation.[3]

Etiology and Pathogenesis

Genetic Basis of ARPKD

All typical forms of ARPKD are caused by mutations in a single gene, *PKHD1* (polycystic kidney and hepatic disease), which encodes multiple, alternatively spliced isoforms predicted to form both membrane-bound and secreted proteins.[4] The largest protein product of *PKHD1*, the fibrocystin/polyductin complex (FPC), contains one membrane-spanning domain and an intracellular C-terminal tail. FPC localizes, at least in part, to the primary cilium and the centrosome in renal epithelial cells.[5] The basic defects observed in ARPKD suggest that FPC mediates the terminal differentiation of the collecting duct and biliary tract. However, the exact function of the numerous isoforms has not been defined, and the widely varying clinical spectrum of ARPKD may depend partly on the nature and number of splice variants that are disrupted by specific *PKHD1* mutations.

Pathogenetic Mechanisms

ARPKD typically begins *in utero,* and the renal cystic lesion appears to be superimposed on a normal developmental sequence. The tubular abnormality primarily involves fusiform and/or saccular dilation of the collecting ducts. Microdissection studies have excluded tubular obstruction as a primary pathogenic mechanism. The biliary lesion involves defective remodeling of the ductal plate *in utero*. As a result, primitive bile duct configurations persist, and progressive portal fibrosis evolves.[6] The remainder of the liver parenchyma develops normally. The defect in ductal plate remodeling is accompanied by abnormalities in the branching of the portal vein. The resulting histopathologic pattern is termed *congenital hepatic fibrosis.*

Autosomal recessive PKD is one of a number of renal cystic diseases associated with congenital hepatic fibrosis, prompting these disorders to be described as *hepatorenal fibrocystic diseases.*[7] The primary cilium appears to play a central role in the pathogenesis ARPKD and other hepatorenal fibrocystic diseases,[8] and thus this set of disorders is encompassed under the broader term *ciliopathies,* in which dysfunction of the cilia-centrosome complex appears to underpin the development of a wide array of phenotypes including renal cystic disease.[9]

Epidemiology

The estimated incidence of ARPKD is 1 per 20,000 live births. It occurs more frequently in Caucasians than in other ethnic populations.[3]

Clinical Manifestations

The clinical spectrum of ARPKD is variable. The majority of cases are identified either *in utero* or at birth. The most severely affected fetuses have enlarged echogenic kidneys and oligohydramnios caused by poor fetal urine output. These fetuses develop the "Potter" phenotype, with pulmonary hypoplasia, a characteristic facies, and deformities of the spine and limbs. At birth, these neonates often have a critical degree of pulmonary hypoplasia that is incompatible with survival. The estimated perinatal mortality is about 30%. Although frequently compromised, renal function is rarely a cause of neonatal death.

For those who survive the first month of life, the reported mean 5-year patient survival is 85% to 90%.[3,10] Morbidity and mortality results from severe systemic hypertension, renal impairment, and portal hypertension from portal-tract hyperplasia and fibrosis.[3,10,11]

Hypertension usually develops in the first several months and ultimately affects 70% to 80% of patients. ARPKD patients have defects in both urinary diluting capacity and concentrating capacity. Newborns can have hyponatremia, presumably resulting from defects in free water excretion.[3] Net acid excretion may be reduced, but metabolic acidosis is not a significant clinical feature.[12] Retrospective studies have noted an increased incidence of pyuria on urinalysis, as well as culture-confirmed urinary tract infections (UTIs).[3]

In the first 6 months of life, ARPKD infants may have a transient improvement in glomerular filtration rate (GFR) caused by renal maturation. Subsequently, a progressive but variable decline in renal function occurs, with patients presenting in the first month of life progressing more rapidly to end-stage renal disease (ESRD) than those presenting at more than one month of age.[12] With advances in effective therapy for ESRD, prolonged survival is common, and for many patients the hepatic complications become the predominant clinical issue.

On average, infants with serum creatinine values above 2.2 mg/dl (200 µmol/l) progress to ESRD within 5 years, but this is highly variable. In longitudinal studies, the probability of renal survival without ESRD is about 85% at 1 year, 70% at 10 years, 65% at 15 years, and 40% at 20 years.[10,11]

In children who present later in childhood or in adolescence, portal hypertension is frequently the predominant clinical abnormality, with hepatosplenomegaly and bleeding esophageal or gastric varices, as well as hypersplenism with consequent thrombocytopenia, anemia, and leukopenia. Hepatocellular function is usually preserved. Ascending suppurative cholangitis is a serious complication and can cause fulminant hepatic failure.[13,14]

Other associated features include growth restriction,[3] although the mechanism is not yet defined, and rarely intracranial aneurysms.[15]

Table 47-1 Renal cystic disorders. http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM. *MSK is generally considered to be a sporadic disorder, but recent studies provide evidence for familial clustering, involving autosomal dominant inheritance with reduced disease penetrance and variability in disease expression.[44]

Pathology

Kidney

The renal involvement is invariably bilateral and largely symmetric. The histopathology varies depending on the age of presentation and the extent of cystic involvement (Fig. 47-2, *A* and *B*).

In the affected neonate, the kidneys can be 10 times normal size but can retain the typical kidney contour. Dilated, fusiform collecting ducts extend radially through the cortex. In the medulla, the dilated collecting ducts are more often cut tangentially or transversely. Up to 90% of the collecting ducts are involved. Associated interstitial fibrosis is minimal in neonates and infants, but increases with progressive disease.

In patients diagnosed later in childhood, the kidney size and extent of cystic involvement tend to be more limited. Cysts can

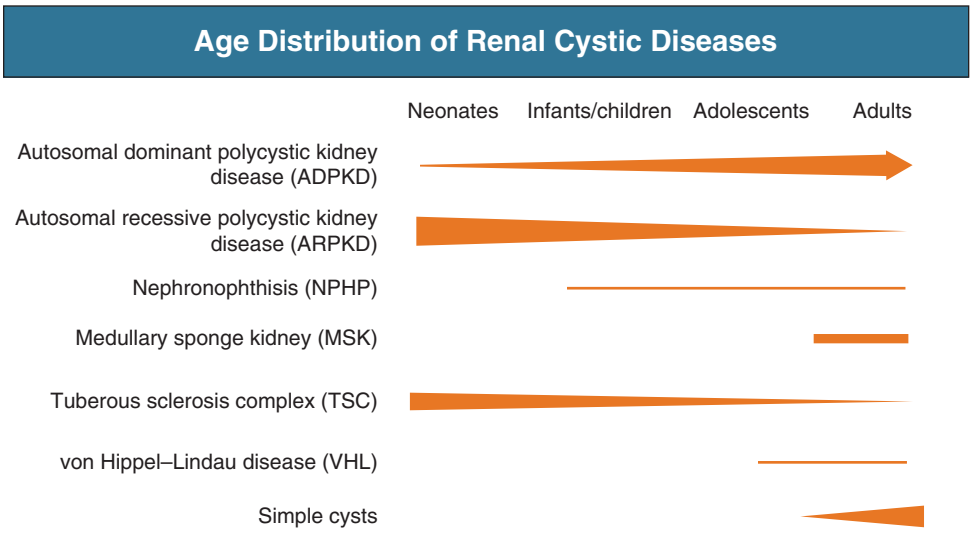

Figure 47-1 Age distribution of patients with renal cystic disorders.

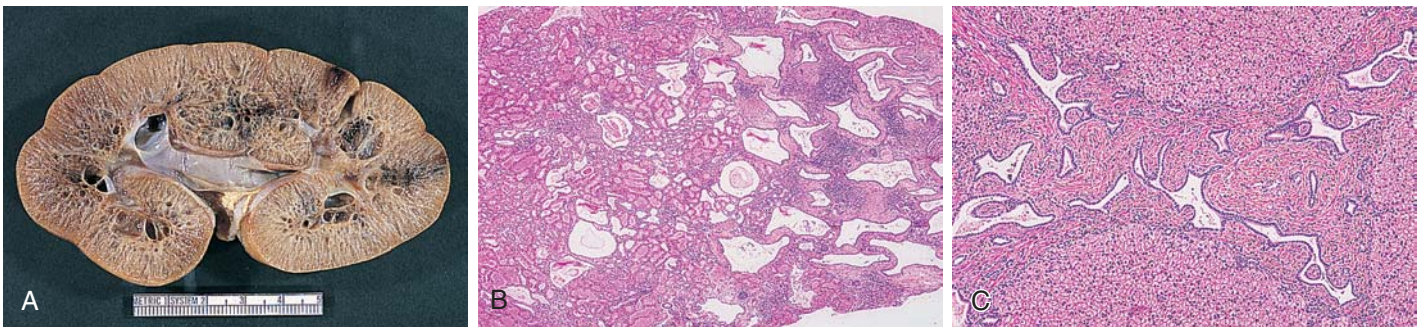

Figure 47-2 Pathologic features of autosomal recessive polycystic kidney disease. A, Cut section of ARPKD kidney from 1-year-old child shows discrete medullary cysts and dilated collecting ducts. **B,** Light microscopy shows later-onset ARPKD kidney with prominent medullary ductal ectasia (hematoxylin-eosin [HE] stain; magnification ×10). **C,** Light microscopy of congenital hepatic fibrosis shows extensive fibrosis of the portal area with ectatic, tortuous bile ducts and hypoplasia of the portal vein (HE stain; ×40).

expand up to 2 cm in diameter and assume a more spherical configuration. Progressive interstitial fibrosis is probably responsible for secondary tubular obstruction. In older children, medullary ductal ectasia is the predominant finding.

Cysts are lined with a single layer of nondescript cuboidal epithelium. The glomeruli and nephron segments proximal to the collecting ducts are initially structurally normal, but are often crowded between ectatic collecting ducts or displaced into subcapsular wedges. The presence of cartilage or other dysplastic elements indicates a diagnosis other than ARPKD, such as cystic dysplasia.

Liver

The liver lesion in ARPKD is characterized by ductal plate malformation.[6] The liver can be either normal in size or somewhat enlarged. Bile ducts are dilated (biliary ectasia) and marked cystic dilation of the entire intrahepatic biliary system (Caroli syndrome) is well described.[16] In neonatal ARPKD, the bile ducts are increased in number, tortuous in configuration, and often located around the periphery of the portal tract. In older children, the biliary ectasia is accompanied by increasing portal tract fibrosis and hypoplasia of the small portal vein branches (Fig. 47-2, *C*). The hepatic parenchyma may be intersected by delicate fibrous septa that link the portal tracts, but the hepatocytes themselves are seldom affected.

Diagnosis

Autosomal recessive PKD must be differentiated from a range of other pediatric renal cystic disorders (Table 47-2).

Imaging

In the past decade, clinical diagnosis has increasingly relied on imaging instead of histopathologic analysis. ARPKD belongs to the hepatorenal fibrocystic diseases,[7] most of which are characterized by large, echogenic kidneys in the fetus and neonate. However, recent studies indicate that to a large extent these disorders can be distinguished by ultrasound.[17] ARPKD kidneys *in utero* are hyperechogenic and display *decreased* corticomedullary differentiation because of the hyperechogenic medulla (Fig. 47-3, *A*). With high-resolution ultrasound, the radial array of dilated collecting ducts may be imaged. In comparison, ADPKD kidneys *in utero* tend to be moderately enlarged with a hyperechogenic cortex and relatively hypoechogenic medulla causing *increased* corticomedullary differentiation.

Kidney size typically peaks at 1 to 2 years of age, then gradually declines relative to the child's body size, and stabilizes by 4 to 5 years.

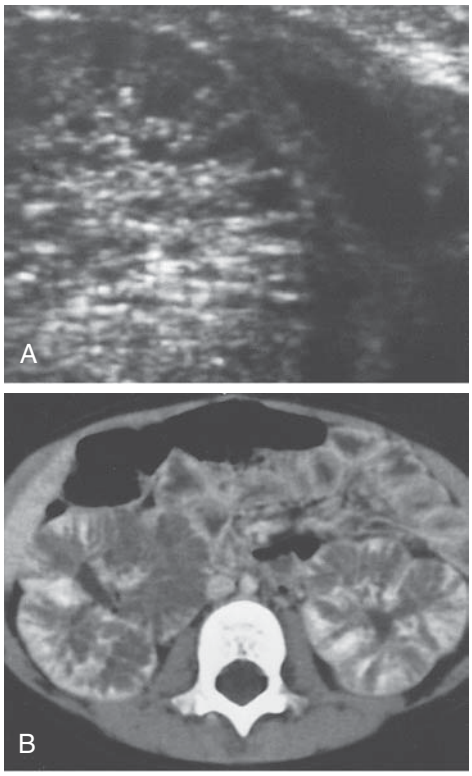

Figure 47-3 Radiologic findings associated with autosomal recessive polycystic kidney disease. A, ARPKD in a neonate. High-resolution ultrasound reveals radially arrayed dilated collecting ducts. **B,** ARPKD in symptomatic 4-year-old girl. Contrast-enhanced CT shows striated nephrogram and prolonged corticomedullary differentiation.

As patients age, there is increased medullary echogenicity, with scattered small cysts measuring less than 2 cm in diameter. These cysts and progressive fibrosis can alter the usual kidney contour, causing ARPKD in some older children to be mistaken for ADPKD. Contrast-enhanced computed tomography (CT) scanning can be useful in delineating the renal architecture in these children (Fig. 47-3, *B*). Bilateral pelvicaliectasis and renal calcifications have been reported in 25% and 50% of ARPKD patients, respectively.[11,18] In adults with medullary ectasia alone, the cystic lesion may be confused with medullary sponge kidney.

The liver may be either normal in size or enlarged. It is usually less echogenic than the kidneys. Prominent intrahepatic bile duct

Table 47-2 Features of pediatric renal cystic disease. *ARPKD,* Autosomal recessive polycystic kidney disease; *CM,* corticomedullary. [1]Meckel-Gruber syndrome (MKS) is a severe, often lethal autosomal recessive disorder characterized by bilateral renal cystic dysplasia, biliary ductal dysgenesis, bilateral postaxial polydactyly, and variable central nervous system (CNS) malformations. The triad of renal cystic disease, occipital encephalocele, and polydactyly is most common. Genes disrupted in MKS have also been identified in nephronophthisis (NPHP) and Joubert patients, suggesting a phenotypic spectrum. [2]Glomerulocystic kidney disease (GCKD) can occur as the infantile manifestation of autosomal dominant polycystic kidney disease (ADPKD). Familial hypoplastic GCKD, caused by mutations in *TCF2*, the gene encoding hepatocyte nuclear factor (HNF-1β), can be associated with maturity-onset diabetes of the young, type 5 (MODY5). [3]A contiguous germ-line deletion of both the *PKD1* and the *TSC2* gene (the PKDTS contiguous gene syndrome; MIM 600273) occurs in a small group of patients with features of tuberous sclerosis complex (TSC), as well as massive renal cystic disease reminiscent of ADPKD, severe hypertension, and a progressive decline in renal function with the onset of end-stage renal disease (ESRD) in the second or third decade of life. [4]Congenital hepatic fibrosis (CHF). [5]Joubert syndrome (JBTS; MIM 213300) is a genetically heterogeneous (JBTS 1-20), autosomal recessive disorder characterized by developmental defects in the cerebellum (cerebellar vermis aplasia) and the eye (coloboma), as well as retinitis pigmentosa, congenital hypotonia, and either ocular motor apraxia or irregularities in breathing patterns during the neonatal period. The disease can be associated with NPHP, and mutations in several *NPHP* genes have been described in JBTS patients. [6]Genetic testing: listed at GeneTests (http://www.genetests.org) and the NIH Genetic Testing Registry (http://www.ncbi.nlm.nih.gov/gtr). *Testing is available for most *NPHP* and *MKS* genes.

dilation suggests associated Caroli syndrome. With age, the portal fibrosis tends to progress, and in older children, ultrasound typically shows hepatosplenomegaly and a patchy increase in hepatic echogenicity.[16,19]

Genetic Testing

With the identification of *PKHD1* as the principal disease gene in ARPKD, genetic testing is available as a clinical diagnostic tool. The mutation detection rate is 80% to 87%. Current diagnostic algorithms include gene-based analysis and haplotype-based genotyping (in informative families).[20,21] Genetic testing is primarily applied in the context of prenatal testing and preimplantation genetic diagnosis.[22] To date, there is limited evidence for genotype-phenotype correlations, except perhaps in affected fetuses.[23] Although patients with two truncating mutations have been reported to have a higher risk of perinatal demise,[21,24] recent studies identified a large, homozygous deletion in an 8-year-old boy.[25] ARPKD is associated with a high frequency of unique, missense changes in *PKHD1*, which can complicate the unequivocal interpretation of gene-based testing. Moreover, about 20% of ARPKD siblings have discordant clinical phenotypes.[10] These data may complicate genetic counseling, and caution must be exercised in predicting the clinical outcome of future affected children.[26]

Treatment

The survival of ARPKD neonates has improved significantly in the last two decades because of advances in mechanical ventilation for neonates and other supportive measures. Aggressive interventions such as unilateral or bilateral nephrectomies and continuous hemofiltration have been advocated in neonatal management, but prospective, controlled studies have yet to be performed.

For those children who survive the perinatal period, blood pressure control is a major clinical issue. Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), adrenergic antagonists, and loop diuretics are effective antihypertensive agents.

The management of ARPKD children with declining GFR should follow the standard guidelines established for chronic kidney disease (CKD) in pediatric patients.[27]

Given the relative urinary concentrating defect, ARPKD children should be monitored for dehydration during intercurrent illnesses associated with fever, tachypnea, nausea, vomiting, or diarrhea. For infants with severe polyuria, thiazide diuretics may be used to decrease distal nephron solute and water delivery. Acid-base balance should be closely monitored and supplemental bicarbonate therapy initiated as needed.

Close monitoring for portal hypertension is warranted in all ARPKD patients. There is no correlation between the severity of the kidney and liver disease.[3,19] Recent studies suggest that the platelet count combined with serial abdominal ultrasound (assessing liver and splenic size) and Doppler flow studies provide good surrogate markers for the portal hypertension severity.[19] Medical management may include sclerotherapy or variceal banding.[16] Surgical approaches such as portocaval or splenorenal shunting may be indicated in some patients. Although hypersplenism occurs quite often, splenectomy is seldom warranted. Unexplained fever with or without elevated transaminase levels suggests bacterial cholangitis and requires meticulous evaluation, sometimes including a percutaneous liver biopsy, to make the diagnosis and guide aggressive antibiotic therapy.

Effective management of systemic and portal hypertension, coupled with successful renal replacement therapy, has allowed long-term patient survival. Therefore, the prognosis in ARPKD, particularly for children who survive the first month of life, is much less bleak than generally thought, and aggressive medical therapy is warranted.

Current treatment of patients with ARPKD is entirely supportive, although preclinical studies suggest that new, targeted therapies may have future benefit for this cohort of patients.[28]

Transplantation

A prolonged period of dialysis in childhood has been associated with both cognitive and educational impairment. Therefore, renal transplantation is the treatment of choice for ESRD in ARPKD patients, and at least one report advocates preemptive nephrectomy in neonates with greatly enlarged kidneys.[29] ARPKD is a recessive disorder, and therefore either parent may be a suitable kidney donor. However, the recent identification of subtle renal and liver ultrasound abnormalities in ARPKD parents[30] suggests caution that requires more extensive follow-up analyses. Native nephrectomies may be warranted in patients with massively enlarged kidneys to allow allograft placement.

In some patients, combined kidney-liver transplantation may be appropriate.[31] Indications include the combination of renal failure and either recurrent cholangitis or significant complications of portal hypertension (e.g., recurrent variceal bleeding, refractory ascites, hepatopulmonary syndrome). In addition, liver transplantation may be a consideration for patients with a single episode of cholangitis in the context of marked abnormalities in the biliary system (Caroli syndrome).[16]

JUVENILE NEPHRONOPHTHISIS–MEDULLARY CYSTIC DISEASE COMPLEX

Definitions

Juvenile nephronophthisis (NPHP) and medullary cystic kidney disease (MCKD) share the same triad of histopathologic features: tubular basement membrane irregularities, tubular atrophy with cyst formation, and interstitial cell infiltration with fibrosis. These histopathologically similar disorders differ only in their mode of transmission, age of onset, and genetic defects. NPHP is an autosomal recessive disorder that presents in childhood, whereas MCKD is an autosomal dominant disorder that occurs in adults. The inclusive term *juvenile nephronophthisis–medullary cystic kidney disease complex* has been used to describe these disorders. NPHP is much more common than MCKD, however, and NPHP has been reported both as an isolated renal disease and in association with a wide range of systemic manifestations, including retinitis pigmentosa, congenital hepatic fibrosis, oculomotor apraxia, and skeletal anomalies. Therefore, these entities are considered separately.

Autosomal Recessive Juvenile Nephronophthisis

An autosomal recessive tubulointerstitial nephropathy, NPHP is one of the most frequent inherited causes of ESRD in children and adolescents.[32] The term *nephronophthisis* derives from the Greek, meaning "progressive loss of nephrons."

Genetic Basis of NPHP

Multiple disease-causing genes have been identified in NPHP patients. Defects in *NPHP1* account for 21% of NPHP, with large, homozygous deletions detected in 80% of affected family members and in 65% of sporadic cases. Mutations in each of the remaining *NPHP* genes cause no more than 3% of NPHP-related disease.[32] Clinical disease expression seems to be exacerbated by oligogenic inheritance, that is, patients carrying two mutations in a single *NPHP* gene, as well as a single-copy mutation in an additional *NPHP* gene. In addition, multiple allelism, or distinct mutations in a single gene, appears to explain the continuum of multiorgan phenotypic abnormalities observed in NPHP, Meckel syndrome, and Joubert syndrome.[33,34]

Most of the protein products of the NPHP-associated genes are expressed in the cilia-centrosome complex,[32,34] and NPHP is considered as one of the ciliopathies.

Clinical Manifestations

Renal Disease Three distinct forms of NPHP—infantile, juvenile, and adolescent—were initially described, based on the age of onset of ESRD. In the infantile form, ESRD consistently occurs before 5 years of age, whereas in juvenile NPHP, the most common form, ESRD occurs at a mean age of 13 years. However, no clear genotype-phenotype correlation exists for this spectrum of presentations, and these disorders should be referred to with the single designation, NPHP.[35,36]

Decreased urinary concentrating capacity is invariable in NPHP and usually precedes the decline in renal function, with typical onset between 4 and 6 years of age. Polyuria and polydipsia are common. Salt wasting develops in most patients with renal impairment, and sodium supplementation is often required until the onset of ESRD. One third of patients become anemic before onset of renal impairment, attributed to a defect in the functional regulation of erythropoietin production by peritubular fibroblasts.[37] Growth restriction disproportionate to the degree of renal impairment is a common finding.

Slowly progressive decline in renal function is typical of NPHP. Although symptoms can be detected after age 2 years, they may progress insidiously, such that 15% of affected patients are recognized only after ESRD has developed. There is no specific treatment. The disease is not known to recur in renal allografts.

Children with the infantile variant develop symptoms in the first few months of life and rapidly progress to ESRD, usually before age 2 years but invariably by age 5. Severe hypertension is common in this disorder.

Unlike patients with polycystic kidney disease or medullary sponge kidney, NPHP patients rarely develop flank pain, hematuria, hypertension, UTIs, or renal calculi.

Associated Extrarenal Abnormalities Extrarenal abnormalities have been described in approximately 10% to 15% of NPHP patients.[38] The most frequently associated anomaly is *retinal dystrophy* caused by tapetoretinal degeneration (Senior-Loken syndrome). Severely affected patients present with coarse nystagmus, early blindness, and a flat electroretinogram (Leber congenital amaurosis); whereas those with moderate retinal dystrophy typically have mild visual impairment and retinitis pigmentosa. Other extrarenal anomalies include oculomotor apraxia (Cogan syndrome), cerebellar vermis aplasia (Joubert syndrome), and cone-shaped epiphyses of the bones. Congenital hepatic fibrosis occurs on occasion in NPHP patients, but the associated bile duct proliferation is mild and qualitatively different from that in ARPKD.

Pathology

In classic NPHP, the kidneys are moderately contracted, with parenchymal atrophy causing a loss of corticomedullary demarcation. Histopathological findings include tubular atrophy with thickened tubular basement membrane, diffuse and severe interstitial fibrosis, and cysts of variable size distributed in an irregular pattern at the corticomedullary (CM) junction and in the outer medulla. However, up to 25% of NPHP kidneys have no grossly visible cysts.

In the typical NPHP renal lesion, clusters of atrophic tubules either alternate with groups of viable tubules showing dilation or with marked compensatory hypertrophy or with groups of collapsed tubules. Multilayered thickening of tubular basement membranes is a prominent histopathologic feature (Fig. 47-4). This pattern is not unique, but the abrupt transition from one type of tubular profile to another suggests NPHP. Moderate interstitial fibrosis, usually without a significant inflammatory cell infiltrate, is interspersed among the atrophic tubules. Spherical, thin-walled cysts lined with a simple cuboidal epithelium may be evident at the CM junction, in the medulla, and even in the papillae. Microdissection studies indicate that these cysts arise from the loop of Henle, distal convoluted tubules, and collecting ducts. Glomeruli may be normal, although some may be completely sclerosed. Other glomeruli show periglomerular fibrosis, and still others have dilation of Bowman space, suggestive of glomerulocystic kidney disease.[39]

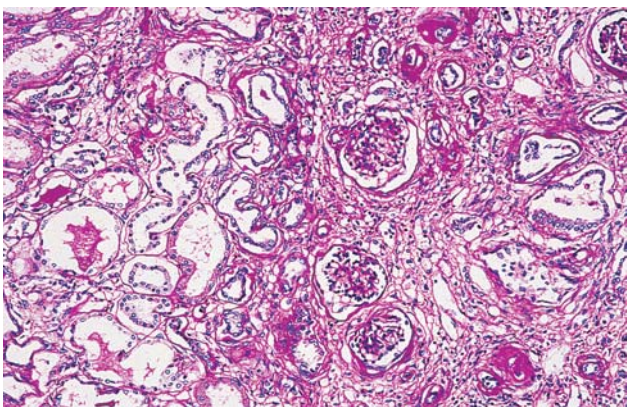

Figure 47-4 Renal pathology in juvenile nephronophthisis. Light microscopy shows tubulointerstitial nephropathy. Atrophic tubules with irregularly thickened basement membranes are surrounded by interstitial fibrosis. Dilated tubules are evident at the corticomedullary junction. (HE stain; ×40.)

In comparison, the infantile form has features of both classic NPHP, such as tubular cell atrophy, interstitial fibrosis, and tubular cysts, and polycystic kidney disease (PKD), including enlarged kidneys and widespread cystic involvement.[36]

Diagnosis

In a child with NPHP and renal impairment, ultrasound typically reveals normal-sized or small kidneys with increased echogenicity and loss of corticomedullary differentiation. On occasion, cysts can be detected at the CM junction or in the medulla. Thin-section CT scanning may be more sensitive than ultrasound in detecting these cysts.

The pathologic findings in NPHP are not unique. Thus, in the early stages of the disease, neither renal imaging nor histopathology can confirm the clinical diagnosis. Molecular testing can be useful in establishing the diagnosis of *NPHP1*-related disease.[40] Newer strategies using next-generation sequencing technologies should allow high-throughput mutation detection for known *NPHP* genes, although defects in these genes account for disease in only 30% to 40% of NPHP patients.[41]

Treatment

Current treatment of NPHP is entirely supportive. However, preclinical studies suggest that new, targeted therapies may have benefit for these patients. Specifically, treatment with OPC31260, a vasopressin receptor 2 antagonist, remarkably attenuated renal cystic disease progression in the *pcy* mouse, a model of *NPHP3*-related disease. Roscovitine, a cyclin-dependent kinase inhibitor, arrested cystic disease progression in the *jck* mouse, a model of *NPHP9*-related disease.[28]

Autosomal Dominant Medullary Cystic Kidney Disease

An autosomal dominant condition, MCKD is much rarer than autosomal recessive NPHP, but histopathologically indistinguishable. Some patients with MCKD have had phenotypically unaffected parents but an affected second- or third-degree relative, suggesting that the disease is poorly recognized in affected family members, or that there is variable penetrance.

Genetic studies indicate that defects in at least two loci (*MCKD1* and *MCKD2*) cause medullary cystic kidney disease. Uremia occurs after age 60 in MCKD1 (Mendelian Inheritance in Man [MIM] 174000), whereas in MCKD2 (MIM 603860), progression to ESRD occurs about age 30. Mutations in the gene *UMOD,* which encodes uromodulin or Tamm-Horsfall protein, have been identified in MCKD2 patients. Subsequently, *UMOD* mutations have also been identified in families with familial juvenile hyperuricemic nephropathy (FJHN; MIM 162000), a dominantly transmitted disorder characterized by MCKD, hyperuricemia, and gout, as well as familial glomerulocystic disease with hyperuricemia (MIM 609886).

Recent studies using new next-generation sequencing technologies in a set of six MCKD1 families have identified an apparently independent mutation that involves the insertion of a single nucleotide into a coding variable-number tandem repeat (VNTR) sequence within the *MUC1* gene that encodes mucin-1.[42]

The diagnosis can usually be made based on the family history, the clinical associations of hyperuricemia and gout, and the ultrasound finding of medullary cysts. Genetic testing is available for *UMOD*-related disease (http://www.genetests.org/).

MEDULLARY SPONGE KIDNEY

Definition

Medullary sponge kidney (MSK) is a relatively common disorder characterized by dilated medullary and papillary collecting ducts that give the renal medulla a spongy appearance. This renal malformation is typically associated with nephrocalcinosis, recurrent calcium nephrolithiasis, bone mineralization defects, and an increased risk of UTI.

Etiology and Pathogenesis

The occasional presence of embryonal tissue in the affected papillae and coexistence of other urinary tract anomalies suggest that MSK results from a developmental defect in the medullary pyramids. In addition, MSK occurs more frequently in individuals with other developmental anomalies or tumors (e.g., congenital hemihypertrophy, Beckwith–Wiedemann syndrome, CAKUT syndrome, Wilms tumor).[43]

In general, MSK is considered to be a sporadic disorder, but recent studies have provided strong evidence for familial clustering of MSK involving autosomal dominant inheritance with reduced disease penetrance and variability in disease expression.[44]

Epidemiology

In the general population, the frequency of MSK may be underestimated because some affected individuals remain entirely asymptomatic. Up to 20% of patients with nephrolithiasis have at least a mild degree of MSK, but excretory urography in *unselected* patients indicates a disease frequency of approximately 1 in 5000 individuals.

Clinical Manifestations

Medullary sponge kidney disease is asymptomatic unless complicated by nephrolithiasis, hematuria, or infection. Symptoms typically begin between the fourth and fifth decade of life, but adolescent presentations have been reported. Stones or granular debris in MSK patients are composed of either pure apatite (calcium phosphate) or a mixture of apatite and calcium oxalate. Several factors appear to contribute to stone formation, including urinary stasis within the ectatic ducts, hypercalciuria, and hypocitraturia. Hyperparathyroidism has also been reported.

Hematuria, unrelated to either coexisting stones or infection, may be recurrent. The bleeding is usually asymptomatic, unless gross hematuria causes clot-related colic. UTI may occur in association with nephrolithiasis or as an independent event. In those with stones, infections are more likely to occur in female than male patients.

Decreased renal concentrating ability and impaired urinary acidification are common clinical features. In most patients, the acidification defect is not associated with overt systemic acidosis, but bone mineralization defects are well described in MSK patients.[43]

Pathology

The pathologic changes are confined to the renal medullary and intrapapillary collecting ducts. Multiple spherical or oval cysts measuring 1 to 8 mm may be detected in one or more papillae. These cysts may be isolated or may communicate with the collecting system. The cysts are frequently bilateral and often contain spherical concretions composed of apatite. The affected pyramids and associated calyces are usually enlarged, and nephromegaly can result when many pyramids are involved. The renal cortex, medullary rays, calyces, and pelvis appear normal, unless complications such as pyelonephritis or urinary tract obstruction become superimposed.

Diagnosis

Abdominal plain radiographs often reveal radiopaque concretions in the medulla (Fig. 47-5, *A*). Historically, the diagnosis has been established by excretory urography (Fig. 47-5, *B*). Retention of contrast media by the ectatic collecting ducts appears either as spherical cysts or more often as diffuse linear striations. The latter imparts a characteristic blush-like pattern to the papillae, the so-called bouquet of flowers or paintbrush appearance. Medullary nephrocalcinosis is a

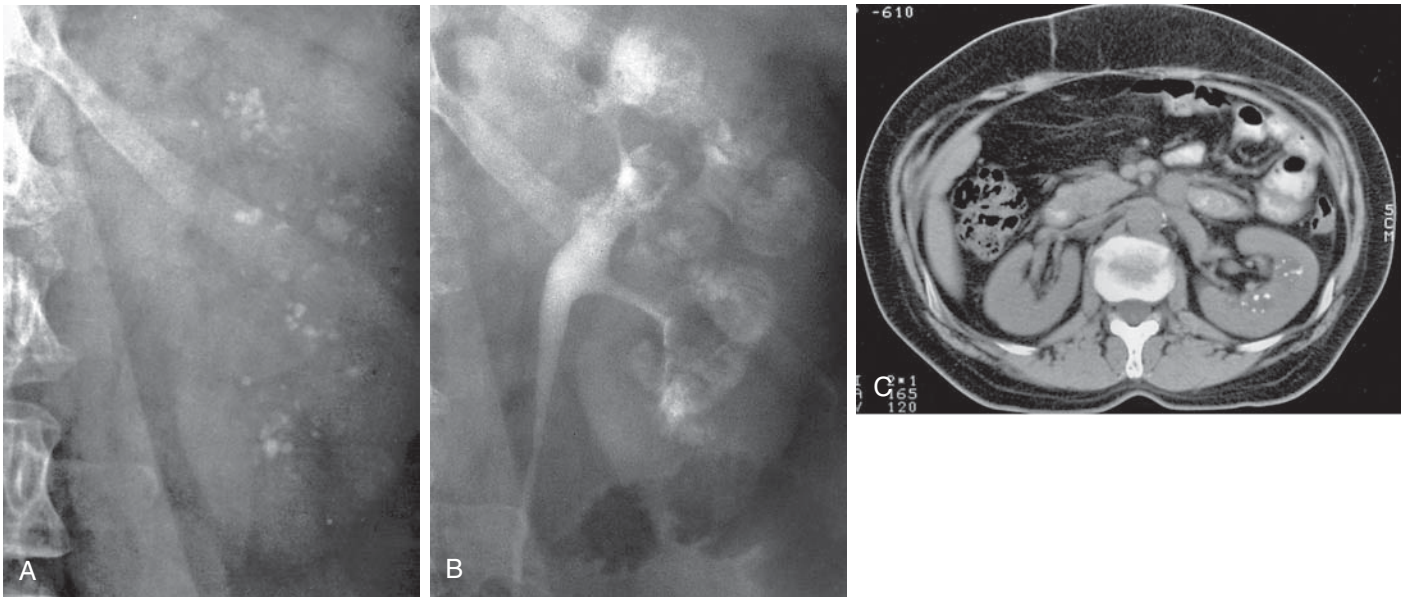

Figure 47-5 Radiologic findings associated with medullary sponge kidney. MSK in symptomatic 52-year-old woman. **A,** Preliminary film shows medullary nephrolithiases. **B,** Ten-minute film from excretory urography shows clusters of rounded densities in the papillae among discrete linear opacities (paintbrush appearance). **C,** Nonenhanced CT reveals densely echogenic foci in the medulla.

common, but not invariable, finding. Urography has been almost completely replaced by CT for routine clinical imaging. Nonenhanced CT may help distinguish MSK from papillary necrosis or even ADPKD (Fig. 47-5, *C*).

Treatment

Asymptomatic patients in whom MSK is detected as an incidental finding require no therapy. Hematuria in the absence of stones or infection requires no intervention. If the tubular ectasia is unilateral and segmental, partial nephrectomy may alleviate recurrent nephrolithiasis and UTI. However, for the majority of patients who have bilateral disease, medical management is sufficient.

Hypercalcuria and hypocitrituria are the predominant factors contributing to nephrolithiasis in MSK. The mainstays of treatment are potassium citrate and high fluid intake. Patients with persistent hypercalcuria and/or recurrent stone formers may benefit from thiazide diuretics. If thiazides are poorly tolerated or contraindicated, inorganic phosphate therapy may be useful. To avoid struvite stone formation, oral phosphates should *not* be used in patients with previous urinary tract infections caused by urease-producing organisms. Patients who form and pass stones recurrently may require lithotripsy or surgical intervention (see Chapter 61).

Urinary tract infection should be treated with standard antibiotic regimens, and for some patients, prolonged therapy may be warranted. Urease-producing organisms, such as coagulase-negative staphylococcus, are particularly problematic as urinary pathogens in MSK. Positive urine cultures, even with relatively insignificant colony counts, must be vigorously pursued.

With proper management of the clinical complications, the long-term prognosis of patients with MSK is excellent. Progression to renal impairment is unusual.

TUBEROUS SCLEROSIS COMPLEX

Definition

Tuberous sclerosis complex (TSC) is an autosomal dominant, tumor-suppressor gene syndrome in which tumor-like malformations, called hamartomas, develop in multiple organ systems, including the kidneys, brain, heart, lungs, and skin.

Etiology and Pathogenesis

Tuberous sclerosis complex results from inactivating mutations in one of two genes, *TSC1* on chromosome 9q32-q34 and *TSC2* on chromosome 16p13, adjacent to the *PKD1* gene.[45] Large deletions involving both *PKD1* and *TSC2* results in the PKD1/TSC2 (PKDTS) contiguous gene deletion syndrome.[46]

The focal nature of TSC-associated disease and the variability of disease expression even within families suggest that *TSC1* and *TSC2* function as tumor suppressor genes.[45] This paradigm hypothesizes that two successive mutations are necessary to inactivate a tumor suppressor gene and cause tumor formation. The first mutation, inherited and therefore present in all cells, is necessary but not sufficient to produce tumors. A second mutation occurs after fertilization and is required to induce tumor transformation. The inactivating germ-line mutations identified in *TSC1* and *TSC2*, as well as the loss of heterozygosity detected in *TSC2*-associated and *TSC1*-associated hamartomas, support the hypothesis that both *TSC1* and *TSC2* function as tumor suppressor genes.[47]

The *TSC2* gene product, tuberin, interacts with hamartin, the product of the *TSC1* gene. The hamartin/tuberin (TSC1/TSC2) complex functions in multiple cellular pathways, primarily by inhibiting the kinase activity of mTOR, the mammalian target of rapamycin, which functions in a protein complex (mTORC1) to regulate nutrient uptake, cell cycle progression, cell growth, and protein translation[45,48] (Fig. 47-6). The *PKD1* gene product, polycystin-1, plays a key role in regulating mTORC1 activity by complexing with tuberin and mTOR, thereby inhibiting the mTOR pathway.[49] In normal, adult kidney, mTOR is inactive. With loss of function of either polycystin-1 or tuberin, mTOR activity is upregulated, contributing to dysregulated cell growth and cystogenesis. In addition, hamartin appears to function via TORC1-independent pathways to regulate the structural integrity of the primary cilium, suggesting that ciliary dysfunction is an additional mechanism in TSC pathogenesis.[50]

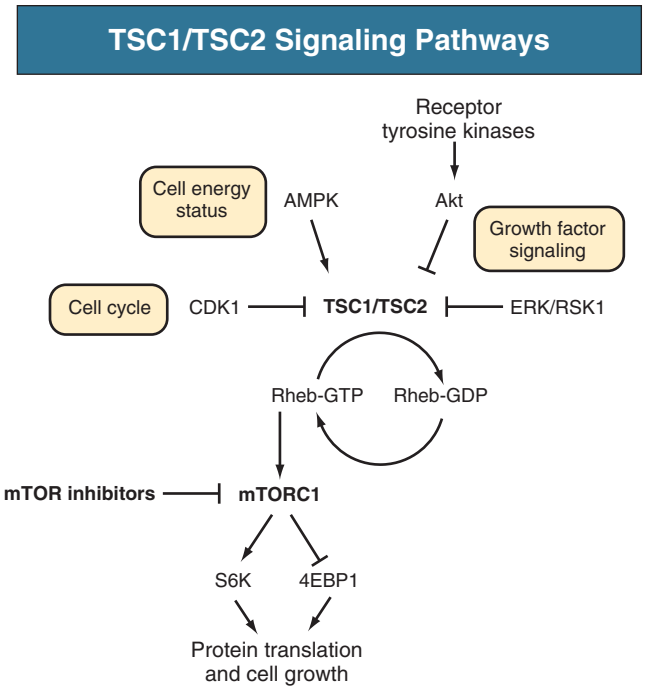

Figure 47-6 The TSC1/TSC2 signaling pathways. Hamartin (TSC1) and tuberin (TSC2) integrate signals from extracellular growth factor binding (via Akt and ERK/RSK1), the intracellular energy status (via AMPK) and the cell cycle (via CDK1) to direct signaling pathways that regulate cellular proliferation, differentiation, and migration. Tuberin contains a guanosine triphosphatase (GTPase)–activating protein (GAP) domain in its carboxy terminus, and when it forms a complex with hamartin (TSC1/TSC2 complex) the small GTPase Rheb is converted from its active GTP-bound state to an inactive GDP-bound state. Rheb is an activator of the mTORC1 kinase, which regulates a number of processes linked to protein synthesis and cell growth (via the ribosomal S6 kinases and the eukaryotic initiation factor 4E–binding protein (4E-BP1). mTORC1 is activated physiologically in response to growth factor signaling, which causes phosphorylation of tuberin, dissociation of the TSC1/TSC2 complex, and increased levels of Rheb-GTP. Inactivation of the TSC1/TSC2 complex through mutations in *TSC1* or *TSC2* leads to inappropriate activation of mTORC1. *(Modified from reference 78.)*

Epidemiology

Tuberous sclerosis complex affects 1 in 6000 to 10,000 individuals.[48] The disease penetrance is quite variable. About 70% of TSC patients are sporadic cases with no family history, and the disease apparently results from new mutational events. Among patients with sporadic disease, mutations in *TSC2* are approximately five times more common than mutations in *TSC1*; whereas the ratio is 1 : 1 in familial

cases.[51] *TSC1*-related disease is milder, apparently because of a reduced rate of "second hits."

Clinicopathologic Manifestations

The clinical features of *TSC1*- and *TSC2*-linked disease are similar, although *TSC2*-linked disease tends to be more severe.[52] The most common clinical manifestations include seizures, mental retardation and/or autism, skin lesions, interstitial lung disease, and tumors in the brain, retina, kidney, and heart. In affected individuals over 5 years of age, the most common skin lesions are facial angiofibromas (Fig. 47-7), hypomelanotic macules, and ungual fibromas.[53]

Kidney involvement occurs frequently in TSC, with up to 60% of patients manifesting renal lesions that include angiomyolipomas (85%), cysts (30% to 47%), and malignancies (2% to 4%).[48,54] Some of the malignant tumors originally thought to be renal cell carcinoma (RCC) have been reclassified as epithelioidangiomyolipomas.[55] Other renal neoplasms, interstitial fibrosis with focal segmental glomerulosclerosis (FSGS), glomerular microhamartomas, and peripelvic and perirenal lymphangiomatous cysts have also been observed in TSC patients. Renal involvement in TSC often progresses insidiously but can result in considerable morbidity, including retroperitoneal hemorrhage, renal impairment (~1%), and death. Renal complications are the most frequent cause of death in TSC patients.[48]

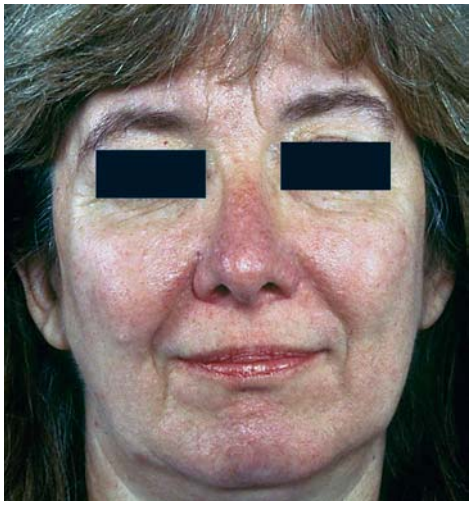

Figure 47-7 Facial angiofibromas in tuberous sclerosis complex. The angiofibromas are small red bumps giving a facial rash in a butterfly distribution and on the chin.

Renal Angiomyolipomas

Angiomyolipomas are hamartomatous structures composed of abnormal, thick-walled vessels, varying amounts of smooth muscle–like cells, and adipose tissue (Fig. 47-8, *A* and *B*). These are the most common renal lesion in TSC patients, evident in about 80% of cases by age 10 years.[48] While solitary angiomyolipomas are found in the general population, particularly among older women, TSC-associated angiomyolipomas are multiple and bilateral, with a young age of onset. Angiomyolipomas rarely occur before 5 years, but increase in frequency and size with age.[48] These angiomyolipomas can be locally invasive, extending into the perirenal fat or more rarely, the collecting system, renal vein, and even the inferior vena cava and right atrium. Lymph node and splenic involvement likely represent multifocal origin rather than metastases.

Clinical manifestations result from hemorrhage (intratumoral or retroperitoneal) or mass effects (abdominal or flank masses and tenderness, hypertension, renal impairment). Women tend to have more numerous and larger angiomyolipomas than men. Pregnancy appears to increase the risk of rupture and hemorrhage.

Renal Cysts

Renal cysts occur less frequently than angiomyolipoma in TSC patients. However, as with angiomyolipoma, renal cysts tend to increase in size and number over time. The concurrence of cysts and angiomyolipomas, easily detected by CT, is strongly suggestive of TSC.

The cysts in TSC can develop in any nephron segment. When limited in number and size, TSC-related cysts are predominantly cortical. In some cases, glomerular cysts predominate.[39] The epithelial lining of the cysts is distinctive and appears to be unique to TSC, with large and acidophilic epithelia containing large, hyperchromatic nuclei with occasional mitotic figures (Fig. 47-8, *C*). Associated papillary hyperplasia and adenomas are common.

A small subset of affected infants can present with massive renal cystic disease, severe hypertension, and a progressive decline in renal function with the onset of ESRD in the second or third decade of life. The majority of these patients have a contiguous germ-line deletion involving both the *TSC2* and the *PKD1* gene, the PKDTS contiguous gene syndrome.[46] Early detection, strict blood pressure control, and prompt therapy for the associated infantile spasms may favorably impact the overall prognosis.

Renal Neoplasms

Many cases of benign epithelial tumors, such as papillary adenomas and oncocytomas, have been reported in TSC patients. However, despite the multiplicity of benign tumors, malignant transformation

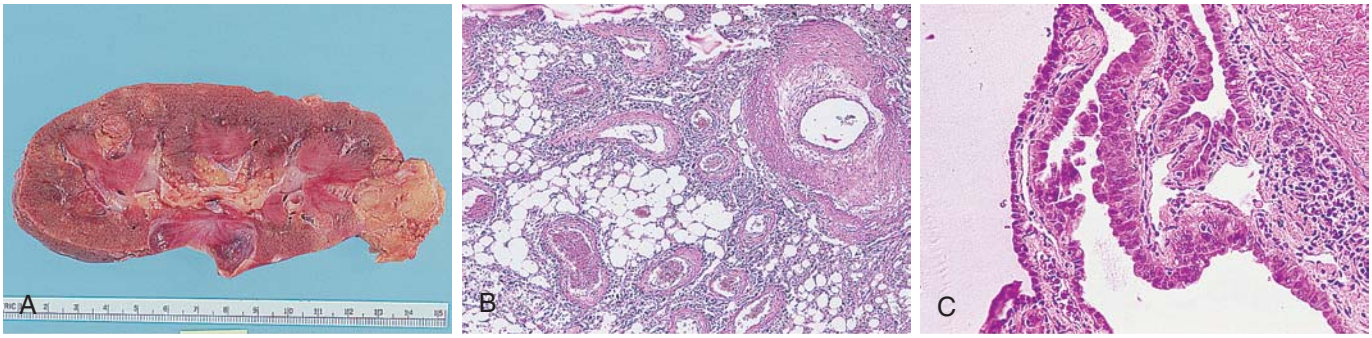

Figure 47-8 Renal pathology in tuberous sclerosis complex (TSC). A, Cut section shows multiple angiomyolipomas in kidney of 60-year-old symptomatic woman. **B,** Light microscopy shows angiomyolipoma containing adipose tissue and spindle smooth muscle–like cells interspersed between abnormal vessels with thickened walls (HE stain; ×16). **C,** Light microscopy shows TSC cysts lined with distinctive epithelia consisting of large, acidophilic cells with hyperchromatic nuclei (HE stain; ×65).

Clinical Diagnostic Criteria for Tuberous Sclerosis Complex*

Major
Facial angiofibromas or forehead plaque
Nontraumatic ungual or periungual fibroma
Hypomelanotic macules (>3)
Shagreen patch (connective tissue nevus)
Multiple retinal nodular hamartomas
Cerebral cortical nodules (tubers)
Subependymal nodule
Subependymal giant cell astrocytoma
Cardiac rhabdomyomas (≥1)
Lymphangioleiomyomatosis
Renal angiomyolipoma

Minor
Multiple, random dental pits
Hamartomatous gastrointestinal or rectal polyps
Bone cysts
White matter radial migration lines
Gingival fibromas
Nonrenal hamartoma
Retinal achromic patch
"Confetti" skin lesions
Multiple renal cysts

Box 47-1 Clinical diagnostic criteria for tuberous sclerosis complex (TSC). *Two major features or one major feature with two minor features indicate definite TSC; one major feature and one minor feature indicate probable TSC; and one major feature or two minor features indicates possible TSC. *(Modified from reference 53.)*

is rare. TSC-associated renal neoplasms are predominantly clear cell renal carcinoma, but there is pathologic heterogeneity, with papillary and chromophobe carcinomas reported.[57] The prognosis of TSC-associated renal carcinomas compared to sporadic renal carcinomas in the general population is unknown. The lifetime risk of developing RCC in the context of TSC is 2% to 3%.[56]

Diagnosis

Tuberous sclerosis complex is a pleiotropic disease in which the size, number, and location of the lesions can be variable, even among affected individuals within the same family. Major and minor criteria have been developed to guide the diagnostic approach (Box 47-1). In this context, the diagnosis of TSC is made when two major features, or one major and two minor ones, can be demonstrated.[53] Imaging is the mainstay for diagnosis of TSC-associated renal lesions. The presence of small cysts and fat-containing angiomyolipomas strongly suggests TSC. The median age at presentation for both renal cysts and angiomyolipoma is 10 years, although these lesions have been detected in infancy.[58]

Annual renal imaging is advised for TSC patients. Historically, ultrasound screening has been the preferred modality because it does not involve radiation, is fast and relatively inexpensive, and has high sensitivity in detecting the fat-rich angiomyolipomas and renal cysts. However, ultrasound is relatively insensitive for detecting fat-poor lesions. CT is superior for detecting fat-poor lesions as well as small angiomyolipomas in diffusely hyperechoic kidneys and in differentiating small angiomyolipomas from perinephric or renal sinus fat (Fig. 47-9). Given that CT carries the risks of contrast nephrotoxicity and radiation exposure, magnetic resonance imaging (MRI) is becoming the preferred renal imaging modality in TSC patients.[48] On occasion, the distinction between an angiomyolipoma and carcinoma cannot be reliably established by imaging, and biopsy is indicated.

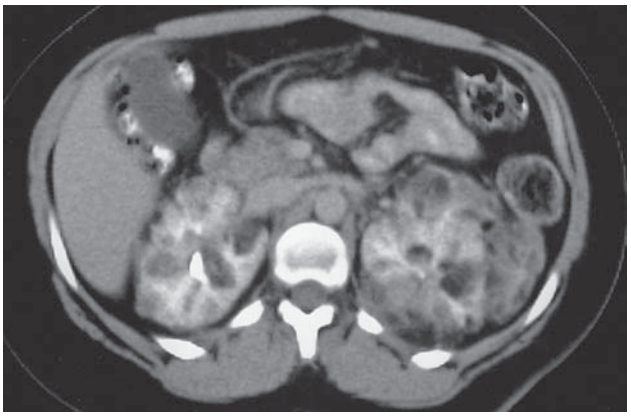

Figure 47-9 Radiologic findings associated with tuberous sclerosis complex. Contrast-enhanced CT showing bilateral angiomyolipomas in a 34-year-old symptomatic woman.

The TSC-associated renal cysts can radiologically mimic simple cysts and, when numerous, ADPKD. In the absence of angiomyolipomas, TSC-related renal cystic disease is suggested by the limited number of cysts compared with ADPKD and the absence of associated hepatic cysts. Although 10% of TSC patients have hepatic angiomyolipomas, hepatic cysts are rare.

Gene-based diagnosis is currently available for *TSC1*- and *TSC2*-related disease, as well as to detect large-scale deletions associated with the PKDTS contiguous gene syndrome (http://www.genetests.org).

Treatment

Renal Angiomyolipomas

Renal angiomyolipomas are benign lesions and often require no treatment. However, given the potential for growth and associated complications, such as pain, bleeding, and hypertension, annual imaging is recommended. Larger angiomyolipomas frequently develop microaneurysms and macroaneurysms, and the risk of serious hemorrhage correlates with aneurysms over 5 mm in diameter.[48] Therefore, these large angiomyolipomas require preemptive treatment with surgical removal in a nephron-sparing procedure or with embolization.[58] In addition to size and complications such as pain or hemorrhage, the inability to exclude an associated renal carcinoma should prompt intervention. When an associated malignancy cannot be excluded, renal-sparing surgery is preferred, such as enucleation or partial nephrectomy.

The increased frequency and size of the angiomyolipomas in women and the reports of hemorrhagic complications during pregnancy suggest that female sex hormones may accelerate the growth of these lesions. Therefore, it is prudent to caution patients with multiple angiomyolipomas about the potential risks of pregnancy and estrogen administration.

As noted, defective mTORC1 signaling is a central feature of TSC. A recent report of the first randomized, double-blind, placebo-controlled Phase III trial of the mTOR inhibitor everolimus, demonstrated a clear advantage for mTOR inhibition over placebo in reducing angiomyolipoma volume, with an acceptable safety profile in patients with TSC.[59]

Renal Cysts

The mainstay of treatment of the TSC-associated renal cystic disease is strict blood pressure control. Surgical decompression of cystic kidneys has been suggested, but no significant beneficial effect has been established.

Renal Carcinoma

Renal carcinoma should be suspected in enlarging, fat-poor lesions or when intratumoral calcifications are present. In these cases, biopsy is indicated. Because renal carcinoma is frequently bilateral in TSC, renal-sparing surgery should be performed whenever possible.

Transplantation

Chronic kidney disease, while rare in tuberous sclerosis, can occur by several different mechanisms, including angiomyolipoma-related parenchymal destruction, progressive renal cystic disease, interstitial fibrosis and FSGS. A large survey study of French dialysis centers indicated that the approximate prevalence of TSC-associated ESRD was 0.7 cases per 1 million. ESRD occurred in 1 per 100 TSC patients and was more frequent in females (63%), with a mean age diagnosis of 29 years.[60] Of note, both dialysis and renal transplantation provide appropriate modes of renal replacement therapy, but the risk of renal hemorrhage related to angiomyolipomas and malignant degeneration in TSC poses special risks. Therefore, it may be advisable that patients with TSC and ESRD undergo bilateral nephrectomy before initiation of renal replacement therapy.

VON HIPPEL–LINDAU DISEASE

Definition

Von Hippel–Lindau disease (VHL) is a dominantly transmitted, multisystem cancer predisposition syndrome associated with tumors of the eyes, cerebellum, spinal cord, adrenal glands, pancreas, and epididymis, as well as renal and pancreatic cysts.[61]

Etiology and Pathogenesis

Von Hippel–Lindau disease is a tumor suppressor disorder, with disease resulting from a germ-line mutation in the *VHL* gene and the subsequent development of a somatic mutation in this gene. In about 80% of patients, VHL is familial, and disease in 20% of cases results from *de novo* mutations. Moreover, *VHL* mutations have been identified in both the germ-line of VHL patients and the sporadic clear cell renal carcinomas, implying that *VHL* plays an important role in the pathogenesis of clear cell renal carcinoma.[62]

The VHL protein (pVHL) plays a critical role as a negative regulator of hypoxia-inducible gene. In the normal physiologic state, pVHL functions in a multiprotein complex that directs a number of proteins, most notably the alpha subunits of the transcription factor, hypoxia-inducible factor (HIF-α), for destruction via the ubiquitination pathway. In cells that lack pVHL, HIF-α subunits are stabilized and bind to HIF-β family members proteins. The heterodimer then translocates to the nucleus, leading to overexpression of HIF-target genes, which encode proteins that regulate glucose uptake, metabolism, extracellular pH, erythropoiesis, angiogenesis (vascular endothelial growth factor [VEGF] and platelet-derived growth factor B), and mitogenesis (transforming growth factor β). This transcriptional dysregulation promotes the pathologic growth and survival of endothelial cells, pericytes, and stromal cells and ultimately their malignant transformation.[48,62,63]

Classification of von Hippel–Lindau Disease Based on Tumor Spectrum

VHL Subtype	Tumor Manifestations
Type 1	Hemangioblastoma (CNS, retina), renal cell carcinoma Low risk for pheochromocytoma and pancreatic endocrine tumors
Type 2A	Hemangioblastoma (CNS, retina), pheochromocytoma, pancreatic endocrine tumors Low risk for renal cell carcinoma
Type 2B	Hemangioblastoma (CNS, retina), renal cell carcinoma, pheochromocytoma, pancreatic endocrine tumors
Type 2C	Predominantly pheochromocytoma Very limited risks for hemangioblastoma and renal cell carcinoma

Table 47-3 Classification of von Hippel–Lindau disease (VHL) based on tumor spectrum. *(Modified from reference 63.)*

Clinical Manifestations

Von Hippel–Lindau disease has an incidence of 1 in 36,000 newborns and has been observed in all ethnic groups.[48,61] Biallelic *VHL* inactivation leads to increased risk of central nervous system (CNS) and retinal hemangioblastomas, clear cell renal carcinomas, pheochromocytomas, pancreatic islet cell tumors, endolymphatic sac tumors, and papillary cystadenomas of the broad ligament (females) and epididymis (males). In addition, cystic changes can occur in the kidney and pancreas.

The VHL-associated diseases appear to cluster into two disease complexes (Table 47-3). In the initial stratification, VHL patients can be subclassified based on a low risk (type 1) or high risk (type 2) of developing pheochromocytoma. Type 1 disease is characterized by large deletions or truncations of the *VHL* gene, which cause complete inactivation of the gene and result in high levels of HIF activity. Type 2 disease primarily involves missense mutations and is associated with partial activity of pVHL. Type 2 patients can be further divided into three subtypes: type 2A, which has a low incidence of renal lesions; type 2B, associated with a high risk of RCC; and type 2C, associated only with pheochromocytoma and no other malignancies.[48,62,63]

Renal cell carcinomas are typically multiple and bilateral. Although RCC may present with hematuria or back pain, detection occurs more often as an incidental finding on unrelated imaging studies or during a screening protocol. The mean age of symptomatic presentation is 35 to 40 years, although patients have been diagnosed in adolescence. In VHL, men and women are equally affected with RCC, in contrast to the male predominance in sporadic RCC. VHL-associated RCC metastasizes to the lymph nodes, liver, lungs, and bones and accounts for about 50% of VHL-related deaths.

In VHL, renal cysts arise from tubular cells that have undergone somatic loss of the wild-type allele. Renal cysts occur in about 60% of patients and are usually bilateral. Deterioration of renal function caused by cystic kidney disease has been reported but is unusual.

Pathology

Renal cell carcinoma is one of the most common tumors in VHL, with a lifetime risk of about 70% for patients with VHL disease.[61] VHL-associated RCCs are mostly of the clear cell type and usually bilateral and multifocal in distribution. Detailed microscopic examination of VHL-associated renal cystic lesions often reveals small foci

Features of Adult Renal Cystic Disease						
Feature	**Simple Cysts**	**ADPKD**	**MSK**	**VHL**	**TSC**	**Acquired Cystic Disease**
Clinical Characteristics						
Clinical onset	>40 yr	30-40 yr	20-40 yr	30-40 yr	10-30 yr	With ESRD
Cysts	Single/multiple	Multiple	Multiple	Few, bilateral	Multiple	Multiple
Cyst infection	Uncommon	Common	Common	Uncommon	Uncommon	Uncommon
Tumors	No	Rare	No	RCC, often bilateral	AML/RCC	Common
Blood pressure	Normal/increased	Increased	Normal	Normal/increased	Normal/increased	Normal/increased

of carcinoma. VHL-associated RCCs tend to have low-grade histology and a better 10-year survival than sporadic RCCs. More advanced RCCs do metastasize and metastatic disease is a major cause of death in VHL patients.

Renal cysts may express carcinoma *in situ* with subsequent progression over time to RCC, presumably from mutations affecting other genetic loci.[48,61]

Diagnosis

The minimum clinical criteria for the diagnosis of VHL in an "at-risk" individual include the presence of a single retinal or cerebellar hemangioblastoma, or RCC, or pheochromocytoma.[61] Up to 50% of affected individuals with familial VHL may manifest only one feature of the syndrome. In presumed sporadic cases (20% of patients), the clinical diagnosis requires two or more retinal or CNS hemangioblastomas, or a single hemangioblastoma and a characteristic visceral tumor.

Molecular analysis of the *VHL* gene is indicated in patients with known or suspected VHL, or in at-risk children from VHL families, given that unsuspected, untreated tumors can cause significant morbidity.[62] Presymptomatic genotyping can be useful in determining the phenotypic classification of VHL and can be used to direct monitoring for a specific subset of tumors. In addition, genotyping can be useful in distinguishing whether a pheochromocytoma has occurred in the context of a *VHL* type 2 mutation, multiple endocrine neoplasia (MEN) type 2, or is nonsyndromic.[63] Genetic testing information is available (http://www.genetests.org/).

In patients with type 2 VHL disease, annual assessment of blood pressure, measurement of urinary catecholamine metabolites, as well as abdominal ultrasound imaging should be initiated at age 2 years. Abdominal MRI and iodine 131–metaiodobenzyl-guanidine (MIBG) scans are indicated if abnormalities are detected. By age 16 years, all patients with VHL should have annual MR scans of the abdomen. Ultrasound is a useful alternative imaging modality in pregnant women. Early detection of renal disease and a multidisciplinary approach to follow-up can substantially improve the longevity of VHL patients.[48,61]

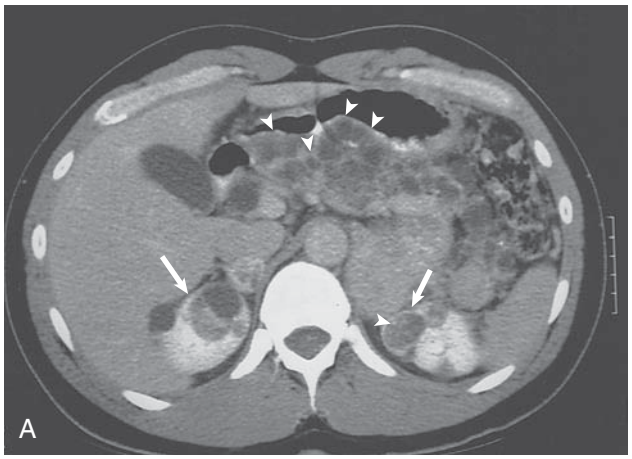
Differential Diagnosis

The differential diagnosis of VHL-associated renal lesions includes several conditions, most notably ADPKD and TSC (Table 47-4). As with VHL, ADPKD affects both genders with a similar mean age at presentation. However, kidney involvement in VHL is characterized by a few bilateral cysts, RCC, normal kidney size, normal blood pressure, and usually normal renal function. Cyst infection, a frequent finding in ADPKD, is uncommon in VHL. RCC is an infrequent complication of ADPKD. Cysts in the liver are frequent in ADPKD and rare in VHL. Pancreatic cysts are rare in ADPKD but can be numerous and scattered through the pancreas in VHL (Fig. 47-10, *A*). The CNS in ADPKD is affected by arterial aneurysms, whereas hemangioblastomas are the CNS manifestation of VHL (Fig. 47-10, *B*).

Tuberous sclerosis complex should be considered in the differential diagnosis of multiple renal tumors. In both TSC and VHL, multiple renal cysts occur. However, the TSC-associated renal tumor is usually an angiomyolipoma and extrarenal lesions readily distinguish VHL and TSC.

Treatment

Surgery continues to be the mainstay for RCC therapy in VHL patients. Optimal management requires surgical intervention before



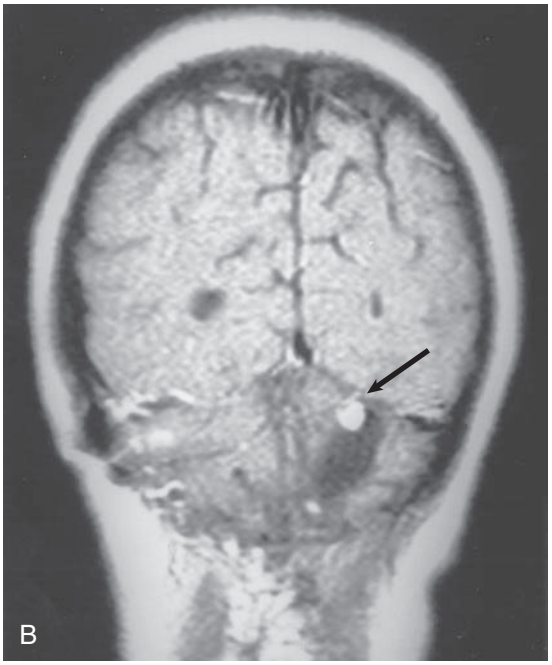


Figure 47-10 Radiologic findings associated with von Hippel–Lindau syndrome. A, Noncontrast CT shows massive cystic involvement of the pancreas *(arrowheads)* and bilateral renal cysts *(arrows)*. **B,** Contrast-enhanced MR image shows a right cerebellar hemangioblastoma with a small enhancing mass *(arrow)*.

renal vein invasion and distant metastases occur, because metastatic lesions respond poorly to chemotherapy and radiation. Nephron-sparing surgery is the procedure of choice when possible (see Chapter 61). Repeated surgical intervention may be required as tumors continue to develop. Laparoscopic surgery may have a role in the future management of these patients.

Bilateral nephrectomy and renal transplantation may be an acceptable alternative to repeated nephron-sparing surgery in patients with VHL-associated RCC. It remains to be determined whether post-transplant immunosuppression enhances the growth of the retinal and CNS hemangioblastomas and other lesions found in patients with VHL.

In terms of medical management, drugs that inhibit HIF-α, or its downstream targets (e.g., VEGF receptor kinase inhibitors), may be therapeutically useful in VHL-related hemangioblastomas and clear cell renal carcinomas.[62,64] A number of clinical trials are currently in progress (http://clinical trials.gov).

SIMPLE CYSTS

Definition

Simple renal cysts are the most commonly acquired renal cystic lesion and occur twice as frequently in men as in women. Simple cysts are usually unilateral and may be solitary or multiple. They rarely occur in children, but become increasingly common with age.[65] In a seminal ultrasound study, unilateral cysts were detected in 1.7% of patients age 30 to 49 years, 11% of patients age 50 to 70, and 22% to 30% of patients over age 70.[66] This age-related increase in cyst incidence has been corroborated by MR studies.[67]

Etiology and Pathogenesis

Simple renal cysts likely originate from the distal convoluted tubule or collecting ducts and may arise from renal tubular diverticula, but the pathogenic mechanisms are unknown. Focal tubular obstruction and renal parenchymal ischemia have both been suggested as etiologic processes. Less likely is the possibility that simple cysts arise from calyceal diverticuli, because simple cysts are often found in the renal cortex, and their frequency increases with age.

Age, smoking, renal dysfunction, and hypertension[68] have been implicated as risk factors for simple cysts. However, these associations may be coincidental, given that the studies were largely retrospective, the cohorts had variable reasons for diagnostic referral, and the observations were not optimally controlled for patient age.[65]

Clinical Manifestations

Simple cysts are typically asymptomatic. However, increasing evidence supports a relationship between simple renal cysts and hypertension.[68] In addition, red blood cell (RBC) abnormalities (increased RBC mass, hematocrit, and hemoglobin) are well described in patients with simple renal cysts.[69] Patients can also present with hematuria, flank pain, evidence of infection or gout, or obstruction of the collecting system. Clinical symptoms are more common with neoplasms than simple cysts. Therefore, the onset of symptoms should suggest an associated malignancy and prompt additional diagnostic studies.[65]

Pathology

Whether unilateral or bilateral, simple cysts are usually spherical in shape and unilocular. They may be solitary or multiple. On average, simple cysts measure 0.5 to 1.0 cm diameter, but 3-cm to 4-cm cysts are not uncommon. Simple cysts can occur in the cortex, where they can protrude from the cortical surface (exophytic cysts), the CM junction or in the medulla. By definition, simple cysts do not communicate with the renal pelvis. The cyst walls are typically thin and transparent, lined with a single layer of flattened epithelium. Cyst fluid is essentially an ultrafiltrate of plasma. After infection, cyst walls can become thickened, fibrotic, and even calcified.

Diagnosis

Simple cysts are most often detected as incidental findings during abdominal imaging studies. Occasionally, they are discovered during radiologic evaluation of palpable abdominal masses, pyelonephritis, or hematuria after abdominal trauma. The critical clinical issue is to distinguish single or multiple simple cysts from cysts associated with ADPKD, other cystic diseases, or RCC. This distinction can usually be made on the basis of patient age, family history, and renal imaging patterns.[65,70]

The ultrasound features of simple cysts include smooth walls, no septae, and no intracystic debris. If the ultrasound pattern is indeterminate, CT should be performed. A classification system for renal cysts based on their appearance and enhancement on CT, described by Bosniak (see Table 61-5), is widely used.[70] Benign cysts (Bosniak Class I) have homogeneous attenuation, no contrast enhancement, thin smooth cyst walls, and no associated calcifications, unless prior infection has occurred.

Treatment

Simple cysts associated with pain or renin-dependent hypertension can be punctured with ultrasound guidance and drained, with a sclerosing agent instilled into the cyst cavity.[71] Laparoscopic or retroperitoneoscopic cyst unroofing may be more appropriate for large cysts containing volumes in excess of 100 ml. Infection with Enterobacteriaceae, staphylococci, and *Proteus* has been reported in simple cysts, and operative or percutaneous drainage is often required in addition to antibiotic treatment.

SOLITARY MULTILOCULAR CYSTS

Solitary multilocular cysts are generally benign neoplasms that arise from the metanephric blastema. These solitary cysts have also been designated multilocular cystic nephroma, benign cystic nephroma, and papillary cystadenoma. By definition, the cystic structures are unilateral, solitary, and multilocular. The cystic locules do not communicate with each other or with the renal pelvis. These locules are lined with a simple epithelium, and the interlocular septa do not contain differentiated renal epithelia structures.

Multilocular cysts represent a spectrum.[72] At one end is cystic nephroma (CN) and at the other end, cystic partially differentiated nephroblastoma (CPDN), in which the septa contain foci of blastemal cells. It is uncertain whether a multilocular cyst represents a congenital abnormality in nephrogenesis, a hamartoma, a partially or completely differentiated Wilms tumor, or a benign variant of Wilms tumor.

A bimodal age distribution has been described,[73] with approximately half the cases occurring in children less than 4 years of age and half the cases detected in adults. The childhood cases (mostly CPDN) are usually found in boys; whereas, multilocular cysts presenting in adulthood (mostly CN) occur more commonly in women. An abdominal or flank mass is the most common clinical feature, as these cysts are typically quite large and often replace an entire pole. Associated hematuria, calculi, urinary tract obstruction, and infection occur in rare cases. Diagnosis can be made by ultrasound or CT (Fig. 47-11).

Almost all multilocular cysts are Bosniak Class III (see Table 61-5), complex renal cysts suspicious for malignancy.[70] CPDN in children may contain blastema and incompletely differentiated metanephric tissue, but usually has a benign course. In adults, associated foci of RCC or sarcoma must be excluded. For both diagnostic accuracy and treatment, partial nephron-sparing surgery is usually required. However, the typical prognosis of solitary multilocular cysts is excellent.

RENAL LYMPHANGIOMATOSIS

Renal lymphangiomatosis is a rare, generally benign disorder characterized by developmental malformation of renal lymphatic channels.[74] It has also been referred to as hilar, pericalyceal, paracalyceal, peripelvic, or parapelvic lymphangiectasis.

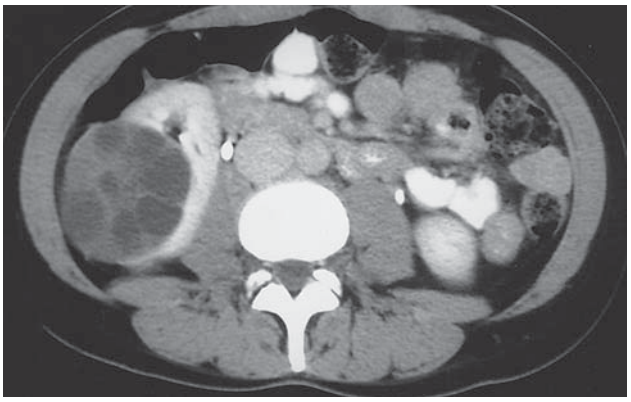

Figure 47-11 Solitary multilocular cyst. Contrast-enhanced CT shows a solitary, septated, and well-circumscribed renal cystic lesion in the right kidney.

The cystic phenotype is widely variable, and the underlying pathogenesis is unclear. The dilation may involve a single lymphatic channel or multiple channels. The lymphangiectasis may be unilateral or bilateral, may be limited to the hilar region, or may extend into the renal parenchyma to the corticomedullary junction. On occasion, renal lymphangiomatosis may be extensive and simulate ADPKD. The thin-walled cysts are lined by lymphatic endothelium, and the cyst fluid is quite distinct from that in ADPKD cysts, because it contains lymphatic constituents such as albumin and lipid.

The characteristic ultrasound or CT findings include multiple, bilateral, small peripelvic cysts that splay the renal hilum, as well as capsular cysts in the perirenal space, both separated by thin septations. Renal lymphangiomas are most often asymptomatic and require no treatment. However, the condition may be exacerbated by pregnancy, resulting in large, perinephric lymph collections and ascites that may require percutaneous drainage.[75]

GLOMERULOCYSTIC KIDNEY DISEASE

Cystic glomeruli are evident in three different clinical contexts: (1) isolated glomerulocystic kidney disease (GCKD); (2) glomerulocystic kidneys associated with heritable malformation syndromes, such as tuberous sclerosis, Meckel syndrome, medullary cystic kidney disease (MCKD2), orofaciodigital syndrome type I, trisomies (9, 13, 18), the short-rib polydactyly syndromes, and Zellweger cerebrohepatorenal syndrome; and (3) glomerular cysts present in dysplastic kidneys.[39]

Isolated GCKD can occur as a sporadic condition, a familial disorder, or as the infantile manifestation of ADPKD. Pathologically, the kidney architecture is normal, with no dysplastic elements in the cortex and no evidence of urinary tract obstruction. Cystic dilation predominantly involves the Bowman space and initial proximal tubule; it is defined as a twofold to threefold dilation of Bowman space versus the normal glomerular dimension. Glomerular cysts can be distributed from the subcapsular zone to the inner cortex. The typical ultrasound pattern in GCKD involves increased echogenicity of the renal cortex with minute cysts, smaller than those evident in ADPKD. Young infants with either familial or sporadic forms of GCKD may also have renal medullary dysplasia and biliary dysgenesis.[39]

Glomerulocystic kidney disease is usually transmitted as an autosomal dominant trait. It is often discovered in infants with a familial history of ADPKD. In these infants, the kidneys are bilaterally

enlarged and diffusely cystic. In non–ADPKD-associated GCKD families, the kidneys are typically normal in size, although on occasion, enlarged kidneys are observed. Several sporadic cases of nonsyndromal GCKD also have been described, suggesting either new, spontaneous mutations or a recessively transmitted disorder.[39]

Familial hypoplastic GCKD (MIM 137920) appears to be a distinct form of GCKD. The kidneys are smaller than normal and often associated with medullocalyceal abnormalities. The disease is pleiotropic among affected family members, with variable associations of hypoplastic GCKD, gynecologic abnormalities, and maturity-onset diabetes of the young type 5 (MODY5), and results from mutations in *TCF2,* the gene encoding hepatocyte nuclear factor 1β (HNF-1β).[76]

ACQUIRED CYSTIC DISEASE

Hypokalemic Cystic Disease

Renal cysts are often seen in association with chronic hypokalemia caused by primary hyperaldosteronism or other renal potassium-wasting disorders. Almost 50% of patients with idiopathic adrenal hyperplasia and 60% of those with adrenal tumors have been found to have renal cysts distributed primarily in the renal medulla. These cysts typically regress after adrenalectomy.[77]

Hilar Cysts

Hilar cysts are spherical accumulations of clear, fat droplet–containing fluid within the renal sinus. These cystic structures are not lined by epithelia. They are most often seen in debilitated patients and may represent atrophy of the renal sinus fat.

Perinephric Pseudocysts

Perinephric pseudocysts are also unlined cavities. They typically occur under the renal capsule or in the perirenal fascia as a result of urine extravasation from a renal cyst after traumatic or spontaneous rupture, or as the posterior extension of a pancreatic pseudocyst. Surgical intervention is indicated for associated urinary tract obstruction. Otherwise, treatment is directed to the underlying cause.

Acquired Cystic Disease in Renal Failure

Acquired cystic disease is a significant complication of prolonged renal failure. It should be considered in the differential diagnosis of cystic disease presenting with longstanding chronic renal impairment (see Table 47-4). Acquired renal cystic disease is discussed further in Chapter 89.

CHAPTER 48

Alport and Other Familial Glomerular Syndromes

Clifford E. Kashtan

ALPORT SYNDROME

Definition

Alport syndrome (AS) is a generalized, inherited disorder of basement membranes caused by mutations affecting specific proteins of the type IV (basement membrane) collagen family. The major features of AS are hematuria, progressive nephritis with proteinuria and declining renal function, sensorineural deafness, and ocular abnormalities. The course of AS is gender dependent; affected males typically have severe disease, whereas the manifestations of AS in women tend to be relatively mild. In 1902, Guthrie[1] provided the first description of familial hematuria. Later studies of Guthrie's family by Hurst[2] and Alport[3] revealed the progressive nature of the nephropathy, its association with deafness, and the poorer prognosis in affected males. In the 1970s, the glomerular basement membrane (GBM) was recognized as the site of the primary abnormality in AS.[4-6] Indirect evidence of abnormalities in type IV collagen[7,8] was followed by mapping of the major AS locus to the X chromosome,[9] cloning of a new type IV collagen gene *(COL4A5)* and its assignment to the same X-chromosomal region,[10] and identification of the first *COL4A5* mutations in patients with X-linked AS.[11]

Etiology and Pathogenesis

Type IV Collagen

Type IV collagen is a major constituent of basement membranes. The type IV collagen family of proteins comprises six isomeric chains, designated α1(IV) to α6(IV). Each of these chains has a major collagenous domain of about 1400 residues containing the repetitive triplet sequence glycine (Gly)–X–Y, in which X and Y represent a variety of other amino acids; a C-terminal noncollagenous (NC1) domain of about 230 residues; and a noncollagenous N-terminal sequence of 15 to 20 residues.

Each type IV collagen molecule is a heterotrimer composed of three α chains. Formation of these heterotrimers is initiated by C-terminal NC1 domain interactions, accompanied by folding of the collagenous domains into triple helices. There is evidence for at least three types of type IV collagen heterotrimer: $\alpha1(IV)_2$–α2(IV); α3(IV)–α4(IV)–α5(IV); and $\alpha5(IV)_2$–α6(IV). Type IV collagen triple helices form open, nonfibrillar networks that associate with laminin assemblies through interactions mediated by nidogen to form basement membranes.

The six type IV collagen genes are arranged in pairs on three chromosomes (Fig. 48-1). The 5′ ends of each gene pair are adjacent to each other, separated by sequences of varying length that contain motifs involved in the regulation of transcriptional activity.

There are several distinct type IV collagen networks in basement membranes: a ubiquitous network comprising the α1(IV) and α2(IV) chains; and other networks, restricted in distribution, composed of α3(IV), α4(IV), and α5(IV) chains, or α5(IV) and α6(IV) chains. GBM contains separate α1–α2(IV) and α3–α4–α5(IV) networks, whereas epidermal basement membranes (EBMs) contain separate networks of α1–α2(IV) chains and α5–α6(IV) chains. A network composed of α1, α2, α5, and α6(IV) chains has been described in smooth muscle basement membranes.[12] These various networks likely have different physical and functional characteristics and interact differently with other matrix components and adjacent cells.

Genetics

Three forms of AS have been established on a molecular genetic basis: an X-linked form resulting from mutations at the *COL4A5* locus, primarily affecting the α5(IV) chain; an autosomal recessive form arising from mutations at the *COL4A3* locus or the *COL4A4* locus, affecting the α3(IV) and α4(IV) chains, respectively, and an autosomal dominant form from heterozygous mutations in *COL4A3* or *COL4A4* (Table 48-1).

X-Linked Alport Syndrome X-linked Alport syndrome (XLAS) is the predominant form of the disease, accounting for about 80% of patients. Several hundred *COL4A5* mutations have been described, mostly missense mutations, splice-site mutations, and deletions of fewer than 10 base pairs.[13,14] A common missense mutation involves replacement of a glycine residue in the collagenous domain of the α5(IV) chain by another amino acid. Such mutations are thought to interfere with the normal folding of the α5(IV) chain into triple helices with other α(IV) chains.

Male patients with *COL4A5* deletions consistently progress to end-stage renal disease (ESRD) during the second or third decade of life and have deafness.[15] This phenotype is associated with most of the missense, nonsense, and splicing mutations of *COL4A5* described so far. Several missense mutations of *COL4A5* have been associated with late-onset (after the third decade) ESRD and with late development of deafness or normal hearing. The severity of disease in a female heterozygous for a *COL4A5* mutation probably depends primarily on the relative activities of the mutant and normal X chromosomes in renal, cochlear, and ocular tissues.

Autosomal Recessive Alport Syndrome Autosomal recessive Alport syndrome (ARAS) arises from mutations affecting both alleles of *COL4A3* or *COL4A4*.[15,16] ARAS should be suspected when an individual exhibits the typical clinicopathologic features of the disease but lacks a positive family history, especially when a young female has findings indicative of severe disease, such as deafness, nephrotic syndrome, and impaired renal function, However, sporadic cases of AS may represent *de novo* mutations at the *COL4A5* locus or a germ-line *COL4A5* mutation in the proband's mother. Most patients with ARAS develop ESRD and deafness before age 30 years, regardless of gender.

Autosomal Dominant Alport Syndrome Heterozygous mutations in *COL4A3* or *COL4A4* typically result in asymptomatic hematuria.[16,17] In some families, however, these mutations may also be associated with progressive nephropathy, that is, autosomal dominant Alport syndrome (ADAS).[18,19] ADAS patients tend to have a slower course to ESRD than those with XLAS or ARAS.[20]

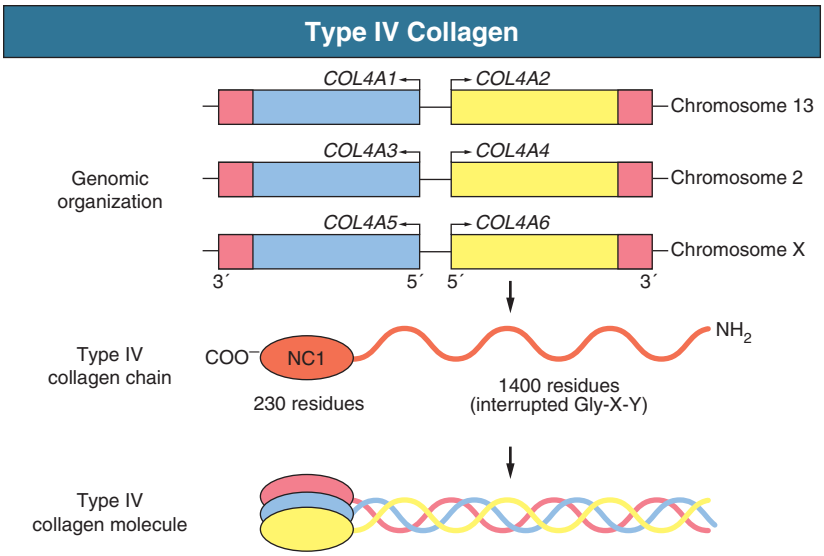

Figure 48-1 Genomic organization of type IV collagen genes. Each type IV collagen chain is synthesized from one of the pairs of type IV collagen genes. Each type IV collagen molecule is a heterotrimer of three type IV collagen chains (see also Fig. 48-4).

Molecular Genetics of Alport Syndrome

Inheritance	Affected Locus	Gene Product
X-linked (XLAS)	*COL4A5*	α5(IV)
X-linked + leiomyomatosis	*COL4A5* + *COL4A6*	α5(IV) + α6(IV)
Autosomal recessive (ARAS)	*COL4A3* *COL4A4*	α3(IV) α4(IV)
Autosomal dominant	*COL4A3* *COL4A4*	α3(IV) α4(IV)

Table 48-1 Molecular genetics of Alport syndrome.

Type IV Collagen in Alport Basement Membranes

The GBMs and tubular basement membranes of males with XLAS usually fail to stain for the α3(IV), α4(IV), and α5(IV) chains but do express the α1(IV) and α2(IV) chains[21] (Fig. 48-2). Women with XLAS frequently exhibit mosaicism of GBM expression of the α3(IV), α4(IV), and α5(IV) chains, whereas expression of the α1(IV) and α2(IV) chains is preserved. Most males with XLAS show no EBM expression of α5(IV), whereas female heterozygotes frequently display mosaicism (Fig. 48-3). Lens capsules of some males with XLAS do not express the α3(IV), α4(IV), or α5(IV) chains, whereas expression of these chains appears normal in other patients.

In most patients with ARAS, GBM shows no expression of the α3(IV), α4(IV), or α5(IV) chains, but α5(IV) and α6(IV) are expressed in Bowman capsule, distal tubular basement membrane, and EBM[20] (Fig. 48-4). Therefore, XLAS and ARAS may be differentiated by immunohistochemical analysis. Basement membrane expression of type IV collagen α chains appears to be normal in patients with ADAS.

These observations indicate that a mutation affecting one of the chains involved in the α3–α4–α5(IV) network can prevent GBM expression not only of that chain but also of the other two chains. Most observational and experimental evidence supports the hypothesis that these effects reflect post-translational events. Some mutant chains are unable to participate in the formation of trimers; as a result, the normal chains that are prevented from forming trimers undergo degradation. Other mutations may allow formation of abnormal trimers that are degraded before deposition in basement membranes can occur (Fig. 48-5).

Clinical Manifestations

Renal Defects

Hematuria is the cardinal finding of AS. Affected males have persistent microhematuria. Many also have episodic gross hematuria, precipitated by upper respiratory infections, usually during the first two decades of life. Hematuria has been discovered in the first year of life in affected boys, in whom it is probably present from birth. Boys who are free of hematuria during the first 10 years of life are unlikely to be affected.

More than 90% of females with XLAS have persistent or intermittent microhematuria, but about 7% of obligate heterozygotes never manifest hematuria.[21] Hematuria appears to be persistent in both males and females with ARAS. About 50% of carriers of *COL4A3* or *COL4A4* mutations have hematuria.[16,17]

Proteinuria is usually absent early in life but develops eventually in all males with XLAS and in both males and females with ARAS. Proteinuria increases progressively with age and may result in the nephrotic syndrome. Proteinuria develops eventually in most heterozygous females.[22] Hypertension also increases in incidence and severity with age. Similar to proteinuria, hypertension is more likely to occur in affected males than in affected females with XLAS, but there are no gender differences in the hypertension frequency in ARAS.

End-stage renal disease develops in all affected males with XLAS, at a rate determined primarily by the nature of the underlying *COL4A5* mutation.[15] Thus, the rate of progression is fairly constant among affected males within a particular family, but there is significant interkindred variability. Significant intrakindred variability in the rate of progression to ESRD has been reported in some families with missense *COL4A5* mutations.

Progression to ESRD in females with XLAS was considered an unusual event until a 2003 European study of several hundred XLAS females found that 12% developed ESRD before age 40 (vs. 90% of XLAS males), increasing to 30% by age 60 and 40% by 80.[22] The risk for ESRD was significantly increased in heterozygotes with proteinuria. The outcome of XLAS in females is presumed to depend on the relative activities of the normal and mutant X chromosomes, but this has yet to be proved. Gross hematuria in childhood, nephrotic syndrome, and the finding of diffuse GBM thickening by electron microscopy are risk factors for chronic kidney disease (CKD) in affected females.[23] Sensorineural deafness and anterior lenticonus are also indicative of an unfavorable outcome in affected women. Both

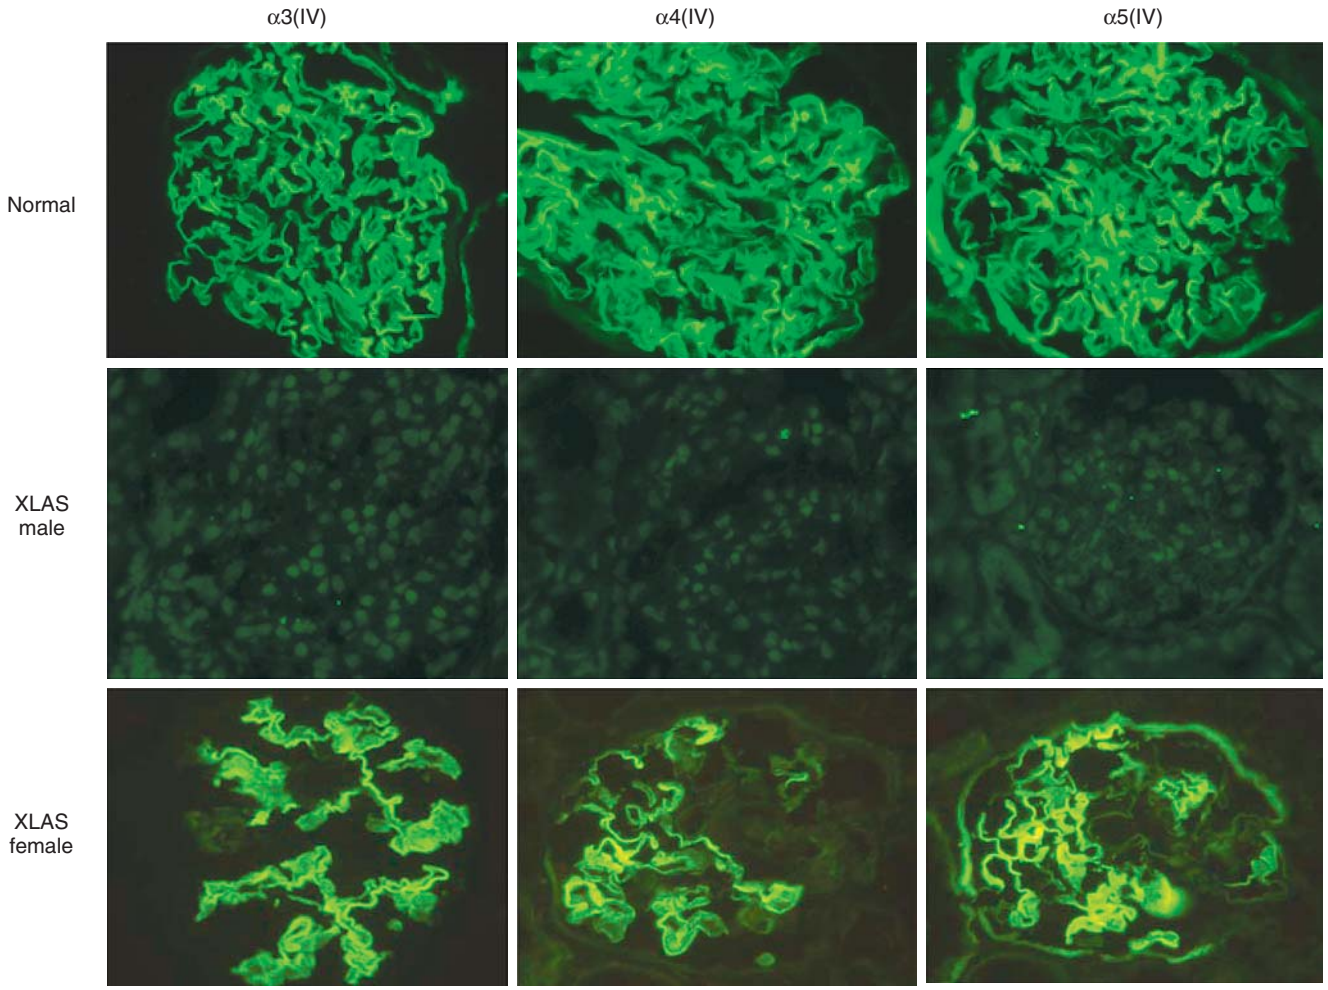

Figure 48-2 Immunohistochemistry of glomerular basement membrane (GBM) in X-linked Alport syndrome (XLAS). In a normal individual *(top row)*, GBM stains strongly for the α3(IV), α4(IV), and α5(IV) chains of type IV collagen. Staining of GBM of an affected male is negative for each of these chains *(middle row)*, whereas an affected female shows mosaic immunoreactivity *(bottom row)*.

males and females with ARAS appear likely to progress to ESRD during the second or third decade of life.

Cochlear Defects

Deafness is frequently but not universally associated with the Alport renal lesion, occurring in about 80% of males and 25% to 30% of females with AS.[15,22] In some families with Alport nephropathy and apparently normal hearing, deafness may occur late and may be very slowly progressive.

Hearing loss in AS is never congenital and usually becomes apparent by late childhood to early adolescence in boys with XLAS and in both boys and girls with ARAS. Hearing impairment in members of families with AS is always accompanied by evidence of renal involvement. There is no convincing evidence that deaf males lacking renal disease can transmit AS to their offspring. In its early stages, the hearing deficit is detectable only by audiometry, with bilateral reduction in sensitivity to tones in the range 2000 to 8000 Hz. In affected males, the deficit extends progressively to other frequencies, including those of conversational speech.

Ocular Defects

Ocular defects occur in 30% to 40% of XLAS males and in about 15% of XLAS females.[15,22] *Anterior lenticonus,* which is virtually pathognomonic of AS, occurs in about 15% of XLAS males and is almost entirely restricted to AS families with progression to ESRD before age 30 years and deafness.[15] Anterior lenticonus is absent at birth, usually appearing during the second to third decade of life, and is bilateral in 75% of patients (Fig. 48-6, *A*). The spectrum and frequencies of ocular lesions appear to be similar in XLAS and ARAS.[24]

Another common ocular manifestation of AS is a maculopathy, which consists of whitish or yellowish flecks or granulations in a perimacular distribution and occurs in 15% to 30% of patients (Fig. 48-6, *B*). The maculopathy does not appear to be associated with any visual abnormalities.

Corneal endothelial vesicles (posterior polymorphous dystrophy) have been observed in AS and may indicate defects in Descemet membrane, the basement membrane underlying the corneal endothelium. Recurrent corneal erosion in AS has been attributed to alterations of the corneal EBM.

Leiomyomatosis

The association of AS with leiomyomatosis of the esophagus and tracheobronchial tree has been reported in about 30 families.[14] Affected females typically exhibit genital leiomyomas as well, with clitoral hypertrophy and variable involvement of the labia majora and uterus. Bilateral posterior subcapsular cataracts also occur frequently in affected individuals. Symptoms usually appear in late

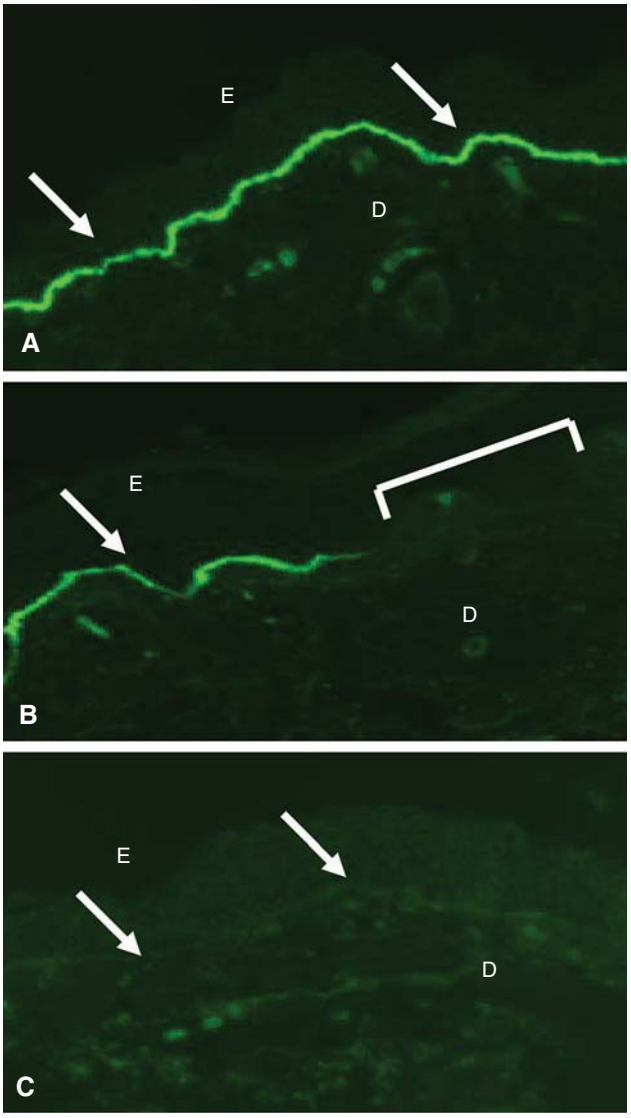

Figure 48-3 Immunohistochemistry of epidermal basement membrane (EBM) in X-linked Alport syndrome. A, In a normal male, EBM shows strong staining for α5(IV) at the dermoepidermal junction *(arrows)* between dermis *(D)* and epidermis *(E)*. **B,** In an affected female, EBM shows mosaic staining *(arrow);* the *white bracket* identifies a length of EBM negative for α5(IV). **C,** In affected males, staining of EBM *(arrows)* for α5(IV) is absent.

childhood and include dysphagia, postprandial vomiting, retrosternal or epigastric pain, recurrent bronchitis, dyspnea, cough, and stridor. All patients with AS–diffuse leiomyomatosis complex have been found to have deletions that encompass the 5′ ends of *COL4A5* and *COL4A6*.

Hematologic Defects

An autosomal dominant syndrome of hereditary nephritis, deafness, and megathrombocytopenia called Epstein syndrome has been described in a small number of families. Families with Fechtner syndrome exhibit these features as well as leukocyte inclusions (May-Hegglin anomaly). Both Epstein and Fechtner syndrome arise from mutations in nonmuscle myosin heavy-chain IIA.[25] Basement membranes of these patients do not exhibit abnormalities in expression of type IV collagen α chains. Therefore, Epstein and Fechtner syndromes are best considered distinct forms of hereditary nephritis rather than variants of AS.

Arterial Abnormalities

Aneurysmal dilation of the thoracic and abdominal aorta and smaller arterial vessels has been described in a small number of males with Alport syndrome.[26]

Pathology

There are no pathognomonic lesions by light microscopy or direct immunofluorescence in AS. In affected males, biopsies obtained before 5 years of age typically show no light microscopy changes. Mesangial hypercellularity and matrix expansion are typically observed in older children and adolescents. Glomeruli of affected males eventually show focal segment glomerulosclerosis, and interstitial fibrosis and tubular atrophy are often found in affected boys older than 10. Light microscopy findings in affected females correlate with proteinuria and kidney function; an affected female of any age who has isolated hematuria is likely to have little or no abnormality by light microscopy. Indirect immunofluorescence of type IV collagen α-chain expression in renal or skin basement membranes can be diagnostic (see earlier discussion) and is increasingly available in specialized laboratories around the world.

Electron microscopy (EM) frequently reveals diagnostic abnormalities. The cardinal fine structural feature of the kidney that occurs in most patients with AS is the variable thickening, thinning, basket weaving, and lamellation of the GBM (Fig. 48-7). The thick segments measure up to 1200 nm in depth, usually have irregular outer and inner contours, and are found more frequently in males than in females. The lamina densa is transformed into a heterogeneous network of membranous strands, which enclose clear electron-lucent areas that may contain round granules of variable density measuring 20 to 90 nm in diameter. There are variable degrees of epithelial foot process fusion.

Not all Alport kindreds demonstrate these characteristic ultrastructural features. Thick, thin, normal, and nonspecifically altered GBMs have all been described. Affected young males, heterozygous females at any age, and, on occasion, affected adult males may have diffusely attenuated GBM measuring as little as 100 nm or less in thickness rather than the pathognomonic lesion. Although diffuse attenuation of GBM has been considered the hallmark of thin basement membrane nephropathy, some patients with this abnormality are members of kindreds with a history of progression to renal failure. Therefore, the significance of an ultrastructural finding of thin GBM must be considered in the context of the family history, basement membrane expression of type IV collagen α chains, and if available, molecular genetic information.

Diagnosis and Differential Diagnosis

Figure 48-8 summarizes the evaluation of patients with hematuria and a positive family history. AS should be included in the initial differential diagnosis of patients with persistent microhematuria after excluding structural abnormalities of the kidneys or urinary tract. The presence on EM of diffuse thickening and multilamellation of the GBM predicts a progressive nephropathy, regardless of family history. However, in a patient with a negative family history, EM cannot differentiate *de novo* XLAS from ARAS. In some patients, the biopsy findings may be ambiguous, particularly in females and young patients of either gender. Furthermore, families with progressive nephritis and *COL4A5* mutations in association with GBM thinning have been described, indicating that the classic Alport GBM lesion is not present in all Alport kindreds.

It is not unusual to see a patient with hematuria or to discover that multiple relatives also have hematuria, although none has ever

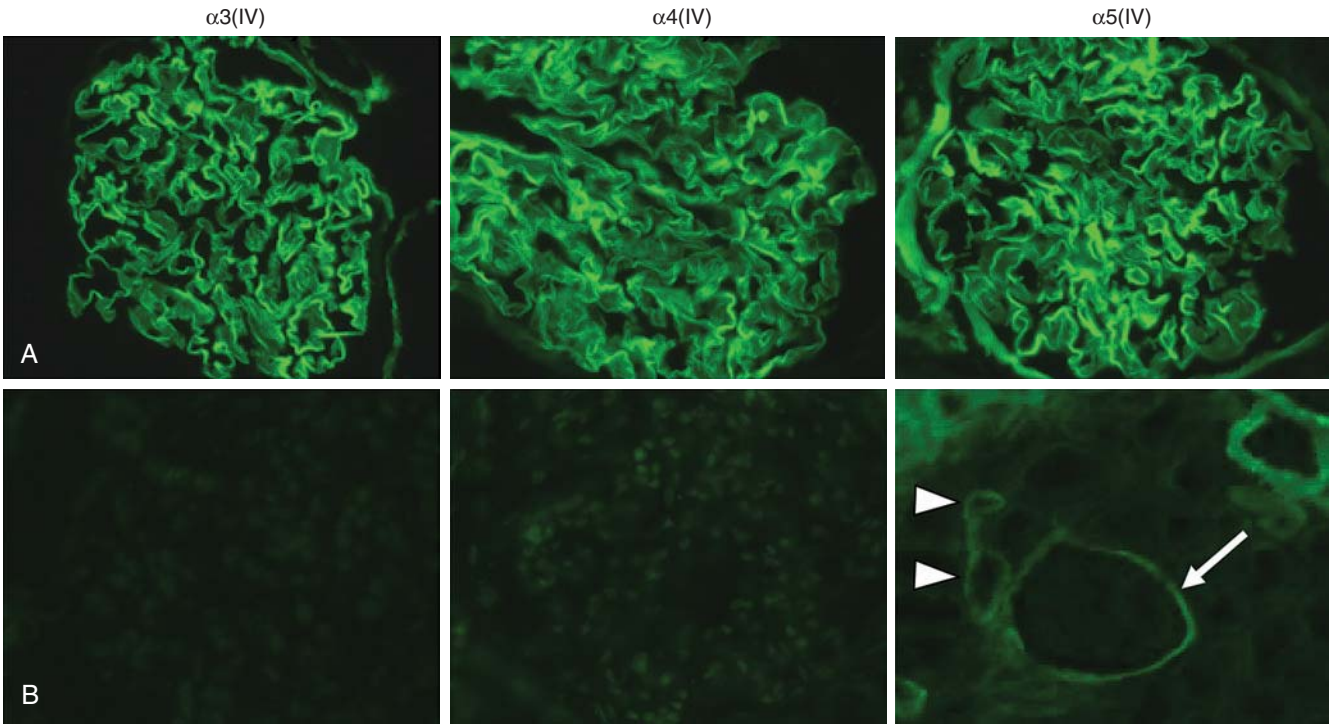

Figure 48-4 Immunohistochemistry of kidney in patient with autosomal recessive Alport syndrome. A, Normal glomerular basement membrane (GBM) and Bowman capsule staining for α3(IV), α4(IV), and α5(IV). **B,** Patient shows no GBM staining, but it is present in Bowman capsule *(arrow)* and distal tubular basement membranes *(arrowheads)*.

undergone kidney biopsy. Who should undergo biopsy in such cases? The natural history of the AS renal lesion suggests that older, male subjects are more likely to exhibit diagnostic ultrastructural GBM abnormalities. In families with a firm diagnosis of AS established, evaluation of individuals with newly recognized hematuria can be limited to ultrasound of the kidneys and urinary tract to exclude coincidental tumor or structural anomalies of the urinary tract.

Absence of the α3, α4, and α5 chains of type IV collagen from GBM and distal tubular basement membrane has not been described in any condition other than AS, making this a diagnostic finding on kidney biopsy (Table 48-2). Examination of skin biopsy specimens by immunofluorescence for expression of α5(IV) in the EBM may be informative, but apparently normal expression of type IV collagen α chains in basement membranes does not exclude the diagnosis of AS. Mosaic expression of α5(IV) is common in heterozygous females. Although mosaic expression of α5(IV) is diagnostic of the carrier state, a normal result does not exclude heterozygosity. A female member of an Alport kindred who does not have hematuria may still be a carrier, but is less likely to exhibit detectable mosaicism than a female with hematuria.

A firm histologic diagnosis of AS cannot always be established, or it may not be possible to determine the mode of transmission, despite careful evaluation of the pedigree and application of the full range of histologic methods. In these situations, genetic analysis may provide information essential for determining prognosis and guiding genetic counseling. Genetic analysis for AS is becoming increasingly available as a clinical assay in commercial laboratories. A current list of laboratories offering molecular genetic diagnosis of Alport syndrome can be found at genereviews.org.

Glomerular diseases that typically occur sporadically may on occasion be heritable and should be considered in the differential diagnosis. These include focal segmental glomerulosclerosis, membranous nephropathy, membranoproliferative glomerulonephritis, IgA nephropathy, and C3 glomerulopathy.

Natural History

Microhematuria, the first and invariable renal manifestation of AS, probably reflects GBM thinning and a tendency to develop focal ruptures because of defective expression of the α3–α4–α5(IV) network. Anterior lenticonus most likely results from the inability of the abnormal lens capsule to maintain the normal conformation of the lens. Ultrastructural studies of Alport cochleae suggest that the hearing deficit may be attributable to a defect in adherence of the organ of Corti to the basilar membrane.[27]

In its early stages, AS is clinically and often histologically indistinguishable from thin basement membrane nephropathy, which typically has a benign outcome. GBM attenuation is therefore an insufficient explanation for the divergent natural histories of the two conditions. What factors initiate and drive the progression of Alport nephropathy to ESRD? Reduction in the quantity of α3(IV), α4(IV), and α5(IV) chains in GBM, as likely occurs in thin basement membrane nephropathy, probably has consequences different from complete loss of these chains, as occurs in most males with XLAS and most patients with ARAS. There is increasing information about the molecular events that occur consequent to the loss of the α3(IV)–α4(IV)–α5(IV) network. In the GBM, the normal transition from the $\alpha1(IV)_2$–$\alpha2(IV)_1$ network of nascent glomeruli to the α3(IV)–α4(IV)–α5(IV) network of mature glomeruli fails to occur, and α1(IV) and α2(IV) chains accumulate in Alport glomeruli as the disease progresses.[28,29] Alport GBM shows overexpression of other matrix proteins that are normally absent from GBM or present in scant quantities, including type V collagen, type VI collagen, laminin α2 chain, and fibronectin. These alterations in GBM composition are unique to AS.[28,30] Both glomerular endothelial cells and podocytes

appear to contribute to the accumulation of these proteins in Alport GBM. Alterations in glomerular extracellular matrix are accompanied by changes in glomerular cell behavior, including expression of transforming growth factor β1, integrins, and matrix metalloproteinases.[31] Activation of fibrogenic pathways in the renal interstitium presumably represents a downstream consequence of glomerular disease.

Treatment

Current clinical practice recommendations for delaying ESRD in AS patients focus on the early introduction of inhibitors of the renin-angiotensin system (RAS) to suppress urinary protein excretion.[32,33] The focus on RAS inhibition is based on experimental and clinical evidence as well as practical considerations. Angiotensin-converting enzyme (ACE) inhibition lengthens survival in mice with ARAS.[33] When ACE inhibition in Alport mice is begun before the onset of proteinuria, the duration of survival is doubled, a therapeutic result thus far not exceeded by any other intervention. ACE inhibition begun after the onset of proteinuria also improves survival in Alport mice, to a lesser but still significant degree. The effect of ramipril on survival was superior to that of candesartan in a murine comparison study.[34]

Analysis of retrospective data collected by the European Alport Registry indicates that ACE inhibitor therapy initiated while glomerular filtration rate (GFR) is still normal delays ESRD by years.[35] This effect has also been shown in pairs of affected brothers discordant for ACE inhibitor therapy.[35] ACE inhibition, angiotensin receptor blockade, and aldosterone inhibition have been shown to reduce proteinuria in children with Alport syndrome, in both uncontrolled and controlled studies.[36] The effect of losartan on proteinuria was greater than the effect of amlodipine.[36] As shown in the ESCAPE trial, ACE inhibitors can be used safely in children with CKD, at doses that achieve suppression of urinary protein excretion.[37] RAS antagonists, especially ACE inhibitors, are relatively inexpensive and widely available. In theory, any child in the world with AS should be able to receive treatment with an ACE inhibitor. This cannot be said for other treatments, such as stem cell therapy, which have shown early promise in murine AS models.[38]

Consensus recommendations for the management of AS children include (1) early screening for hematuria in at-risk children; (2) regular determination of urinary albumin and protein excretion on diagnosis; and (3) initiation of angiotensin blockade once overt proteinuria develops. The goal of blockade is to reduce the urine protein-creatinine (PC) ratio by 50% in children with a ratio of 0.2 to 1 mg/mg, or to less than 0.5 mg/mg in those with a ratio greater than 2 mg/mg.[32] A randomized trial examining the effect of angiotensin blockade on the transitions from isolated hematuria to microalbuminuria to overt proteinuria is underway in Europe (EARLY PRO-TECT). Future clinical trials comparing angiotensin blockade to other therapies, alone or in combination, will be needed to identify the most effective approaches to delaying and preventing ESRD in patients with Alport syndrome.

Transplantation

At present, renal transplantation is the only available treatment for AS. Graft survival in patients with familial nephritis is equivalent to that in patients with other diagnoses. However, anti-GBM glomerulonephritis involving the renal allograft is a rare but dramatic manifestation of AS, occurring in 2% to 3% of male AS patients who undergo transplantation (see Chapter 24).

Are women who are heterozygous for *COL4A5* mutations suitable kidney donors? Clearly, those with proteinuria, hypertension, or reduced GFR should not donate, nor should the woman with hearing loss. For heterozygotes with hematuria but normal renal function and hearing, no long-term follow-up information is available on the impact of uninephrectomy in such women. Given the recent finding that 30% to 40% of heterozygous women may eventually develop ESRD, however, the risk that a heterozygous donor will ultimately develop significant renal impairment must be higher than for the usual kidney donor. However, a common clinical scenario is a mother choosing to donate to her son with AS, and the choices of the whole family should be considered.

THIN BASEMENT MEMBRANE NEPHROPATHY: FAMILIAL AND SPORADIC

Definition

Isolated glomerular hematuria may occur as a familial or sporadic condition and is often associated with a renal biopsy finding of excessively thin GBM. The term *benign familial hematuria* was used in the past to describe disease kindreds in whom multiple individuals in several generations have isolated hematuria without progression to ESRD. More recently, thin basement membrane nephropathy (TBMN) has been used to identify both familial and sporadic isolated hematuria associated with attenuated GBM. It is likely that several disorders that differ at the molecular level are associated with GBM thinning, and in some patients, it is probably a normal variant. In general, this discussion applies to both familial and sporadic TBMN.

Similar to Alport syndrome, familial TBMN is an inherited GBM disorder manifested by chronic hematuria, but it differs clinically from AS in several important respects: (1) extrarenal abnormalities

Immunostaining for Type IV Collagen in Alport Syndrome				
Type IV Collagen Group	**Glomerular Basement Membranes**	**Bowman Capsules**	**Distal Tubular Basement Membrane**	**Epidermal Basement Membrane**

Table 48-2 Immunostaining for type IV collagen in Alport syndrome. *In some Alport kindreds, staining of basement membranes for type IV collagen chains is entirely normal. Therefore, a normal result does not exclude a diagnosis of X-linked Alport syndrome. †Some heterozygous females have normal basement membrane immunoreactivity for type IV collagen chains. Therefore, a normal result does not exclude the carrier state.

are rare; (2) proteinuria, hypertension, and progression to ESRD are unusual, seen in less than 10% of affected individuals, and extremely unusual before age 40; (3) gender differences in expression of TBMN are not apparent; and (4) transmission is autosomal dominant. TBMN and early AS may be difficult to differentiate histologically because diffuse GBM attenuation is characteristic of both. However, the GBM of patients with TBMN remains attenuated over time, rather than undergoing the progressive thickening and multilamellation that occurs in AS.

Etiology and Pathogenesis

Although TBMN is an autosomal dominant condition, a negative family history may not be reliable because patients are frequently unaware that they have relatives with hematuria. Familial TBMN has been localized to *COL4A3* or *COL4A4* in numerous kindreds.[39,40] Of heterozygous carriers of a *COL4A3* or *COL4A4* mutation, 50% or more have hematuria.[16,17] However, linkage to *COL4A3* and *COL4A4* has been excluded in other families with isolated hematuria, indicating that TBMN is a genetically heterogeneous condition.

Immunohistologic studies of type IV collagen in GBM of patients with TBMN have found no abnormalities in the distribution of any of the six α chains. Immunohistologic evaluation of GBM type IV collagen may therefore be useful in the differentiation of TBMN from AS (see later discussion).

Clinical Manifestations

An estimated 20% to 25% of patients referred to a nephrologist for evaluation of persistent hematuria will prove to have thin GBM on renal biopsy. Individuals with TBMN typically have persistent microhematuria that is first detected in childhood. In some patients, microhematuria is intermittent and may not be detected until adulthood. Episodic macroscopic hematuria, often in association with upper respiratory infections, is not unusual. The hematuria of TBMN appears to be lifelong.

Overt proteinuria and hypertension are unusual in TBMN but have been reported. Some of these patients may have actually had AS, in which the predominant abnormality of GBM was attenuation rather than thickening and multilamellation. Other glomerular disorders, such as IgA nephropathy and focal or global glomerulosclerosis, may occur concurrently with TBMN.

Pathology

Light and immunofluorescence microscopy are unremarkable in typical cases of TBMN. Most patients exhibit diffuse thinning of the whole GBM and of the lamina densa (Fig. 48-9). GBM width is age and gender dependent in normal individuals. Both the lamina densa and the GBM increase rapidly in thickness between birth and 2 years of age, followed by gradual thickening into adulthood. GBM thickness in adult men (373 ±42 nm) exceeds that in adult women (326 ±45 nm).[41] Each EM laboratory should establish a consistent technique for measuring GBM thickness and determine its own reference range for GBM width to make comparisons with published data meaningful. Typically, a value of 250 nm will accurately separate adults with normal GBM from those with TBMN. For children, the cutoff is in the range of 200 to 250 nm. Intraglomerular variability in GBM width is minimal in patients with TBMN.

Diagnosis and Differential Diagnosis

If the family history indicates autosomal dominant transmission of isolated hematuria without deafness or ocular abnormalities, if there is no family history of CKD, and if kidney and urinary tract imaging studies are normal, a presumptive diagnosis of TBMN can often be made without kidney biopsy (see Fig. 48-7). When family history is negative or unknown or there are atypical coexisting features, such

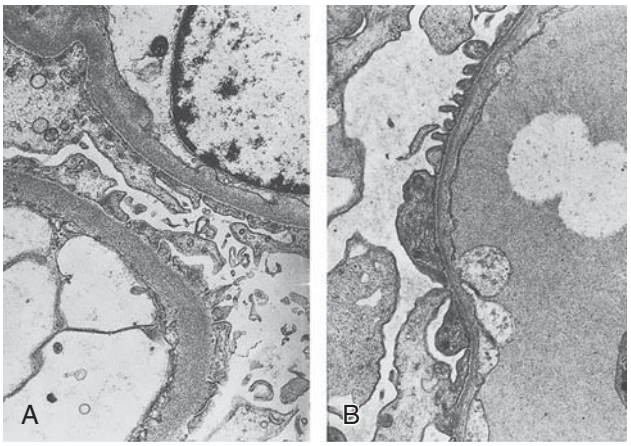

Figure 48-9 Thin basement membrane nephropathy. Electron micrographs of renal biopsy specimens. **A,** Normal glomerular capillary wall. **B,** Thin basement membrane nephropathy at the same magnification. Note the diffuse and uniform attenuation of the GBM and the lamina densa. *(From reference 63.)*

as proteinuria and deafness, renal biopsy may be very informative. A finding of thin GBM may be further characterized by examining the distribution of type IV collagen α chains in the kidney. Normal distribution of these chains provides supportive but not conclusive evidence for a diagnosis of TBMN. Marked variability in GBM width within a glomerulus in a patient with persistent microhematuria should raise suspicion of AS, although focal lamina densa splitting has been described in TBMN. Genetic analysis may confirm a heterozygous mutation in *COL4A3* or *COL4A4*.

Treatment

Patients with TBMN should be reassured but not lost to follow-up examination. The risk for chronic renal impairment is small (likely <5%) but real. Urinalysis and measurement of blood pressure and renal function are recommended every 1 to 2 years.

FABRY DISEASE (ANDERSON-FABRY DISEASE)

Definition

Fabry disease comprises the clinical and the pathologic manifestations of hereditary deficiency of the enzyme α-galactosidase A (α-Gal A), resulting in the intracellular accumulation of neutral glycosphingolipids with terminal α-linked galactosyl moieties (Fig. 48-10). Anderson[42] and Fabry[43] each described the characteristic skin lesions of this condition in 1898 and noted the association of proteinuria with the skin lesion, for which Fabry coined the term *angiokeratoma corporis diffusum*.

Etiology and Pathogenesis

More than 100 mutations causing Fabry disease have been identified in the gene for α-Gal A, which is located on the X chromosome. Most of the described mutations are associated with the classic Fabry phenotype, in which there is multisystem involvement. Certain missense mutations have been identified in patients with a mild phenotype limited to cardiac abnormalities.[44]

Deficiency of α-Gal A leads to progressive intracellular accumulation of neutral glycosphingolipids, particularly those with

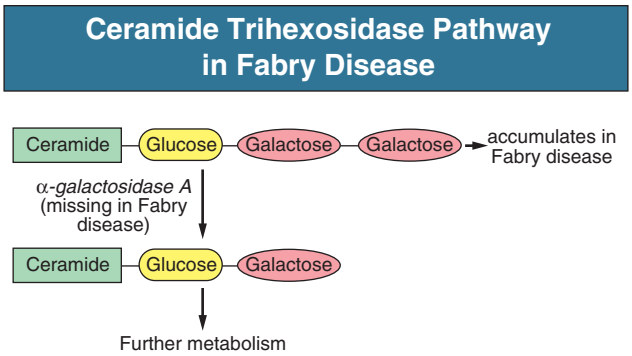

Figure 48-10 Ceramide trihexosidase pathway in Fabry disease. α-Galactosidase A deficiency leads to tissue accumulation of trihexosylceramide.

α-galactosyl moieties, the most abundant of which is globotriaosylceramide (Gb3). Glycosphingolipids are normal constituents of the plasma membrane, the membranes of intracellular organelles, and circulate in association with apolipoproteins. The glycosphingolipids that accumulate in Fabry disease are identical to those found in normal tissue. All tissues except red blood cells accumulate Gb3, with the highest concentrations found in the diseased kidney.

Clinical Manifestations and Pathology

Classic Fabry disease is a multisystem disorder, with prominent and potentially devastating involvement of the kidneys, heart, and peripheral and central nervous system. As expected for an X-linked disorder, severe clinical manifestations occur in hemizygous males, whereas heterozygous females exhibit a variable but typically less severe course. In affected males, the initial features of the disease are seen in childhood and early adolescence and consist of paresthesias and pain in the hands and feet with episodic pain crises. The course of the disease is variable but usually leads to ESRD in the third to sixth decade. Myocardial or cerebral infarctions are typical terminal events. Severe Fabry disease in a female reflects extensive inactivation of the X chromosome carrying the normal α-Gal A allele.

Renal Defects

Although the earliest manifestation of renal involvement is a concentrating defect, the nephropathy of Fabry disease typically manifests as mild to moderate proteinuria, sometimes with microhematuria, beginning in the third decade. Nephrotic syndrome is unusual. Urinary oval fat bodies, with a Maltese cross configuration when viewed with a polarizing microscope, are a result of the large amounts of glycosphingolipid in the urine (see Chapter 4, Fig. 4-2, *B*). Deterioration of renal function is gradual, with hypertension and ESRD developing by the fourth or fifth decade of life. Heterozygous women typically display mild renal involvement but may develop ESRD.

Light microscopy shows striking glomerular changes with additional abnormalities of tubular epithelium and vessels (Fig. 48-11). Glomerular visceral epithelial cells are enlarged and packed with small, clear vacuoles, which represent glycosphingolipid material that has been extracted during processing. Vacuoles may also be seen in parietal epithelial cells and the epithelial cells of the distal convoluted tubule and loop of Henle, but only rarely in mesangial cells, glomerular endothelial cells, or proximal tubular epithelial cells. There is progressive segmental and global glomerulosclerosis. Vacuoles are also observed in endothelial cells and smooth muscle cells of arterioles and arteries.

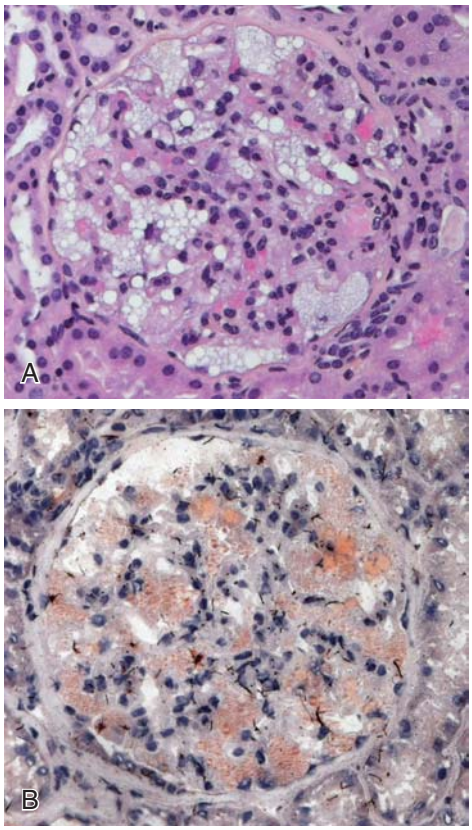

Figure 48-11 Light microscopy of a renal biopsy specimen in Fabry disease. Glomerular epithelial cell glycosphingolipid deposition demonstrated by **A,** vacuolation on hematoxylin-eosin staining (magnification ×20), and **B,** oil red O staining (×20). *(Courtesy Dr. Paolo Menè and Dr. Antonella Stoppacciaro, University of Rome.)*

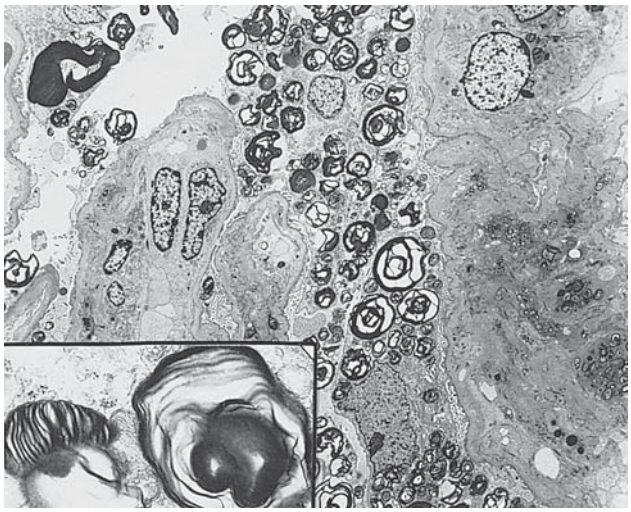

Figure 48-12 Electron micrograph of a renal biopsy specimen in Fabry disease. Glycosphingolipid is deposited in cytoplasmic vacuoles in glomerular visceral epithelial cells. *Inset,* Cytoplasmic vacuoles contain electron-dense material in parallel arrays (zebra bodies) and in concentric whorls (myelin figures). *(Courtesy Dr. J. Carlos Manivel.)*

On EM, there are abundant inclusions within lysosomes, particularly within visceral epithelial cells (Fig. 48-12). The inclusions (myelin figures) are typically round, comprising concentric layers of dense material separated by clear spaces. The layers may be arranged in parallel (zebra bodies). Detachment of visceral epithelial cells from the underlying basement membrane may be observed. Inclusions are also observed in heterozygous females, although usually in smaller numbers than in affected males. Typical inclusions may be noted in excreted renal tubular cells.

Figure 48-13 Angiokeratoma in Fabry disease. Note the multiple periumbilical angiokeratomas. *(Courtesy Dr. S. Waldek.)*

The progression of Fabry nephropathy to ESRD probably reflects two parallel processes. Visceral epithelial cell dysfunction, which results in proteinuria, is followed by visceral epithelial cell detachment and necrosis, leading to capillary loop collapse and segmental sclerosis. Simultaneously, progressive impairment of arteriolar flow may develop, as enlarging endothelial cells impinge on vascular lumina, resulting in ischemic glomerular damage.

Heart Defects

Glycosphingolipid accumulation in coronary arterial endothelial cells and in the myocardium results in coronary artery narrowing, which may lead to angina, myocardial infarction, or congestive heart failure. Arrhythmias and valvular lesions have been identified. Certain missense mutations affecting α-Gal A may present as isolated left ventricular hypertrophy (LVH).[44]

Nervous System

Autonomic dysfunction is a prominent feature of Fabry disease, typically manifested by hypohidrosis, acral paresthesias, and altered intestinal motility. Cerebrovascular symptoms tend to appear during the fourth decade and include hemiparesis, vertigo, diplopia, dysarthria, nystagmus, nausea and vomiting, headache, ataxia, and memory loss. The vertebrobasilar circulation is preferentially involved. Symptoms are often recurrent. Life-threatening intracerebral hemorrhage and infarction are not unusual. Dementia arising from glycosphingolipid accumulation in small cerebral blood vessels has also been described.

Skin

Angiokeratomas usually appear during the second decade of life, presenting as dark-red macules or papules of variable size (Fig. 48-13). Typical locations include the lower trunk, buttocks, hips, genitalia, and upper thighs. The number of lesions varies from none up to 40. On histologic examination, angiokeratomas consist of dilated small veins in the upper dermis, covered by hyperkeratotic epidermis. Telangiectasias may be noted, especially behind the ears.

Eyes

Characteristic corneal opacities are common in both men and women with Fabry disease. These lesions, termed *verticillata,* are

identified by slit-lamp examination and are whorls of whitish discoloration that radiate from the center of the cornea. Cataracts and dilated conjunctival or retinal vessels may be observed.

Lungs

Dyspnea and cough are common in men with Fabry disease, often with airflow limitation on spirometry. This may be a consequence of fixed narrowing of the airways caused by glycosphingolipid accumulation.

Diagnosis

Diagnosis of affected males can usually be made clinically, with the additional information from slit-lamp eye examination. The diagnosis should be confirmed by demonstrating decreased or absent α-Gal A activity in serum, leukocytes, cultured skin fibroblasts, or tissue. Atypical variants may have enzyme activity up to 35% of normal. Heterozygous females have intermediate levels of α-Gal A activity, but values may be in the low-normal range, making measurement of enzyme activity an insensitive way of diagnosing carriers. Alternatives include careful slit-lamp eye examination, measurement of urinary ceramide digalactoside and trihexoside, and molecular techniques. Current information on laboratories offering sequencing of the α-Gal gene can be obtained at gene reviews.org. Identification of carriers is particularly relevant when family members are being considered as living kidney donors.

Fabry disease should be considered in patients with unexplained ESRD,[45] especially if LVH is present or there is a history of stroke.[46]

Treatment

Until recently, clinicians could offer little beyond palliative, symptomatic care, but the introduction of enzyme replacement therapy with recombinant human α-Gal A (agalsidase) has transformed the treatment of Fabry disease. Randomized clinical trials showed that agalsidase administration during 5 to 6 months resulted in reduced plasma and urine Gb3; amelioration of neuropathic pain; enhanced quality of life; clearing of Gb3 deposits from kidney, heart, and skin; and improved cerebral blood flow.[47,48] A multicenter longitudinal study showed that agalsidase stabilized renal function in patients with mild to moderate renal impairment at baseline and reduced left ventricular mass in those with LVH at baseline during 1 to 2 years of treatment.[49] However, the impact of enzyme replacement therapy on long-term renal outcome is still unclear.[50,51] Addition of ACE inhibitor and/or angiotensin receptor blocker (ARB) therapy to enzyme replacement can result in sustained reductions in proteinuria.[52] In patients with ESRD, agalsidase infusion may be combined with hemodialysis, because there is little clearance of the enzyme by dialysis.[53] Agalsidase therapy has been recommended for all affected males and symptomatic carrier females, but the drug is prohibitively expensive in many parts of the world.[54] An alternative treatment approach based on chemical "chaperones" is under investigation.[55,56]

Renal transplantation is an effective treatment of advanced Fabry nephropathy but does not ameliorate the extrarenal manifestations. Transplanted kidneys from deceased donors or unaffected living donors may develop glycosphingolipid inclusions, but these are generally infrequent and clinically insignificant. Fabry heterozygotes should not become kidney donors. Coronary artery and cerebrovascular disease are the major causes of mortality in patients with Fabry disease who have undergone renal transplantation. Renal allograft recipients with Fabry disease are candidates for agalsidase treatment.[54]

Fabry Disease in Childhood

Because it is often not appreciated that the signs and symptoms of Fabry disease, particularly pain crises, acroparesthesias, angiokeratomas, and corneal opacities, typically have their onset in childhood, the diagnosis is frequently delayed until well into adult life.[57] Symptomatic children with Fabry disease are potential candidates for agalsidase therapy.

NAIL-PATELLA SYNDROME

Definition

Nail-patella syndrome (NPS) is an autosomal dominant condition characterized by hypoplasia or absence of the patellae, dystrophic nails, dysplasia of the elbows and iliac horns, and renal disease.

Etiology and Pathogenesis

The NPS locus was identified in 1998 as the LIM homeodomain transcription factor *LMX1B*.[58,59] A variety of mutations in *LMX1B* have been found in NPS patients, including missense, splicing, insertion or deletion, and nonsense alterations. The results of *in vitro* studies of the transcriptional effects of mixing wild-type and mutant *LMX1B* suggest that NPS results from haploinsufficiency of *LMX1B*, rather than a dominant-negative effect.[60] Although *LMX1B* appears to be important for normal limb and kidney development, the precise mechanisms for the renal effects of *LMX1B* mutations remain under investigation.

Clinical Manifestations

Renal Defects

Clinically apparent renal disease occurs in less than half of NPS patients. The nephropathy is usually benign, with about a 10% risk for progression to ESRD. The clinical signs of NPS nephropathy appear in adolescence or young adulthood and typically include microscopic hematuria and mild proteinuria, although some patients develop nephrotic syndrome and mild hypertension. The severity of the renal manifestations may differ substantially in related individuals.

Skeletal Defects

The patellae are absent or hypoplastic in more than 90% of patients with NPS and may be associated with effusions and osteoarthritis of the knees (Fig. 48-14). In about 80% of patients, osseous processes project posteriorly from the iliac wings (iliac horns), which is pathognomonic (Fig. 48-15). Anomalies of the elbows include aplasia, hypoplasia, and posterior processes at the distal end of the humeri.

Nails

Nail abnormalities occur in about 90% of patients and are typically bilateral and symmetric. Fingernails are affected more often than toenails. The nails may be absent or dystrophic with discoloration, koilonychia, longitudinal ridges, or triangular lunulae.

Pathology

The only specific features of the NPS renal lesion are ultrastructural; EM shows multiple irregular lucencies of the GBM, giving it a moth-eaten appearance (Fig. 48-16). Such lucencies may also be observed in the mesangium. These lucent areas sometimes contain cross-banded collagen fibrils, which are more easily observed after staining with phosphotungstic acid (Fig. 48-17). The fibrils, which are type

III collagen,[61] tend to be arranged in clusters, and the surrounding GBM is often thickened. This may be observed in the kidneys in the absence of clinically evident renal disease, but fibrils have not been found in extraglomerular basement membranes. Cross-banded fibrils of type III collagen have been seen in GBM of patients with glomerular disease who lack nail or skeletal abnormalities, sometimes as a familial condition with autosomal recessive inheritance (collagen III glomerulopathy; see Chapter 28). It is uncertain whether there is a pathogenetic relationship between collagen type III glomerulopathy and NPS.

Treatment

No specific therapy is available for the nephropathy of NPS. There has been no reported recurrence in transplanted kidneys. Because nail-patella syndrome is an autosomal dominant disorder, careful evaluation of potential living related kidney donors for features of NPS is essential.

CHAPTER 49

Inherited Disorders of Sodium and Water Handling

Peter Gross and Peter Heduschka

Glomerular filtration yields about 150 liters of water, 21,000 mmol of sodium (Na^+), and 750 mmol of potassium (K^+) in a healthy individual in 24 hours, yet only minute fractions of these quantities are excreted eventually as urine. This remarkable volume reduction is accomplished by highly active tubular transport. Inherited defects of tubular transport proteins may thus lead to major fluid and electrolyte derangements. This chapter describes disorders arising in the thick ascending limb of Henle loop and thereafter; proximal tubular disorders are described in Chapter 50 and disturbances of acidification in Chapter 12.

Genetic studies have unraveled the molecular basis of most of the inherited tubular disorders, establishing specific diagnoses more clearly and explaining the corresponding pathogenesis more reliably than previously possible. It is hoped that improved therapies will be developed in time. Diagnostic genetic testing is available for a number of the disorders discussed in this chapter (see www.genetests.org).

PHYSIOLOGY OF SODIUM AND WATER REABSORPTION

Sodium Reabsorption

In all tubular epithelial cells, a basolateral energy requiring Na^+,K^+–adenosine triphosphatase (ATPase) will ensure that intracellular Na^+ is kept at low levels while K^+ is high. The resulting concentration gradients of Na^+ across the apical cell membrane drive passive Na^+ reabsorption from the tubular lumen to the cell interior. Apical Na^+ channels and transport proteins serve to regulate the Na^+ reabsorption, and the proteins involved differ from one tubular segment to the next.

In the proximal tubule, an apical Na^+-hydrogen (H^+) exchange protein (NHE3) facilitates most of the Na^+ reabsorption. It is inhibitable by acetazolamide. The thick ascending limb (TAL) of Henle loop has an apical Na^+-K^+-$2Cl^-$ cotransporter (NKCC2) that can be blocked by furosemide and bumetanide. For efficient Na^+ reabsorption by NKCC2, K^+ must be returned through the renal outer medulla K^+ channel (ROMK) from the cell to the low K^+ tubular fluid (Fig. 49-1). It is also important that sodium transport by this segment is dependent on a basolateral chloride (Cl^-) channel (ClC-Kb) and an accessory protein of ClC-Kb called *barttin* (see Fig. 49-1).

The distal convoluted tubule reabsorbs Na^+ by a unique apical Na^+-Cl^- cotransporter (NCCT). The protein is specifically inhibited by thiazides (Fig. 49-2). A basolateral ClC-Kb chloride channel is also necessary for efficient sodium reabsorption.

In the collecting duct, the apical epithelial sodium channel (ENaC) regulates Na^+ reabsorption. Amiloride and triamterene specifically block ENaC, whereas the mineralocorticoid aldosterone upregulates ENaC (Fig. 49-3). Figure 49-4 provides an overview of tubular proteins of Na^+ reabsorption and their corresponding inheritable disorders (see also Chapters 2 and 7).

Water Reabsorption

In most nephron segments, water follows sodium chloride (NaCl, salt) passively through aquaporins, the constitutively open water transport proteins in apical and basolateral tubular cell membranes. The collecting duct is different, however, and is equipped with apical aquaporin 2 (AQP2), the sole water channel in the kidney that can be regulated on a short-term basis by vasopressin. In this way, the collecting duct provides for eventual fine-tuning of water reabsorption or excretion (Fig. 49-5; see also Chapters 2 and 8).

DISORDERS OF SODIUM HANDLING

Figure 49-6 provides an overview of inherited disorders of Na^+ transport. On clinical grounds, four different phenotypes can broadly be distinguished, as follows:

1. Hypokalemia and normal blood pressure (Bartter syndrome, Gitelman syndrome).
2. Hypokalemia and high blood pressure (Liddle syndrome, apparent mineralocorticoid excess, glucocorticoid-remediable hyperaldosteronism, adrenal 17α-hydroxylase deficiency, adrenal 11β-hydroxylase deficiency).
3. Hyperkalemia and normal blood pressure (pseudohypoaldosteronism, adrenal 21-hydroxylase deficiency, adrenal aldosterone synthase deficiency).
4. Hyperkalemia and high blood pressure (Gordon syndrome).

Some of the disorders are caused by mutated renal transport proteins (e.g., Gitelman syndrome). In others, the genetic defect resides in the adrenals, and the changes in adrenal mineralocorticoids and glucocorticoids create the renal phenotype.

CONDITIONS WITH HYPOKALEMIA, METABOLIC ALKALOSIS, AND NORMAL BLOOD PRESSURE

Bartter Syndrome

Bartter syndrome is rare and is manifests in childhood or in the perinatal period with severe hypokalemia, metabolic alkalosis, and low-normal blood pressure (BP), all of which are caused by tubular wasting of Na^+ and Cl^-.[1] In contrast, Gitelman syndrome is mostly a disorder of adults, and hypomagnesemia is a defining feature.[2]

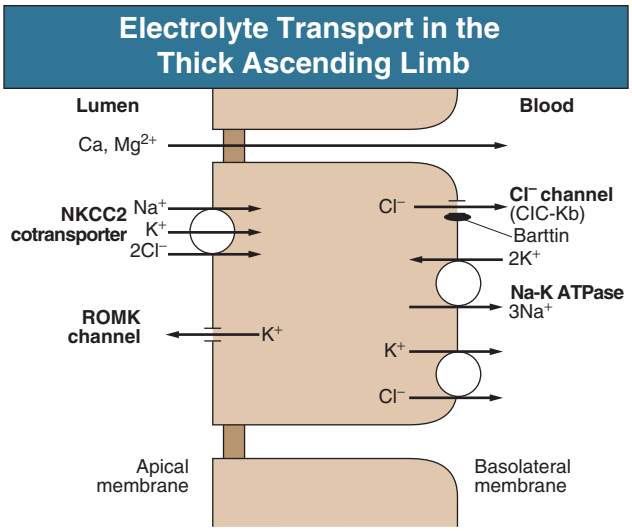

Figure 49-1 Electrolyte transport in thick ascending limb of the loop of Henle. The furosemide-sensitive Na^+-K^+-$2Cl^-$ *(NKCC2)* cotransporter is driven by low intracellular Na^+ and Cl^- concentrations produced by the Na^+,K^+-ATPase pump, the K^+-Cl^- cotransporter, and the basolateral Cl^- channel (ClC-Kb). The β subunit (barttin) is crucial for normal functioning of the ClC-Kb channels. Apical K^+ recycling through the low-conductance, ATP-sensitive renal outer medullary K^+ *(ROMK)* channel ensures the efficient functioning of the NKCC2 cotransporter.

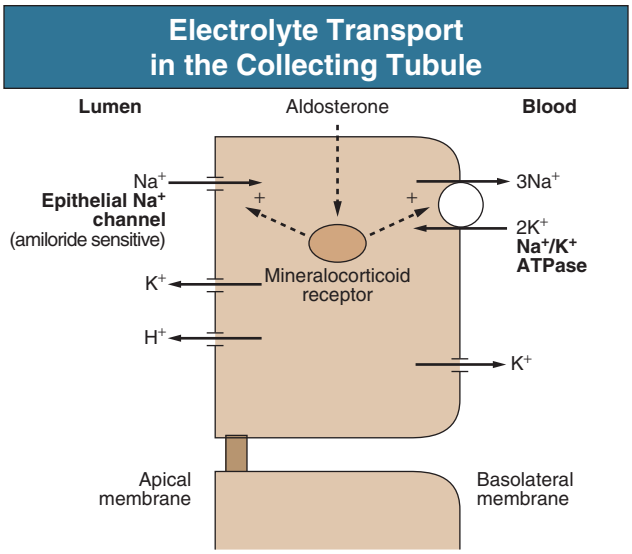

Figure 49-3 Electrolyte transport in principal cell of the collecting tubule. Reabsorption of Na^+ occurs through the amiloride-sensitive epithelial Na^+ channel (ENaC). Its uptake is coupled to K^+ and H^+ secretion. Aldosterone increases the activity of ENaC and Na^+,K^+-ATPase, which increases Na^+ reabsorption and K^+ and H^+ secretion, resulting in hypokalemic alkalosis. Cortisol is also a ligand for the mineralocorticoid receptor but is normally removed by oxidation by 11β-hydroxysteroid dehydrogenase to cortisone.

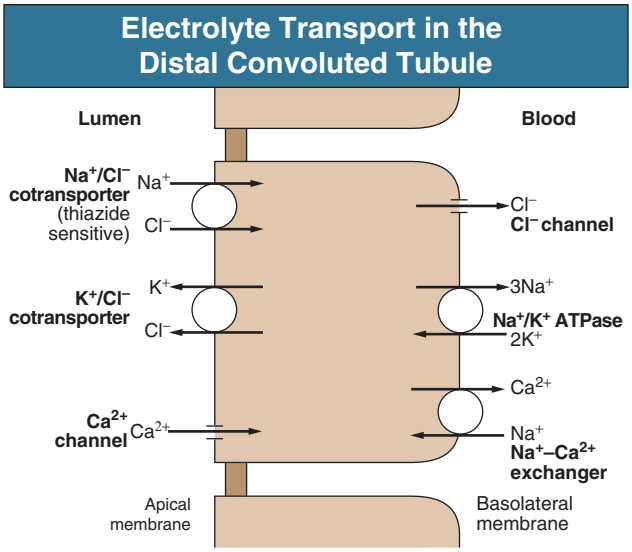

Figure 49-2 Electrolyte transport in the distal convoluted tubule. Reabsorption of Na^+ and Cl^- occurs across the apical membrane by the thiazide-sensitive Na^+-Cl^- cotransporter (NCCT), and these ions leave the cell through the Cl^- channels and through the Na^+,K^+-ATPase pump. Calcium ions enter the cell through the Ca^{2+} channels and exit through the Na^+-Ca^{2+} exchanger.

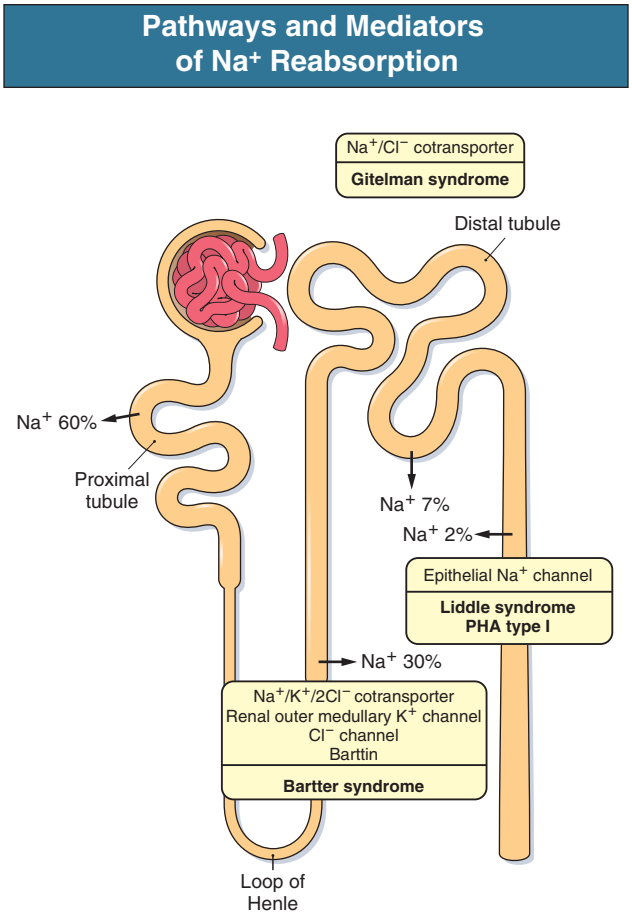

Figure 49-4 Pathways and mediators involved in Na^+ reabsorption. Almost 60% of the filtered Na^+ is reabsorbed in the proximal tubule. The distal portions of the nephron reabsorb the remainder. The chief mediators involved in Na^+ reabsorption and disorders resulting from their mutations are shown in boxes. *PHA,* Pseudohypoaldosteronism.

Pathogenesis

Bartter syndrome is caused by TAL dysfunction and by inactivating mutations of each of its major transport proteins: NKCC2 for Bartter syndrome type 1; ROMK for type 2; ClC-Kb, type 3; and barttin, type 4[3-6] (Table 49-1; see also Fig. 49-1). The pathogenic consequences of these mutations are broadly similar in all four varieties, except that the more severe phenotypes (types 1, 2, and 4) are manifested earlier in life.

Loss of function of any one of the four transport proteins will impair NaCl reabsorption by the TAL, increasing the delivery of salt

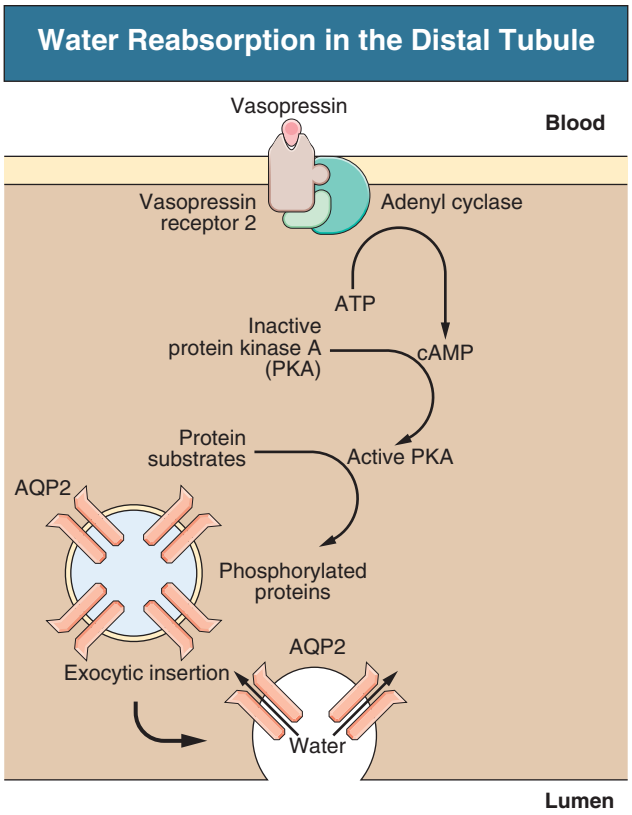

Figure 49-5 Water reabsorption in the distal tubule. The aquaporin AQP2, which is exclusively present in the principal cells of the collecting tubules and ducts, is the chief vasopressin-regulated water channel. Activation of cAMP-dependent protein kinase A mediates protein phosphorylation that triggers exocytic insertion of AQP2 channels into the apical membrane. These channels increase the water permeability of the apical membrane, facilitating water transport.

to the distal nephron. NaCl reabsorption is stimulated in those segments, but compensates only partly for the salt wasting; it is associated with distal secretion of K^+ and H^+. The net loss of NaCl from the nephron will cause plasma volume contraction, low-normal BP, and secondary hyperaldosteronism. The loss of K^+ and H^+ will be followed by severe hypokalemia and metabolic alkalosis. Hypokalemia and increased angiotensin II (Ang II) also stimulate prostaglandin E_2 (PGE_2) production.

Reduced Cl^- absorption in the loop of Henle inhibits voltage-driven paracellular absorption of Ca^{2+}, causing hypercalciuria, an

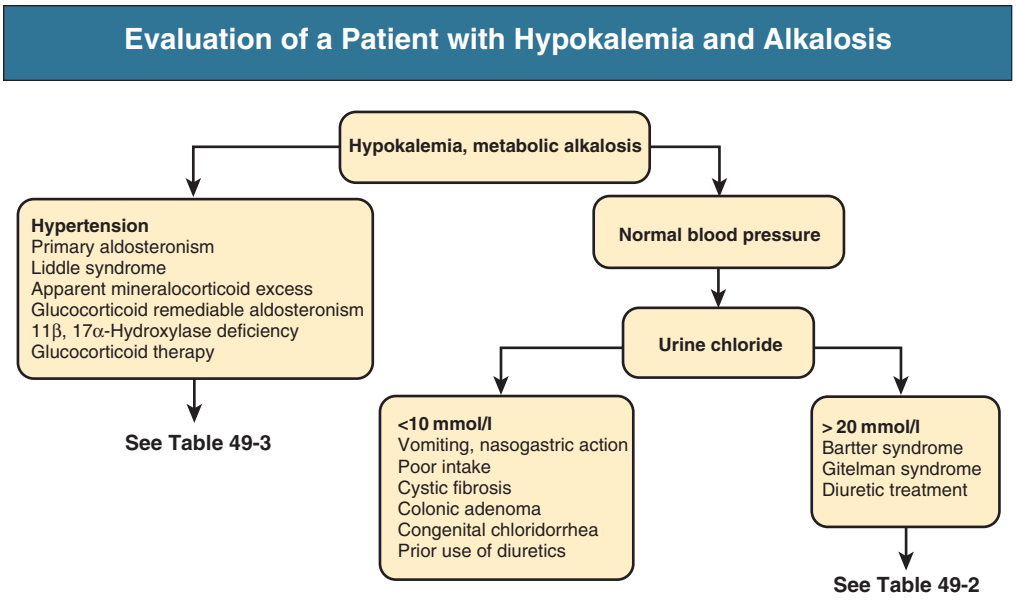

Figure 49-7 Evaluation of a patient with hypokalemia and metabolic alkalosis.

important feature of Bartter syndrome that may be associated with nephrocalcinosis.

Inactivating mutations of barttin also cause deafness because barttin-dependent chloride transport is crucial to endolymph production in the inner ear.[6] In some individuals with mutation of ClC-Kb (type 3), there is a mixed Bartter and Gitelman syndrome.[7] In these patients, the features of Bartter syndrome are associated with hypomagnesemia and hypocalciuria. Age at presentation is 1 month to 29 years. This mixed syndrome may be explained by the overlapping distribution of ClC-Kb, which is also expressed in the distal tubule, the site affected in Gitelman syndrome.[7] Finally, gain-of-function mutations in the extracellular calcium ion–sensing receptor also cause a Bartter-like syndrome.[8] The receptor is normally expressed in TAL, and its activation inhibits salt reabsorption similar to furosemide; also, this syndrome is associated with hypocalcemia.[8]

Clinical Manifestations

Bartter syndrome from mutations in NKCC2, ROMK, or barttin has a more severe phenotype than that caused by mutations of ClC-Kb. The more severe phenotype typically presents in the perinatal period and is called *antenatal* Bartter syndrome. The milder variety is called *classic* Bartter syndrome.

The clinical features of antenatal Bartter syndrome include hypokalemia and metabolic alkalosis in a newborn with vomiting and failure to thrive. There may also be a history of polyhydramnios and premature delivery. Polyuria, hypercalciuria, and high urinary chloride concentrations are characteristic. Nephrocalcinosis may manifest later in life. A prenatal diagnosis of Bartter syndrome may be made by demonstration of high Cl^- concentrations in amniotic fluid.

Patients with classic Bartter syndrome develop normally during the first 2 to 5 years of life. Thereafter, vomiting, polyuria, recurrent episodes of dehydration, and fever may become apparent. Carpopedal spasms and fatigue are common. Many children show developmental delay. The BP is low normal. The laboratory features are comparable to those described previously, but nephrocalcinosis is usually absent.

Diagnosis

A newborn or a young child with vomiting, dehydration, low-normal BP, severe hypokalemia, and metabolic alkalosis is likely to have Bartter syndrome if there is high urinary Cl^- and K^+. The suspected diagnosis will receive further support if supplements of K^+ and Cl^- are inefficient in correcting the severe hypokalemia and BP. Diuretics will not be found in the urine. Hypomagnesemia and hypocalciuria are absent. Secondary hyperaldosteronism is a regular feature. In questionable cases, genotyping should be used to confirm the diagnosis.

Differential Diagnosis

In syndromes of chronic severe hypokalemia with metabolic alkalosis, the differential diagnosis may be facilitated greatly by taking into consideration the associated BP and the urinary chloride concentration (Fig. 49-7).

Hypertension indicates disorders related to hyperaldosteronism. If Bartter syndrome is associated with a normal or low-normal BP, however, extrarenal or renal Cl^- and Na^+ losses are the cause. Extrarenal loss of sodium occurs in diarrhea, vomiting, or burns and is characterized by very low Cl^- concentrations in the urine, often 1 mmol/l. By contrast, renal loss of salt with high urinary Cl^- and Na^+ is typical of Bartter syndrome, Gitelman syndrome, and diuretic use. The absence of hypomagnesemia and hypocalciuria will then argue against Gitelman syndrome (Table 49-2). Genotyping is recommended to diagnose overlap of Bartter and Gitelman syndromes.

Treatment

Patients with the neonatal form of Bartter syndrome have marked fluid and electrolyte disturbances that need to be corrected carefully. Saline infusion may be required in the neonatal period. Potassium chloride supplementation is always necessary.[9] Addition of spironolactone or triamterene may be useful in correcting hypokalemia, but the effect of these drugs is usually transient. Angiotensin-converting enzyme (ACE) inhibitors have been used for correction of hypokalemia, with conflicting results. Magnesium deficiency may aggravate renal K^+ wasting and, if present, should be corrected.

The efficacy of long-term treatment with prostaglandin synthase inhibitors, such as indomethacin (1 to 3 mg/kg/24 h) or ibuprofen, is well established.[9] These act by reducing cortical perfusion and decreasing delivery of Na^+ and Cl^- to the distal nephron, ameliorating many of the features of the disease. The amplifying effect of prostaglandins on the renal tubules is also neutralized. Treatment

Features Differentiating Bartter and Gitelman Syndrome

Feature	Bartter Syndrome		Gitelman Syndrome
	Neonatal	*Classic*	
Age at onset	Neonatal period	Infancy/ childhood	Childhood/ later
Maternal hydramnios	Common	Rare	Absent
Polyuria, polydipsia	Marked	Present	Rare
Dehydration	Present	Often present	Absent
Tetany	Absent	Rare	Present
Growth retardation	Present	Present	Absent
Urinary calcium	Very high	Normal or high	Low
Nephrocalcinosis	Present	Rare	Absent
Serum magnesium	Normal	Occasionally low	Low
Urine prostaglandins (PGE_2)	Very high	High or normal	Normal
Response to PG synthetase inhibitors* (e.g., indomethacin)	Good	Good	Rare

Table 49-2 Features differentiating Bartter and Gitelman syndromes. In addition to these clinical and laboratory features, molecular diagnosis is now possible; *PGE_2*, prostaglandin E_2. *Improvement of hypokalemia and renal salt wasting.

results in reduction of polyuria and polydipsia, restitution of normal growth and activity, and correction of hypokalemia, although serum K^+ rarely exceeds 3.5 mmol/l. Plasma levels of renin and aldosterone decrease to the normal range.

Outcome

If not treated, Bartter patients may succumb to episodes of dehydration, electrolyte disturbance, or intercurrent infection. With appropriate therapy, most children improve clinically and show catch-up growth; pubertal and mental developments are usually normal. Lifelong therapy is needed. Chronic tubulointerstitial nephropathy caused by persistent hypokalemia, hypercalciuria, and nephrocalcinosis may lead to progressive decline in renal function. There are anecdotal reports of renal transplantation in patients with end-stage renal disease (ESRD). The biochemical parameters return to normal after transplantation.

Gitelman Syndrome

Gitelman syndrome is an autosomal recessive condition also characterized by hypokalemic metabolic alkalosis, but with hypocalciuria and hypomagnesemia.

Pathogenesis

The similarity between the features of Gitelman syndrome and those caused by thiazide administration originally suggested that the defect might be in the distal convoluted tubule. The condition has now been linked to inactivating mutations in the gene for NCCT (see Figs. 49-2 and 49-4).[10] Loss of NCCT function results in Na^+ and Cl^- wasting from this segment, leading to hypovolemia with secondary activation of the renin-aldosterone system. However, the resulting increase in collecting tubule Na^+ reabsorption is counterbalanced by K^+ and H^+ excretion, causing hypokalemic alkalosis. The distal convoluted tubule normally reabsorbs only 7% to 8% of the filtered Na^+ and Cl^- load. The degree of volume contraction, the stimulation of the renin-angiotensin system, and the amount of K^+ loss are therefore not substantial enough to stimulate PGE_2 production.

The hypocalciuria may be caused by enhanced proximal tubular calcium reabsorption, secondary to plasma volume contraction. The renal magnesium wasting is caused by downregulation of the epithelial magnesium channel TRPM6 in distal convoluted tubules.

Clinical Manifestations and Diagnosis

The prevalence of Gitelman syndrome is estimated at approximately 1:40,000 in Caucasian populations. The severity of symptoms varies widely. More severely affected patients complain of generalized and muscle weakness, inability to work for extended periods, salt craving, and a preference for licorice. Cardiac disturbances, muscle cramps, and tetany are only exceptionally present. Chondrocalcinosis of the knees does occur later in life, a result of hypomagnesemia. Laboratory evaluation will show moderate hypomagnesemia, severe hypokalemia, hypocalciuria, high urinary chloride concentration, and absence of thiazides from the urine. BP will be in the low-normal range. These findings establish the diagnosis. Genotyping should be performed in questionable or incomplete syndromes.

Treatment

There is no consensus on the best mode of treatment for Gitelman syndrome. Magnesium at 5 to 15 mmol/day (e.g., as magnesium oxide or aspartate) and potassium supplements are usually given to improve muscle weakness or cramps. However, dosing may be limited by diarrhea and abdominal discomfort. In exceptional cases, parenteral Mg^{2+} has been infused. Indomethacin, cyclooxygenase-2 (COX-2) inhibitors, and spironolactone are usually not helpful. The long-term prognosis for cardiac and renal function as well as for general health is good.

CONDITIONS WITH HYPOKALEMIA, METABOLIC ALKALOSIS, AND HYPERTENSION

Conditions with hypokalemia, metabolic alkalosis, and hypertension all have true or apparent mineralocorticoid excess.

Liddle Syndrome (Pseudohyperaldosteronism)

Liddle syndrome is an autosomal dominant syndrome of hypertension and variable degrees of hypokalemic metabolic alkalosis. The patients resemble those with primary hyperaldosteronism, but levels of mineralocorticoid hormones are not increased. Renin and aldosterone are suppressed, and there is no response to spironolactone or epleronone.[11] However, triamterene and amiloride, which are aldosterone-independent inhibitors of distal Na^+ transport, correct hypertension, renal K^+ loss, and hypokalemia.[12]

Pathogenesis

Liddle syndrome is related to mutations of the β or γ subunit of the collecting duct ENaC.[13] The mutations result in truncations of the cytoplasmic C-terminal tail of the affected subunits. Collecting duct sodium reabsorption depends on the channel density present in the apical cell membrane. Channel density is regulated by removal of ENaC from the cell membrane, ubiquitination, and degradation. In Liddle syndrome, the mutated ENaC protein cannot be recognized by NEDD4, a ubiquitin ligase protein; thus the channels remain in the cell membrane for prolonged periods.[12] This action results in enhanced sodium reabsorption, hypertension, and hypokalemic alkalosis (see Fig. 49-3).

Features of Liddle Syndrome, Apparent Mineralocorticoid Excess, and Glucocorticoid-Remediable Aldosteronism			
Feature	**Liddle Syndrome**	**AME**	**GRA**
Inheritance	Autosomal dominant	Autosomal recessive	Autosomal dominant
Chief features	Significant hypertension, polyuria, growth retardation	Low birth weight, early-onset hypertension, polyuria, growth retardation	Significant hypertension, hemorrhagic stroke
Plasma aldosterone	Reduced	Reduced	Elevated
Plasma renin activity	Reduced	Reduced	Reduced
Urinary mineralocorticoid metabolites	Normal	Elevated ratios of THF + allo-THF to THE; free cortisol to cortisone	Elevated cortisol C-18 oxidation products
Response of the Hypertension to:			
Glucocorticoids	No	Satisfactory	Satisfactory
Triamterene	Satisfactory	Satisfactory	Satisfactory
Spironolactone	No	Satisfactory	Satisfactory

Table 49-3 Features of Liddle syndrome, apparent mineralocorticoid excess (AME), and glucocorticoid-remediable aldosteronism (GRA). These syndromes are all characterized by hypokalemia, metabolic alkalosis, and hypertension; *THE,* tetrahydrocortisone; *THF,* tetrahydrocortisol.

Clinical Manifestations and Diagnosis

Liddle syndrome is a rare disorder of hypertension in teenage children[12] that is associated with hypokalemic metabolic alkalosis and low blood levels of renin and aldosterone. The original patient developed renal failure from an unknown cause and eventually underwent transplantation.[14] Thereafter, her BP normalized, and renin and aldosterone responded normally to provocative measures.

This condition should be differentiated from primary hyperaldosteronism, apparent mineralocorticoid excess, and glucocorticoid-remediable aldosteronism (Table 49-3), as well as 11β-hydroxylase (steroid 11β-monooxygenase) or 17α-hydroxylase (steroid 17α-monooxygenase) deficiency. Activating mutations of the mineralocorticoid receptor (MR) have been reported and should also be differentiated.[15]

Treatment

Therapy consists of Na^+ restriction and K^+ supplements. Triamterene directly inhibits apical Na^+ channels, resulting in increased urinary Na^+ and decreased K^+ excretion and resolution of hypertension. Amiloride usually normalizes the BP and K^+ levels. However, most patients with Liddle syndrome continue to have growth restriction. Because the pathogenetic disorder is not correctable with age, lifelong therapy is required.

Apparent Mineralocorticoid Excess

Pathogenesis

Apparent mineralocorticoid excess (AME) is an autosomal recessive condition resulting from deficiency of the type II (renal and placental) isoform of the enzyme 11β-hydroxysteroid dehydrogenase. Clinical features of AME closely mimic those of Liddle syndrome.[16]

In normal conditions, aldosterone is the principal mineralocorticoid regulating electrolyte and water balance, through its effects on distal renal tubules and cortical collecting ducts. After binding to the MR, aldosterone increases synthesis of various proteins, chiefly Na^+,K^+-ATPase on the basolateral surface and ENaC on the apical surface. These proteins increase Na^+ reabsorption and K^+ secretion in the distal tubules (see Fig. 49-3). Cortisol is also a ligand for the MR and shows potent sodium-retaining activity. Cortisol is, however, normally metabolized by 11β-hydroxysteroid dehydrogenase to cortisone, which lacks such an action.

Loss-of-function mutations in the gene encoding 11β-hydroxysteroid dehydrogenase have been detected in patients with the inherited form of AME.[17,18] As a consequence, in the kidney, intracellular metabolic clearance of cortisol is severely impaired. The accumulation of cortisol causes nonspecific MR stimulation, followed by increased Na^+ reabsorption with K^+ and H^+ secretion. 11β-Hydroxysteroid dehydrogenase is also expressed in the placenta; The enzyme's reduced activity might be related to the low birth weight characteristic of AME patients. Carbenoxolone and glycyrrhizic acid (found in licorice compounds) are potent inhibitors of this enzyme. Consumption of these agents may be associated with features similar to AME.

Clinical Manifestations and Diagnosis

Apparent mineralocorticoid excess is characterized by an onset of hypertension in childhood, hypokalemia, metabolic alkalosis, very low plasma levels of renin and aldosterone, and increased metabolites of cortisol in the urine. There may be a history of low birth weight and subsequent failure to thrive.

The diagnosis of AME is made by finding, on gas chromatography or mass spectroscopy, elevated urinary levels of hydrogenated metabolites of cortisol (tetrahydrocortisol plus allotetrahydrocortisol) compared with cortisone (tetrahydrocortisone). The ratio of urinary free cortisol to cortisone is also increased.[19] Heterozygotes may occasionally show hypertension, normal serum K^+, suppressed plasma renin and aldosterone, and moderately elevated urinary cortisol to cortisone metabolite ratio. A variant of AME, called AME type 2, has similar clinical features but a milder urinary steroid profile.[20]

Treatment

Treatment with oral dexamethasone (0.75 to 5 mg/day) suppresses cortisol secretion, resulting in reduced Na^+ reabsorption and amelioration of hypertension and hypokalemia. Urinary concentrations of metabolites of cortisol and cortisone are only moderately affected. As in Liddle syndrome, patients with AME respond to treatment with K^+ supplements combined with triamterene or amiloride. Spironolactone is effective in AME patients, although not in those with Liddle syndrome. Mineralocorticoid blockade is preferred as long-term therapy, to avoid adverse effects of dexamethasone.

Renal transplantation is followed by normalization of cortisol metabolism, biochemical abnormalities, and hypertension.[21]

Glucocorticoid-Remediable Aldosteronism

Glucocorticoid-remediable aldosteronism (GRA) appears to be the most common monogenic form of human hypertension. It is an autosomal dominant condition. Patients present with typical features of primary hyperaldosteronism: hypertension, suppressed plasma renin activity, and hypokalemia. Unlike primary hyperaldosteronism (due to aldosterone-producing adrenal adenoma), hypersecretion of aldosterone in GRA can be reversed by the administration of corticosteroids. Affected individuals have early-onset hypertension. There is a high prevalence of hemorrhagic stroke, largely as a result of ruptured intracranial aneurysms. Hypokalemia is typically mild but becomes more pronounced if diuretics are given. Serum potassium levels may occasionally be normal.

Pathogenesis

Patients with GRA have adrenocorticotropic hormone (ACTH)–sensitive aldosterone production occurring in the zona fasciculata of the adrenal gland, which is usually responsible only for cortisol synthesis. Normal individuals synthesize aldosterone in the zona glomerulosa. The two isoenzymes of 11β-hydroxylase involved in the biosynthesis of aldosterone and cortisol are steroid 11β-hydroxylase (CYP11B1) and aldosterone synthase (CYP11B2), respectively (Fig. 49-8). The genes for these isoenzymes are located close to each other on the long arm of chromosome 8. Unequal meiotic crossovers may produce hybrid genes by fusion of the promoter end of *CYP11B1* with the coding sequence of *CYP11B2,* so that *CYP11B2* encoding aldosterone synthase is inappropriately regulated by ACTH, as is *CYP11B1*.[16] Abnormal expression of this chimeric gene in the adrenal zona fasciculata has been shown by *in situ* hybridization.

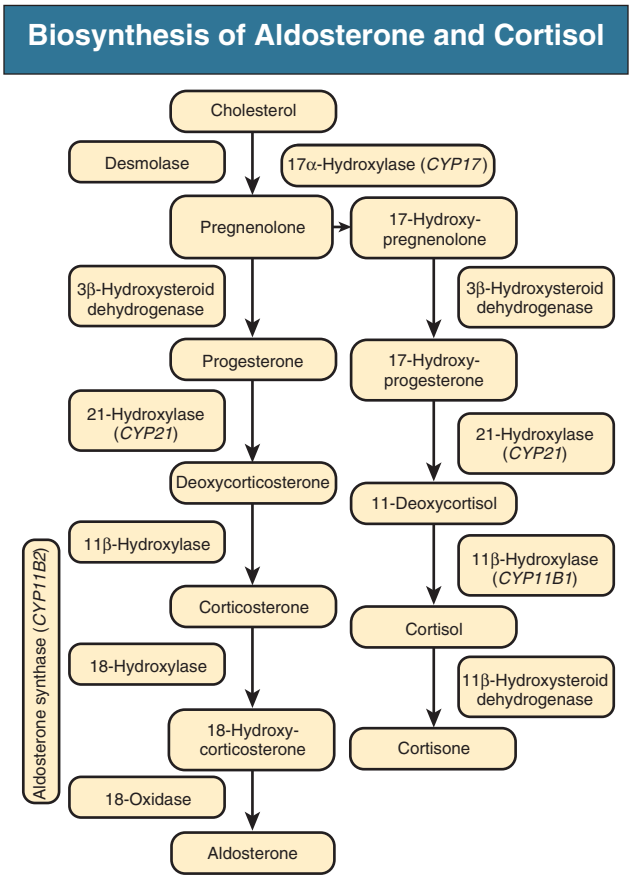

Figure 49-8 Biosynthesis of aldosterone and cortisol. Although cortisol and aldosterone both require 11β-hydroxylation of precursors, these steps are catalyzed by different isoenzymes: steroid 11β-hydroxylase (CYP11B1) and aldosterone synthase (CYP11B2), respectively. Aldosterone synthase also mediates two further conversions. Common enzyme deficiencies leading to derangement in sodium and water balance are shown. Cortisol is converted peripherally by 11β-hydroxysteroid dehydrogenase to cortisone.

Diagnosis

Patients with GRA are often misdiagnosed as having primary hypertension. Hypertensive patients with early-onset hypertension, early cerebral hemorrhage (<40 years), hypokalemia before or after diuretic therapy, and refractoriness to standard antihypertensive medication are candidates for GRA testing. Similar to other genetic forms of hypertension (Liddle syndrome, AME, Gordon syndrome), plasma renin activity is low. Although the mean aldosterone levels are high, determination of serum aldosterone has poor sensitivity as a screening test. In GRA, the aldosterone-renin ratio is elevated (>300), whereas in primary hypertension, AME, and Liddle syndrome, it is not increased.

The biochemical hallmark of GRA is overproduction and excretion of cortisol C-18 oxidation products, reflecting the action of aldosterone synthase on cortisol in the zona fasciculata. Large amounts of the so-called hybrid steroids (18-hydroxycortisol and 18-oxocortisol) can be found in the urine by specialized steroid laboratories.

Dexamethasone leads to suppression of blood aldosterone levels. When 0.5 mg of dexamethasone is given every 6 hours for 2 days, it suppresses aldosterone to undetectable levels (<4 ng/dl).

Direct screening for the hybrid gene *CYP11B1/CYP11B2* can also be performed and confirms the diagnosis[22] (test can be obtained at www.brighamandwomens.org/Departments_and_Services/medicine/services/endocrine/Services/gra/default.aspx).

Treatment

Treatment with low-dose corticosteroid is effective in GRA patients. Typically, 0.125 to 0.25 mg of dexamethasone or 2.5 to 5 mg of prednisolone is administered at bedtime. Therapeutic goals are normotension and normalization of biochemical markers (urinary 18-oxosteroid, serum aldosterone). MR antagonists (spironolactone, eplerenone) and ENaC antagonists such as amiloride and triamterene are also useful treatments. Antihypertensive therapy with β-blockers and ACE inhibitors is less likely to be effective.

Incomplete Phenotypes

Occasional patients with Liddle syndrome, AME, or GRA either do not express the complete phenotype or have mild clinical or biochemical features and are considered to have primary hypertension. Poor BP control with conventional therapy should suggest an alternative diagnosis. Hypokalemia may not be a feature at presentation but develops with diuretic treatment. These conditions should be considered in patients with early-onset hypertension, failure to thrive, or a strong family history. The response to specific treatment with potassium-sparing diuretics or corticosteroids may suggest the diagnosis.

Adrenal Enzymatic Disorders

Inherited deficiency of 11β- or 17α-hydroxylase also causes mineralocorticoid excess with hypertension and hypokalemic metabolic alkalosis (see Fig. 49-8).

Deficiency of 17α-hydroxylase (CYP17) impairs normal production of cortisol and adrenal androgens, resulting in pseudohermaphroditism in genetic males and primary amenorrhea in females.

Features of Renal-limited and Multisystem Forms of Pseudohypoaldosteronism Type I		
Feature	**Renal-Limited Form**	**Multisystem Form**
Underlying defect	Mineralocorticoid receptor	Epithelial sodium channel
Affected organs	Kidney only	Kidney, sweat, salivary glands, distal colon
Inheritance	Autosomal dominant	Autosomal recessive
Salt wasting	Variable	Severe
Blood renin, aldosterone	Very high	Very high aldosterone
Sweat, salivary Na^+	Normal	High
Clinical features	Salt wasting variable, during stress	Severe salt wasting, hyperkalemia, severe skin infections, respiratory infections (mimics cystic fibrosis)
Treatment	Sodium chloride supplements for 1-3 years Carbenoxolone is effective in some patients (creates situation similar to AME)	Lifelong sodium chloride supplements; strict potassium restriction; prophylactic antibiotics if recurrent skin sepsis; no response to carbenoxolone
Prognosis	Improvement usually by 6-8 years, need for salt supplement diminishes	Improvement rare with age

Table 49-4 Features of renal-limited and multisystem forms of pseudohypoaldosteronism type 1. *AME,* Apparent mineralocorticoid excess.

Cortisol deficiency results in increased ACTH secretion, low levels of renin and aldosterone, hypokalemia, metabolic alkalosis, and hypertension. Diagnosis is confirmed by finding excessive levels of deoxycorticosterone and corticosterone in the urine. Administration of corticosteroids corrects the mineralocorticoid excess state.

Deficiency of 11β-hydroxylase (CYP11B1) also impairs cortisol production but results in excessive androgens. Genetic females show pseudohermaphroditism, whereas males have virilization. The cortisol deficiency results in high blood levels of ACTH, deoxycortisol, and deoxycorticosterone; corticosterone levels are normal. Hypokalemia is variable. Diagnosis is confirmed by measurement of high levels of tetrahydro-11-deoxycortisol in the urine. Hypokalemia is variable. Treatment with corticosteroids corrects hypertension and hypokalemia; renin levels increase, but aldosterone remains low because of the biosynthetic defect.

CONDITIONS WITH HYPONATREMIA, HYPERKALEMIA, METABOLIC ACIDOSIS, AND NORMAL BLOOD PRESSURE

Conditions with hyponatremia, hyperkalemia, metabolic acidosis, and normal BP have features of mineralocorticoid deficiency either because of a synthetic defect or because of end-organ resistance.

Pseudohypoaldosteronism

Pseudohypoaldosteronism (PHA) is a state of renal tubular (and other tissue) unresponsiveness to the action of aldosterone.[23] Symptoms start in early infancy with marked salt wasting and failure to thrive.

Type 1 PHA includes at least two major entities, with either renal or multiple target organ defects; the renal form is more common. The inheritance of renal-limited PHA type 1 is autosomal dominant but may be sporadic. Loss-of-function mutations of the gene for the mineralocorticoid receptor (located on 4p) have been identified.[24] Multiple end-organ (multisystem) PHA type 1 is a severe autosomal recessive disorder with multiple target organ resistance to the action of mineralocorticoids and is associated with inactivating mutations of α, β, or γ subunits of ENaC.[25] Table 49-4 compares the features of the two major PHA type 1 forms.

Aldosterone Biosynthetic Defects

Patients with defects in aldosterone biosynthesis show salt wasting with hyponatremia, hyperkalemia, hypovolemia, and elevated plasma renin activity.[26] The enzymes cholesterol desmolase, 3β-hydroxysteroid dehydrogenase, and 21-hydroxylase are required for synthesis of cholesterol and aldosterone, whereas aldosterone synthase is selectively responsible for aldosterone production in the adrenal cortex (see Fig. 49-8). Table 49-5 compares characteristics of diseases with aldosterone biosynthetic defects.

Deficiency of 21-Hydroxylase

Mutations in the gene encoding 21-hydroxylase (*CYP21*) result in two major forms of the disease: a virilizing form and the more common salt-wasting type.[27] Patients with signs only of androgen excess are said to have the virilizing form. Female infants show varying degrees of pseudohermaphroditism, whereas affected males have normal or precocious sexual development. Patients with the salt-wasting type present with hyponatremia, hyperkalemia, and moderate to severe volume depletion.

The diagnosis of 21-hydroxylase deficiency should be suspected in any newborn with genital ambiguity, salt wasting, or hypotension. Blood levels of progesterone, 17-hydroxyprogesterone, and dehydroepiandrosterone are raised several-fold above normal.

Patients with electrolyte imbalance and shock require resuscitation with intravenous fluids and salt supplements. Replacement therapy with oral hydrocortisone and 9α-fludrocortisone is required long term. Some amelioration of the tendency to salt wasting may be seen with age because of the ability of children to regulate their dietary salt intake and maturation of proximal tubular function.

Reconstructive genital surgery may be required in females with genital ambiguity. Fetal DNA analysis and demonstration of elevated 17-hydroxyprogesterone in amniotic fluid allow prenatal detection of affected female infants. Treatment of the mother with dexamethasone from early in gestation reduces virilization of genitalia of the affected female fetus.

Aldosterone Biosynthetic Defects				
Defective Enzyme	**21-Hydroxylase**	**3β-Hydroxysteroid Dehydrogenase**	**Cholesterol Desmolase**	**Aldosterone Synthase**
Incidence	Most common (1:11,000-23,000 births)	Rare	Rare	Rare
Aldosterone	Deficient	Deficient	Deficient	Deficient
Cortisol production	Deficient	Deficient	Deficient	Normal cortisol
ACTH	Loss of feedback inhibition	Loss of feedback inhibition	Loss of feedback inhibition	Normal feedback inhibition
Adrenal hyperplasia	Yes	Yes	Yes	No
Genital ambiguity	In females	In females	In females	No
Clinical features	Children with failure to thrive; hyponatremia, hyperkalemia, acidosis, and hypotension			
Elevated metabolites	17-Hydroxyprogesterone	Dehydroepiandrosterone		Corticosterone
Therapy	Oral hydrocortisone and 9α-fludrocortisone			9α-Fludrocortisone

Table 49-5 Characteristics of diseases with aldosterone biosynthetic defects. *ACTH,* Adrenocorticotropic hormone.

A CONDITION WITH HYPERKALEMIA, METABOLIC ACIDOSIS, AND HYPERTENSION

Pseudohypoaldosteronism Type 2 (Gordon Syndrome)

The clinical inverse of Gitelman syndrome, Gordon syndrome is an autosomal dominant condition characterized by hypertension, hyperkalemia, and mild hyperchloremic metabolic acidosis.

Pathogenesis

Two genes have been identified as responsible for PHA type 2.[28] The genes encode two members of the with-no-lysine kinase family: WNK1 and WNK4. The WNK kinases are both expressed in the kidney within the convoluted tubule and the collecting ducts. WNK4 acts as a negative regulator of thiazide-sensitive NCCT function (see Fig. 49-2), reducing cell surface expression of NCCT. WNK4 also downregulates ROMK and epithelial chloride flux. Mutations in *WNK4* are missense and cause loss of function, so that WNK4 loses its ability to suppress NCCT and ROMK. Transporter overactivity consequently leads to Na^+ and K^+ retention. WNK1 prevents WNK4 from interacting with NCCT. Mutations in *WNK1* are intronic deletions that increase WNK1 expression. WNKs are intriguing targets for novel antihypertensive agents.

Clinical Manifestations and Diagnosis

Hyperkalemia may be present from birth, but as in GRA, hypertension may not be manifested until later in life. Patients show hyperchloremic metabolic acidosis; plasma renin and aldosterone are reduced to variable degrees.

Treatment

As specific inhibitors of the NCCT, thiazides are able to correct completely the clinical and biochemical features of Gordon syndrome.

NEPHROGENIC DIABETES INSIPIDUS

Congenital nephrogenic diabetes insipidus (NDI) is a rare polyuric disorder identified by the failure to concentrate urine despite normal or elevated levels of vasopressin. Glomerular filtration rate (GFR) and solute excretion rate are normal. Congenital NDI is caused by mutations in key proteins controlling water reabsorption in the distal tubule (see Fig. 49-5). Acquired diabetes insipidus is much more common, and its diagnosis and management are discussed in Chapter 8.

Pathogenesis

More than 90% of patients have X-linked recessive NDI with mutations in *AVPR2,* the gene at Xq28 coding for the arginine vasopressin receptor (AVPR). Mutant proteins are conformationally different, resulting in intracellular trapping of the receptor, which is retained in the endoplasmic reticulum. On occasion, the receptor may be expressed on the cell surface but is unable to bind vasopressin or to trigger an appropriate cyclic adenosine monophosphate (cAMP) response.[29] In less than 10% of the families, congenital NDI has an autosomal recessive inheritance, and mutations have been identified in the gene for aquaporin 2 located on chromosome 12q13. Similar to X-linked NDI, most autosomal recessive *AQP2* mutations are held back in the endoplasmic reticulum. A rare autosomal dominant form of NDI, also caused by mutation in *AQP2,* has been reported. These mutations lead to mistransporting of AQP2 mutant proteins to the basolateral membrane instead of the apical membrane.[30] Reduced expression of AQP2 may result in acquired NDI secondary to lithium or demeclocycline therapy.

Clinical Features

Manifestations of congenital NDI appear within the first weeks of life. Males with *AVPR2* mutations have marked polyuria and excessive thirst, which is often not recognized in early infancy. Unless the condition is suspected early, children have recurrent episodes of severe hypernatremic dehydration, occasionally complicated by convulsions.[31] Delayed development and mental retardation are possible consequences of these episodes. Cranial computed tomography may occasionally show dystrophic calcification in the basal ganglia and the cerebral cortex.

A reduced intake of calories because of the large quantities of water that are ingested leads to growth failure beginning in early childhood. Increased urine volumes may result in dilation of the lower urinary tract. Renal cortical damage from recurrent episodes of severe dehydration may result in impairment of renal function. Heterozygous females may show variable degrees of polyuria and

polydipsia. The onset and severity of clinical features of autosomal recessive NDI are similar to those of the X-linked form.

Diagnosis

Episodes of dehydration are marked by hypernatremia, hyperchloremia, and occasionally elevated levels of urea and creatinine. Polyuria with low urine osmolality (<200 mOsm/kg) and hypernatremia with plasma Na^+ concentration above 150 mmol/l and plasma osmolality above 300 mOsm/kg are highly suggestive of either vasopressin deficiency (central diabetes insipidus) or resistance to its action (NDI). Central diabetes insipidus is more common than NDI. Primary polydipsia resembles true diabetes insipidus in that compulsive water drinking results in polyuria with low urine osmolality; however, the plasma osmolality in primary polydipsia is normal or borderline low.

To confirm the lack of renal concentrating ability and to distinguish NDI from central diabetes insipidus and primary polydipsia, a vasopressin test is performed. Desamino-8-D-arginine vasopressin (DDAVP) is administered nasally (5 to 10 μg in neonates and infants, 20 μg in children) or by an intramuscular injection (0.4 to 1.0 μg in infants and young children, 2 μg in older children). Hourly urine collection is done during the next 6 hours. After administration of DDAVP, patients with NDI fail to show a rise of urine osmolality, from 200 to 300 mOsm/kg (normal, >800 mOsm/kg). Those with central diabetes insipidus and primary polydipsia concentrate urine appropriately.

Persistence of polyuria for years may result in a washout of the medullary countercurrent concentration mechanism. Several days of treatment with DDAVP may be required to elicit an appropriate response in these patients. In patients in whom primary polydipsia is strongly suspected, supervised reduction of fluid intake during several days may restore normal sensitivity to DDAVP.

Differential Diagnosis

Patients with central diabetes insipidus show hypernatremia with inappropriately dilute urine, no primary renal disease, and a rise in urine osmolality after administration of vasopressin or its analogues. Central diabetes insipidus usually results from posterior pituitary neuronal damage, which may be secondary to tumors (craniopharyngioma, optic glioma, metastasis), Langerhans cell histiocytosis, trauma (e.g., fracture of base of skull), or infections (meningitis, encephalitis). Deficiency of vasopressin may also be familial, with an autosomal dominant inheritance. Mutations of *AVP-NPII,* the gene for vasopressin–neurophysin II, have been reported.[32] The onset of vasopressin deficiency in the familial form may not be apparent until after the first few years of life. Central diabetes insipidus may also occur with the autosomal recessive syndrome of diabetes insipidus, diabetes mellitus, optic atrophy, and deafness (DIDMOAD, or Wolfram syndrome), which is autosomal recessive.

Many patients with central diabetes insipidus or NDI have a partial defect in vasopressin secretion or action. They are therefore able to concentrate urine to varying degrees after DDAVP administration, making precise diagnosis difficult. Measurement of plasma vasopressin in relation to plasma osmolality after an osmotic stimulus, such as fluid restriction, allows differentiation in these patients. Patients with severe or partial central diabetes insipidus always show subnormal vasopressin levels relative to plasma osmolality. In contrast, the values from patients with NDI or psychogenic polydipsia are always within or above the normal range.

Magnetic resonance imaging of the brain produces a bright spot on T1-weighted images of the posterior pituitary in normal individuals and also those with NDI or primary polydipsia. This signal is absent in most patients with central diabetes insipidus.

The differential response of clotting factors and urine osmolality to DDAVP is useful in differentiating X-linked (*AVPR2* abnormalities) from autosomal recessive (*AQP2* mutations) NDI. Patients with *AQP2* abnormalities show normal increases in factor VIII and von Willebrand factor after DDAVP infusion; this response is absent in those with an *AVPR2* defect.[31,33] Sequencing of *AVPR2* and *AQP2* is useful in identification of the molecular defect underlying NDI. Congenital NDI should also be differentiated from acquired forms of NDI (see Chapter 8).

Treatment

Appropriate management of patients with NDI prevents episodes of dehydration, allowing normal physical growth and development. Patients must have adequate water intake to prevent dehydration. The renal solute load is minimized by restriction of dietary protein and salt intake. Adequate energy and nutrients, depending on the age, should be provided to promote normal growth and development.

Thiazide diuretics, such as hydrochlorothiazide (1 to 2 mg/kg every 12 hours), when combined with reduction of salt intake, are effective in reducing urine output. Thiazides inhibit salt reabsorption in distal convoluted tubules, which leads to mild volume depletion. Hypovolemia stimulates fluid reabsorption in the proximal tubules, thereby diminishing water delivery to the collecting ducts. The antipolyuric effect can be enhanced by combination therapy with amiloride (0.1 to 0.2 mg/kg every 8 to 12 hours).

Because prostaglandins normally antagonize the action of vasopressin, prostaglandin synthase inhibitors are also effective in reducing urine volume and free water clearance. Not all nonsteroidal anti-inflammatory drugs are equally potent in inhibiting renal prostaglandin synthesis. Indomethacin (1 mg/kg every 12 hours) is used most often but may reduce GFR and cause gastrointestinal side effects.

CHAPTER 50

Fanconi Syndrome and Other Proximal Tubule Disorders

John W. Foreman

The proximal tubule is responsible for the reabsorption of the bulk of a number of solutes, including glucose, amino acids, bicarbonate, and phosphate. This chapter describes a number of disorders, mainly heritable, that affect proximal tubule reabsorption, although Chapters 10 and 12 discuss discuss familial forms of hyperphosphaturia and renal tubular acidosis, respectively.

Most nonelectrolyte solutes are reabsorbed in the proximal tubule through specific transport proteins that cotransport them in conjunction with sodium (Fig. 50-1). The driving force for this solute transport is the electrochemical gradient for sodium entry maintained by the enzyme Na^+,K^+-ATPase. Most disorders of isolated solute reabsorption are related to defects in specific transport proteins, whereas disorders affecting multiple solutes, such as Fanconi syndrome, are probably secondary to defects in energy generation, Na^+,K^+-ATPase activity, or dysfunction of cellular organelles involved with membrane protein recycling.

FANCONI SYNDROME

Definition

In the 1930s, de Toni, Debré, and coworkers and Fanconi independently described several children with the combination of renal rickets, glycosuria, and hypophosphatemia. Fanconi syndrome now refers to a global dysfunction of the proximal tubule leading to excessive urinary excretion of amino acids, glucose, phosphate, bicarbonate, uric acid, and other solutes handled by this nephron segment. These losses lead to the clinical problems of acidosis, dehydration, electrolyte imbalance, rickets, osteomalacia, and growth failure. Numerous inherited or acquired disorders are associated with Fanconi syndrome (Box 50-1).

Etiology and Pathogenesis

The sequence of events leading to Fanconi syndrome is incompletely defined and probably varies with each cause. Possible mechanisms include widespread abnormality of most or all of the proximal tubule carriers, such as a defect in sodium binding to the carrier or insertion of the carrier into the brush border membrane, "leaky" brush border membrane or tight junctions, inhibited or abnormal Na^+,K^+-ATPase pump, or impaired mitochondrial energy generation (Fig. 50-1). An abnormality in energy generation has been implicated in a number of disorders, including hereditary fructose intolerance, galactosemia, mitochondrial cytopathies, and heavy metal poisoning, as well as in a number of experimental models of Fanconi syndrome. Abnormal subcellular organelle function, such as the lysosome in cystinosis or the megalin-cubilin endocytic pathway in Dent disease, is also a cause of Fanconi syndrome (Fig. 50-2).

In adults, the most common causes of persistent Fanconi syndrome are an endogenous or exogenous toxin such as a heavy metal, a medication, and a dysproteinemia. In children, the most common persistent cause is an inborn error of metabolism, such as cystinosis. Specific causes of Fanconi syndrome are discussed after a general description of the clinical manifestations and treatment of the syndrome.

Clinical Manifestations

Fanconi syndrome gives rise to a number of clinical abnormalities (Box 50-2).

Aminoaciduria

Aminoaciduria is a cardinal feature of Fanconi syndrome. Virtually every amino acid is found in excess in the urine, thus the term *generalized aminoaciduria.* There are no clinical consequences, however, because the losses are trivial, 0.5 to 1 g/day, in relation to the dietary intake.

Glycosuria

Glycosuria secondary to proximal tubule dysfunction is another of the cardinal features of Fanconi syndrome and results from impaired tubular reabsorption of glucose. It is often one of the first diagnostic clues. As with aminoaciduria, glycosuria rarely causes symptoms, such as weight loss or hypoglycemia.

Hypophosphatemia

Hypophosphatemia, secondary to impairment in phosphate reabsorption, is a common finding in Fanconi syndrome. Assessment of tubular phosphate handling can be made by measuring the maximum phosphate reabsorption in relation to the glomerular filtration rate (TmP/GFR) on fasting urine and blood samples. Elevated parathyroid hormone (PTH) and low vitamin D levels also may play a role in the phosphaturia of Fanconi syndrome, although these hormonal abnormalities are not always present. A few patients have impaired conversion of 25-hydroxyvitamin D to 1,25-hydroxyvitamin D; metabolic acidosis, another feature of Fanconi syndrome, may also impair this conversion. Another mechanism for the hypophosphatemia is impairment of the megalin-dependent reabsorption and degradation of filtered PTH.[1] Unabsorbed PTH then binds to receptors in more distal portions of the proximal tubule, leading to increased endocytosis of apical phosphate transporters and increased phosphaturia. The hypophosphatemia, especially if accompanied by hyperparathyroidism and low 1,25-hydroxyvitamin D levels, often leads to significant bone disease, presenting with pain, fractures, rickets, or growth failure.

Hyperchloremic Metabolic Acidosis

Hyperchloremic metabolic acidosis, another feature of Fanconi syndrome, is a result of impaired bicarbonate reabsorption by the proximal tubule (proximal or type 2 renal tubular acidosis; see

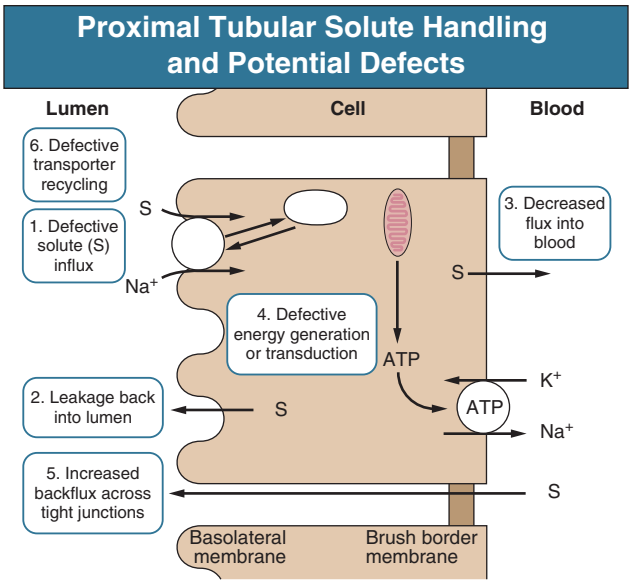

Figure 50-1 Defects and potential defects in proximal tubular solute handling. Solute uptake by the brush border membrane from the lumen is coupled to Na^+ influx. The favorable electrochemical driving force for luminal Na^+ is maintained by the Na^+,K^+-ATPase pump. Transported solute is then either used by the cell or returned to the blood across the basolateral membrane. Fanconi syndrome could arise because of a defect in one of six areas as shown. *ATP,* Adenosine triphosphate.

Causes of Fanconi Syndrome

Inherited Causes

Cystinosis
Galactosemia
Hereditary fructose intolerance
Tyrosinemia
Wilson disease
Lowe syndrome
Dent disease
Glycogenosis
Mitochondrial cytopathies
Idiopathic

Acquired Causes*

Drugs: *cisplatin, ifosfamide, tenofovir, cidofovir, adefovir,* didanosine, gentamicin, azathioprine, valproic acid (sodium valproate), suramin, streptozocin (streptozotocin), ranitidine
Dysproteinemias: *multiple myeloma, Sjögren syndrome, light-chain proteinuria, amyloidosis*
Heavy metal poisoning: lead, cadmium
Other poisonings: Chinese herbal medicine, glue sniffing
Other: nephrotic syndrome, renal transplantation, acute tubular necrosis

Box 50-1 Causes of Fanconi syndrome. *More common acquired causes are shown in italics.

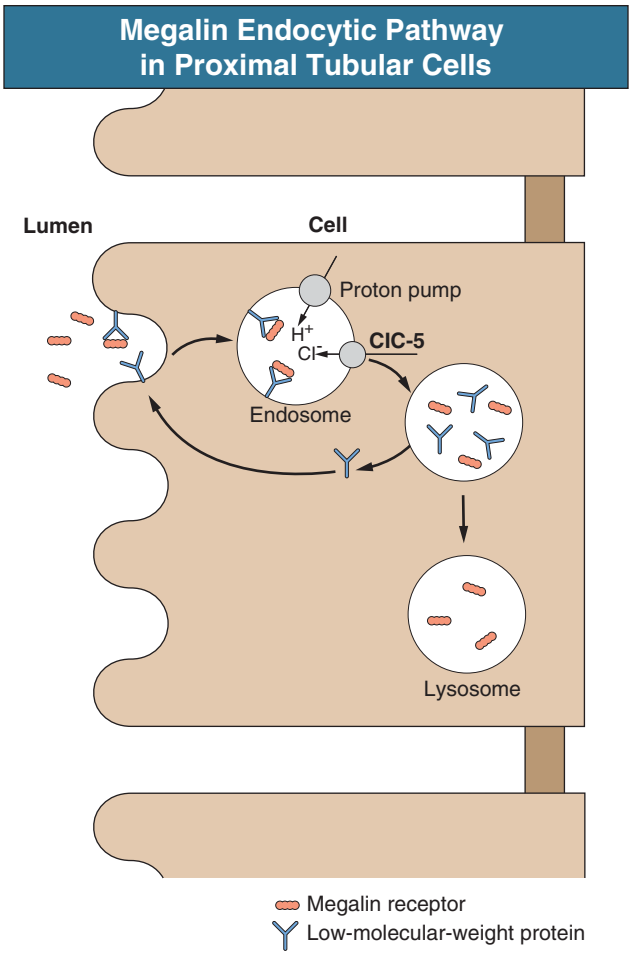

Figure 50-2 Megalin-cubilin endocytic pathway in proximal tubular cells. Low-molecular-weight proteins in the luminal fluid bind to the megalin-cubilin complex and are endocytosed. The recycling of megalin and further catabolism of these proteins depend on acidification of the vesicle by a proton pump. The ClC-5 chloride channel provides an electrical shunt for efficient functioning of the proton pump. This endocytosis pathway plays a role in membrane transporter recycling, and disruption of this pathway interferes with absorption of other luminal solutes.

Features of Fanconi Syndrome

Metabolic Abnormalities

Glycosuria
Hyperaminoaciduria
Hypophosphatemia
Acidosis
Hypokalemia
Hypouricemia
Hypocarnitinemia

Clinical Features

Rickets, osteomalacia
Growth retardation
Polyuria
Dehydration
Proteinuria

Box 50-2 Features of Fanconi syndrome.

Chapter 12). This impaired reabsorption can lead to the loss of more than 30% of the normal filtered load of bicarbonate. As the serum bicarbonate concentration ($[HCO_3^-]$) falls, the filtered load falls, and excretion drops such that the serum $[HCO_3^-]$ usually remains between 12 and 18 mmol/l. On occasion, there is an associated defect in distal acidification, usually in association with longstanding hypokalemia or nephrocalcinosis. Ammoniagenesis is usually normal or increased because of the hypokalemia and acidosis, unless there is an associated impairment in GFR.

Natriuresis and Kaliuresis

Natriuresis and kaliuresis are common in Fanconi syndrome and can give rise to significant, even life-threatening problems. These electrolyte losses are in part related to impaired bicarbonate reabsorption, with the subsequent urinary excretion of sodium and potassium ions with the bicarbonate. In some cases, sodium and potassium losses are so great that metabolic alkalosis and hyperaldosteronism result, simulating Bartter syndrome despite the lowered bicarbonate threshold. The clearance of potassium may be twice that of the GFR, and the resulting severe hypokalemia can cause sudden death.

Polyuria and Polydipsia

Polyuria, polydipsia, and frequent bouts of severe dehydration are common symptoms in young patients with Fanconi syndrome. The polyuria is mainly related to the osmotic diuresis from the excessive urinary solute losses; but some patients have an associated concentrating defect, especially those with prolonged hypokalemia.

Growth Retardation

Growth retardation in children with Fanconi syndrome is multifactorial. Hypophosphatemia, disordered vitamin D metabolism, and acidosis contribute to growth failure, as do chronic hypokalemia and extracellular volume contraction. Glycosuria and aminoaciduria probably do not play a role. However, even with correction of all these metabolic abnormalities, most patients fail to grow, especially those with cystinosis.

Hypouricemia

Hypouricemia, caused by impairment in renal handling of uric acid, is often present in Fanconi syndrome, especially in adults. Urolithiasis from the uricosuria has only rarely been reported, probably because the urine flow and pH are increased, inhibiting uric acid crystallization.

Proteinuria

Proteinuria is usually minimal, except when Fanconi syndrome develops in association with the nephrotic syndrome. Typically, only low-molecular-weight proteins (<30,000 daltons) are excreted, such as vitamin D and A–binding proteins, enzymes, immunoglobulin light chains, and hormones.

Treatment of Fanconi Syndrome

Therapy, whenever possible, should be directed at the underlying causes of Fanconi syndrome (see later discussion). This includes avoidance of the offending nutrient in galactosemia, hereditary fructose intolerance, or tyrosinemia; treatment of Wilson disease with penicillamine and other copper chelators; or treatment of heavy metal intoxication by chelation therapy. In these patients, resolution of Fanconi syndrome usually is complete.

In other patients with Fanconi syndrome, therapy is directed at the biochemical abnormalities secondary to the renal solute losses and at the bone disease often present in these patients. The proximal renal tubular acidosis (type 2 RTA) usually requires large doses of alkali for correction. Some patients benefit from hydrochlorothiazide to minimize the volume expansion associated with these large doses of alkali. Potassium supplementation usually is also needed, especially if there is a significant RTA. The use of potassium citrate, lactate, or acetate will correct not only the hypokalemia but also the acidosis. A few patients will require sodium supplementation along with potassium. Again, the use of a metabolizable anion will aid in the correction of the acidosis. Rarely, patients may need sodium chloride supplementation. Usually, these patients have alkalosis when untreated as a result of large urinary NaCl losses, which lead to volume contraction that overrides the RTA. Magnesium supplementation may be required. Adequate fluid intake is essential. Correction of hypokalemia and its effect on the concentrating ability of the distal tubule may lessen the polyuria.

Bone disease is multifactorial, including hypophosphatemia, urinary loss of vitamin D–binding protein and vitamin D, decreased synthesis of calcitriol in some patients, hypercalciuria, and chronic acidosis. Hypophosphatemia should be treated with 1 to 3 g/day of oral phosphate with the goal of normalizing serum phosphate levels. Many patients with Fanconi syndrome will require supplemental vitamin D for adequate treatment of the rickets and osteomalacia. It is unclear whether standard vitamin D (calciferol [ergocalciferol]) or a vitamin D metabolite is better for supplementation. Currently, most clinicians use a vitamin D metabolite, such as 1,25-dihydroxycholecalciferol (calcitriol). These metabolites obviate the concern of inadequate vitamin D hydroxylation by the proximal tubule mitochondria and reduce the risk for prolonged hypercalcemia because of their shorter half-life. Vitamin D therapy will also improve the hypophosphatemia and lessen the risk for hyperparathyroidism. Supplemental calcium is indicated in those with hypocalcemia after supplemental vitamin D is started. Hyperaminoaciduria, glycosuria, proteinuria, and hyperuricosuria usually do not lead to clinical difficulties and do not require specific treatment. Carnitine supplementation, to compensate for the urinary losses, may improve muscle function and lipid profiles, but the evidence is inconsistent.

INHERITED CAUSES OF FANCONI SYNDROME

Cystinosis

Definition

Cystinosis, or cystine storage disease, is characterized biochemically by excessive intracellular storage, particularly in lysosomes, of the amino acid cystine.[2] Three different types of cystinosis can be distinguished based on clinical course and age at onset and the intracellular cystine content. Benign or adult cystinosis is associated with cystine crystals in the cornea and bone marrow only, as well as the mildest elevation in intracellular cystine levels; no renal disease occurs. Infantile or nephropathic cystinosis is the most common form of cystinosis and is associated with the highest intracellular levels of cystine and the earliest onset of renal disease. In the intermediate or adolescent form, intracellular cystine levels are between those of the infantile and adult forms, with later onset of renal disease.

Etiology and Pathogenesis

Nephropathic cystinosis is transmitted as an autosomal recessive trait localized to the short arm of chromosome 17, with an estimated incidence of 1 in 200,000 live births. The *CTNS* gene codes for a lysosomal membrane protein, cystinosin, that mediates the transport of cystine from the lysosome.[3] The benign and intermediate forms

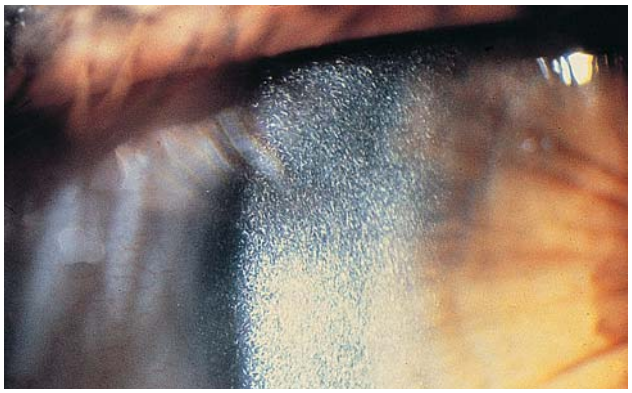

Figure 50-3 Corneal opacities in cystinosis. Tinsel-like refractile opacities in the cornea of a patient with cystinosis under slit-lamp examination. *(From reference 4.)*

of cystinosis are also associated with *CTNS* mutations but still have some functional transport protein, leading to lower intracellular cystine levels and slower onset of renal disease in the intermediate form and no renal disease in the benign form.

Clinical Manifestations

The first clinical symptoms and signs in nephropathic cystinosis are those of Fanconi syndrome and usually appear in the second half of the first year of life. Subtle abnormalities of tubular function can be demonstrated earlier in families with index cases, but there always is a delay between birth and the first symptoms. Rickets is common after the first year of life, along with growth failure. The growth failure occurs before the GFR declines and despite correction of electrolyte and mineral deficiencies. The GFR invariably declines and end-stage renal disease (ESRD) occurs by late childhood.

Nephrocalcinosis is relatively common, and a few patients have developed renal calculi. Photophobia is another common symptom that occurs by 3 years of age and is progressive. Older patients with cystinosis may develop visual impairment and blindness. Children with cystinosis usually have fair complexions and blond hair, but dark hair has been observed in some. Cystinosis has been observed in other ethnic groups but is less common than in Caucasians.

The diagnosis is based on the demonstration of elevated intracellular levels of cystine, usually in white blood cells or skin fibroblasts. Patients with nephropathic and intermediate cystinosis have intracellular cystine levels that exceed 2 nmol half-cystine per mg protein (normal <0.2 nmol half-cystine per mg protein). Heterozygotes for cystinosis will have levels that range from 0.2 to 1 nmol half-cystine/mg protein. A slit-lamp demonstration of corneal crystals strongly suggests the diagnosis[2] (Fig. 50-3). A prenatal diagnosis can be made with amniocytes or chorionic villi.

Common late complications of cystinosis include hypothyroidism, splenomegaly and hepatomegaly, decreased visual acuity, swallowing difficulties, pulmonary insufficiency, and corneal ulcerations.[5] Less frequently, older patients have developed insulin-dependent diabetes mellitus, myopathy, and progressive neurologic disorders. Decreased brain cortex has also been noted on imaging in some patients. Older patients may develop vascular calcification, especially of the coronary arteries, which can lead to myocardial ischemia.

Pathology

The morphologic features of the kidney in cystinosis vary with the stage. Early in the disease, cystine crystals are present in tubular epithelial cells, interstitial cells, and rarely glomerular epithelial cells[6,7] (Fig. 50-4, *A*). A swan-neck deformity or thinning of the first part of the proximal tubule is an early finding but is not unique to cystinosis. Later, there is pronounced tubular atrophy, interstitial fibrosis, and abundant crystal deposition with giant cell formation of the glomerular visceral epithelium, segmental sclerosis, and eventual glomerular obsolescence. Electron microscopy (EM) studies have demonstrated intracellular crystalline inclusions consistent with cystine (Fig. 50-4, *B*). Peculiar "dark cells," unique to the cystinotic kidney, have also been observed.

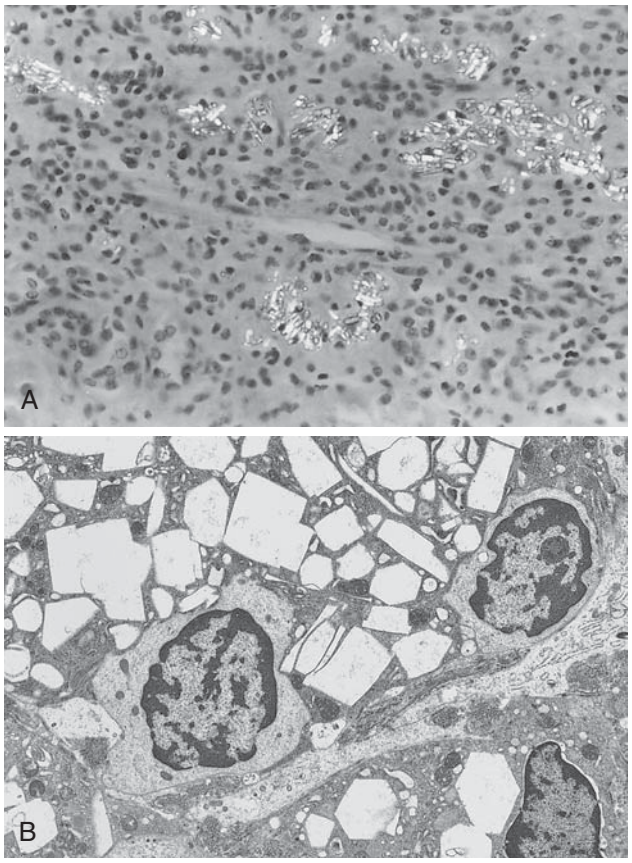

Figure 50-4 Cystine crystals in the kidney in cystinosis. A, Crystals are seen in photomicrograph of alcohol-fixed nephrectomy specimen, taken through incompletely crossed polarizing filters. Birefringent crystals are evident in tubular epithelial cells and free in the interstitium. **B,** Electron micrograph of a renal biopsy specimen shows hexagonal, rectangular, and needle-shaped crystals in macrophages within the interstitium. (Original magnification ×3000.) *(**A** from reference 6; **B** from reference 7.)*

Treatment

Nonspecific therapy for infantile cystinosis consists of vitamin D therapy and replacement of the urinary electrolyte losses, followed, in due course, by the management of the progressive renal failure (Table 50-1). Cysteamine therapy has now been shown to lower tissue cystine levels and slow the decline in GFR, especially in children with a normal serum creatinine concentration treated before 2 years of age[8] (Fig. 50-5). Cysteamine therapy also improves linear growth but not Fanconi syndrome. The most common problems associated with cysteamine therapy are nausea, vomiting, and a foul odor and taste. Treatment should begin with a low dose of cysteamine soon after the diagnosis is made, increased during 4 to 6 weeks to 60 to 90 mg/kg/day in four divided doses as close to every 6 hours as possible. Slowly increasing the dose minimizes the risk for neutropenia, rash, and arthritis. Leukocyte cystine levels should be checked every 3 to 4 months to monitor effectiveness and compliance, with the goal of achieving and maintaining a cystine level of

below 2.0 and preferably below 1.0 nmol half-cystine/mg protein. A long-acting formulation of cysteamine should be available soon that will allow twice-daily dosing. A 50-mM solution of cysteamine applied topically onto the eye has proved useful in depleting the cornea of cystine crystals, but it requires administration 6 to 12 times a day to be effective.

Treatment of ESRD in these children poses no greater problems than in other children. Successful renal transplantation reverses the renal failure and Fanconi syndrome but does not appear to improve the extrarenal manifestations of cystinosis. Cysteamine therapy should be continued after transplantation. Cystine does not accumulate in the transplanted kidney, except in infiltrating immunocytes.

Galactosemia

Etiology and Pathogenesis

Galactosemia is an autosomal recessively inherited disorder of galactose metabolism. It is most often the result of deficient activity of the enzyme galactose 1-phosphate uridyltransferase, the incidence of which is 1 in 62,000 live births.[9] Deficiency of this enzyme leads to the intracellular accumulation of galactose 1-phosphate, with damage to the liver, proximal renal tubule, ovary, brain, and lens. A less frequent cause of galactosemia is a deficiency of galactose kinase, which forms galactose 1-phosphate from galactose. Cataracts are the only manifestation of this form of galactosemia.

The pathogenesis of the symptoms of galactosemia is not clear. Accumulation of galactose 1-phosphate subsequent to the ingestion of galactose can inhibit a number of pathways for carbohydrate metabolism, and its level correlates somewhat with clinical symptoms. Defective galactosylation of proteins has also been postulated. Proposed as a pathogenetic mechanism, formation of galactitol from galactose by aldose reductase is probably responsible for the cataract formation.

Clinical Manifestations

Affected infants ingesting milk containing lactose, the most common source of galactose in the diet, rapidly develop vomiting, diarrhea, and failure to thrive. Jaundice from unconjugated hyperbilirubinemia is common, along with severe hemolysis. Continued intake of galactose leads to hepatomegaly and cirrhosis. Cataracts appear within days after birth, although at first they often are detectable only with a slit lamp. Mental retardation may develop within a few months. Fulminant *Escherichia coli* sepsis has been described in a number of infants, possibly a consequence of inhibited leukocyte bactericidal activity.

In addition to these clinical findings, galactose intake leads within days to hyperaminoaciduria and albuminuria. Increased urine sugar excretion is principally a result of galactosuria and not glycosuria. There seems to be little or no impairment in glucose handling by the renal tubule. Galactosemia should be suspected whenever there is a urinary reducing substance that does not react in a glucose oxidase test. The diagnosis can be confirmed by demonstration of deficient transferase activity in red blood cells, fibroblasts, leukocytes, or hepatocytes. Most infants with galactosemia are found through newborn metabolic screening.

Treatment

Galactosemia is treated by elimination of galactose from the diet. Acute symptoms and signs resolve in a few days. Cataracts will also regress to some extent. Even with early elimination of galactose, however, a common outcome in galactosemia is developmental delay, speech impairment, ovarian dysfunction, and growth retardation. Profound intellectual deficits are rare even in infants treated late.

Hereditary Fructose Intolerance

Etiology and Pathogenesis

Hereditary fructose intolerance is another disorder of carbohydrate metabolism associated with Fanconi syndrome.[10] Fructose intolerance is inherited as an autosomal recessive trait, with an estimated incidence of 1 in 20,000 live births. It is caused by a deficiency of the

Treatment of Cystinosis

Problem	Therapy
Removal of lysosomal cystine	Cysteamine, 0.235 g/m^2 q6h to maintain leukocyte cystine level <1 nmol half-cystine*/mg protein
Correction of Tubulopathy	
Dehydration	2-6 l/d fluid
Acidosis	2-15 mmol/kg/d K^+ citrate
Hypophosphatemia	1-4 g/d K^+ phosphate
Rickets	0.25-1 µg/d calcitriol
Adjunct therapies	NaCl, carnitine, indomethacin, hydrochlorothiazide
Later Therapies	
Growth failure	Growth hormone
Hypothyroidism	Thyroxine
Renal failure	Renal replacement therapy, ideally renal transplantation

Table 50-1 Treatment of cystinosis. *By convention, units are half-cystine because the cystine originally was converted to two cysteine molecules, or "broken in half," before measurement.

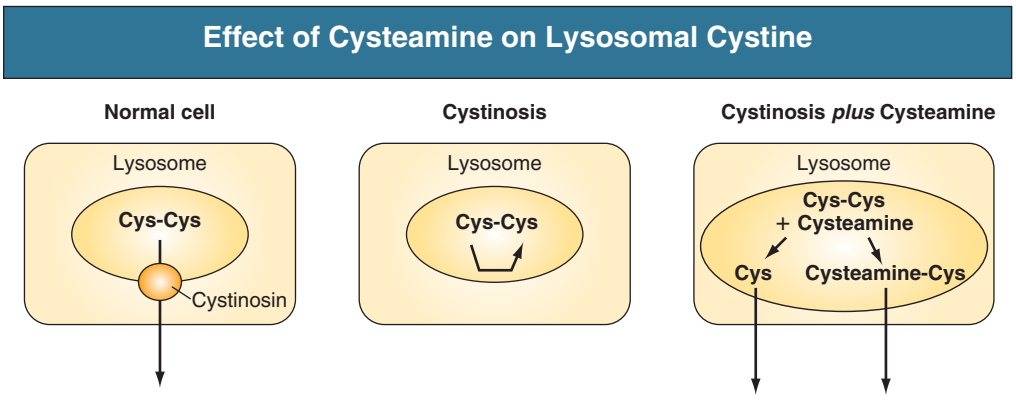

Figure 50-5 Effect of cysteamine on lysosomal cystine. In cystinosis, the transporter (cystinosin) for cystine *(Cys-Cys)* egress from the lysosome is defective. Cysteamine can easily enter the lysosome and combine with cystine, forming cysteine *(Cys)* and the mixed disulfide cysteamine-cysteine. Both these compounds can exit the lysosome through a transporter other than the cystine carrier.

B isoform of the enzyme fructose 1-phosphate aldolase, which cleaves fructose 1-phosphate into D-glyceraldehyde and dihydroxyacetone phosphate. Deficient activity of aldolase B leads to tissue accumulation of fructose 1-phosphate and reduced levels of adenosine triphosphate (ATP).

Clinical Manifestations

Symptoms of hereditary fructose intolerance appear at weaning when fruit, vegetables, and sweetened cereals that contain fructose or sucrose are introduced. Children with this disorder experience nausea, vomiting, and symptoms of hypoglycemia shortly after ingestion of fructose, sucrose, or sorbitol. These symptoms may progress to convulsions, coma, and even death, depending on the amount consumed. When they are exposed to fructose, infants may have a catastrophic illness, with severe dehydration, shock, acute liver impairment, bleeding, and acute kidney injury (AKI). Concomitant serum biochemical findings after fructose ingestion are decreased glucose, phosphate, and bicarbonate and increased uric acid and lactic acid. Chronic exposure to fructose leads to failure to thrive, hepatomegaly and fatty liver, jaundice, hepatic cirrhosis, and nephrocalcinosis. Children with hereditary fructose intolerance learn to avoid sweets.

Diagnosis

The diagnosis should be suspected when symptoms develop after the ingestion of fructose. This can be confirmed by assaying the activity of fructose 1-phosphate aldolase in a liver biopsy specimen and increasingly by genetic testing using leukocytes.

Treatment

Treatment of hereditary fructose intolerance involves strict avoidance of foods containing fructose and sucrose, but because most patients develop a strong aversion to such foods, this is usually easy. The greatest risk occurs during infancy, before those affected learn to avoid fructose.

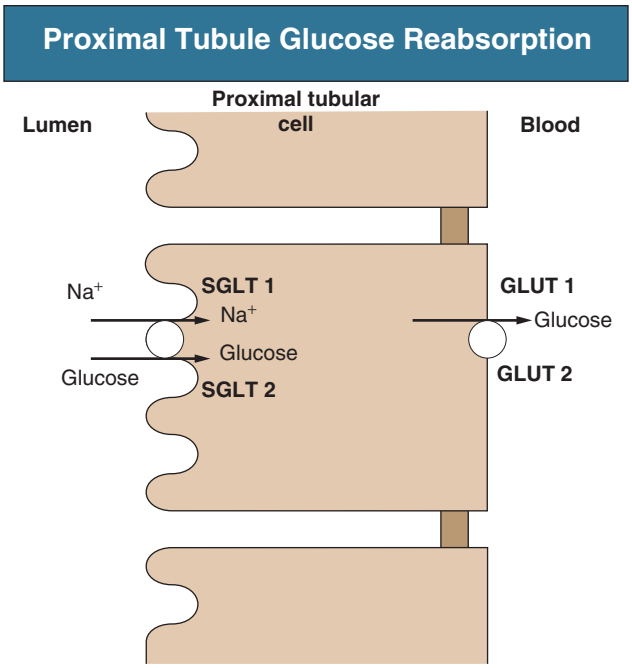

Figure 50-6 Proximal tubule glucose reabsorption. Glucose enters the proximal tubule cell coupled to Na^+ reabsorption from the lumen through a high-capacity, low-affinity transporter (SGLT2) in the early proximal tubule and a low-capacity, high-affinity transporter (SGLT1) in the late proximal tubule. Glucose exits the cell through the transporters GLUT1 and GLUT2 located in the late and early proximal tubule, respectively.

Glycogenosis

Most patients with glycogen storage disease and Fanconi syndrome have an autosomal recessive disorder characterized by heavy glycosuria and increased glycogen storage in the liver and kidney, known as the Fanconi-Bickel syndrome, or *glucose-losing syndrome,* because the glucose losses can be massive.[11] The defect is deficient activity of the sugar transporter GLUT2 (Fig. 50-6). GLUT2 facilitates sugar exit from the basolateral side of the proximal tubule and intestinal cell and sugar entry and exit from the hepatocyte and pancreatic β cell. A few patients with type I glycogen storage disease have mild Fanconi syndrome but not Fanconi-Bickel syndrome. The therapy for this disorder is directed at the renal solute losses, treatment of rickets (which can be severe), and frequent feeding to prevent ketosis. Uncooked cornstarch has been shown to lessen the hypoglycemia and to improve growth.

Tyrosinemia

Definition

Hereditary tyrosinemia type I, also known as *hepatorenal tyrosinemia,* is a defect of tyrosine metabolism affecting the liver, kidneys, and peripheral nerves.[12]

Etiology and Pathogenesis

The cause of hereditary tyrosinemia type I is a deficiency of fumarylacetoacetate hydrolase (FAH) activity; it is an autosomal recessive disorder. Decreased or absent FAH activity leads to accumulation of maleylacetoacetate (MAA) and fumarylacetoacetate (FAA) in affected tissues. These compounds can react with free sulfydryl groups, reduce intracellular levels of glutathione, and act as alkylating agents. MAA and FAA are not detectable in plasma or urine but are converted to succinylacetoacetate and succinylacetone. Succinylacetone is structurally similar to maleic acid, a compound that causes Fanconi syndrome experimentally in rats and may be the cause of Fanconi syndrome in humans affected with tyrosinemia.

Clinical Manifestations

The liver is the major organ affected, evident as early as the first month of life. Such infants usually have severe disease and die in the first year. All children with tyrosinemia will eventually develop macronodular cirrhosis, and many develop hepatocellular carcinoma. Acute, painful peripheral neuropathy and autonomic dysfunction can also occur. Proximal renal tubular dysfunction is evident in all patients with tyrosinemia, especially those presenting after infancy. Nephromegaly is very common, and nephrocalcinosis may be seen. Glomerulosclerosis and impaired GFR may be seen with time.

Diagnosis

The diagnosis should be suspected with elevated plasma tyrosine and methionine levels together with their *p*-hydroxy metabolites. The presence of succinylacetone in blood or urine is diagnostic of hereditary tyrosinemia type I.

Treatment

The institution of a diet low in phenylalanine and tyrosine dramatically improves the renal tubular dysfunction. Nitisinone, which inhibits the formation of MAA and FAA, dramatically improves the renal and hepatic dysfunction.[12] Liver transplantation has been successfully used to treat patients with severe liver failure and to prevent

the development of hepatocellular carcinoma. Liver transplantation leads to rapid correction of Fanconi syndrome.

Wilson Disease

Definition

Wilson disease is an inherited disorder of copper metabolism that affects numerous organ systems.[13,14] It has an overall incidence of 1 in 30,000 live births. About 40% of patients present with liver disease, 40% with extrapyramidal symptoms, and 20% with psychiatric or behavioral abnormalities.

Etiology and Pathogenesis

Wilson disease is caused by a defect in the P-type copper–transporting adenosine triphosphatase ATP7B, which is highly expressed in the liver, kidney, and placenta. It impairs biliary copper excretion and the incorporation of copper into ceruloplasmin. These abnormalities cause excessive intracellular accumulation of copper in the liver, with subsequent overflow into other tissues, such as brain, cornea, and renal proximal tubule.

Clinical Manifestations

Excessive storage of copper in the kidney leads to renal tubular dysfunction in most patients and full-blown Fanconi syndrome in some. Hematuria also has been noted. Renal plasma flow and GFR decrease as the disease progresses, but death from extrarenal causes occurs before the onset of renal failure. Fanconi syndrome usually appears before the onset of hepatic failure. Hypercalciuria with development of renal stones and nephrocalcinosis also have been reported. Besides proximal tubular dysfunction, abnormalities in distal tubular function, decreased concentrating ability, and distal renal tubular acidosis (type 1 RTA) have also been observed. Neurologic abnormalities, such as dysarthria and gait disturbances, may be the presenting symptom in young adults with Wilson disease. Kayser-Fleischer rings, dense brown copper deposits around the iris, may be visible but typically can be seen only with a slit lamp.

Pathology

Histologic examination of the kidney in untreated Wilson disease shows either no alteration on light microscopy or only some flattened proximal tubular cells without recognizable brush borders. EM shows loss of the brush border, disruption of the apical tubular network, electron-dense bodies probably representing metalloproteins in the subapical region of tubule cell cytoplasm, and cavitation of the mitochondria with disruption of the normal cristae pattern. Rubeanic acid staining shows intracytoplasmic copper granules. The copper content of kidney tissue is greatly elevated.

Diagnosis

The diagnosis of Wilson disease should be suspected in children and young adults with unexplained neurologic disease, chronic active hepatitis, acute hemolytic crisis, behavioral or psychiatric disturbances, or the appearance of Fanconi syndrome. In such patients, the presence of Kayser-Fleischer rings is an important clue in making the diagnosis. Serum ceruloplasmin levels are decreased in 96% of patients with Wilson disease. A greatly increased urinary copper level is also useful in making the diagnosis, especially if it increases significantly with D-penicillamine. Liver copper levels are increased in untreated patients. Mutational analysis is also available.

Treatment

Treatment with penicillamine, 1 to 1.5 g/day, reverses the renal dysfunction and may reverse the hepatic and neurologic disease, depending on the degree of damage before the onset of therapy. Recovery, however, is quite slow. Trientine can also chelate copper and is indicated in patients who cannot tolerate penicillamine. Tetrathiomolybdate is a potent agent in removing copper from the body and has been used in some patients with neurologic disease to prevent the immediate worsening of symptoms that can occur with penicillamine. Zinc salts, which induce intestinal metallothionein and blockade of intestinal absorption of copper, are useful in maintenance therapy. Liver transplantation has been successful in some patients but should be reserved for those with liver failure.

Lowe Syndrome

Lowe syndrome (oculocerebrorenal syndrome) is characterized by congenital cataracts and glaucoma, severe mental retardation, hypotonia with diminished to absent reflexes, and renal abnormalities.[15,16] Fanconi syndrome is followed by progressive renal impairment. ESRD usually does not occur until the third to fourth decade of life.

Lowe syndrome is transmitted as an X-linked recessive trait. Despite this inheritance pattern, Lowe syndrome has occurred in a few females. The defective gene codes for phosphatidyl inositol 4,5-bisphosphate 5-phosphatase, OCRL1, involved with cell trafficking and signaling.

Light microscopy of the kidney is normal early in the disorder, with endothelial cell swelling and thickening and splitting of the glomerular basement membrane seen by EM. In the proximal tubule cells, there is shortening of the brush border and enlargement of the mitochondria, with distortion and loss of the cristae. Only symptomatic treatment is available.

Dent Disease

Definition

Dent disease is an X-linked recessive disorder characterized by low-molecular-weight proteinuria, hypercalciuria, nephrolithiasis, nephrocalcinosis, and rickets.[17-19] Affected males often have aminoaciduria, phosphaturia, and glycosuria. Renal failure is common and may occur by late childhood. Hemizygous females usually have only proteinuria and mild hypercalciuria. X-linked recessive nephrolithiasis and X-linked recessive hypophosphatemic rickets have similar features, and most have a defect in the renal ClC-5 chloride channel. Dent disease type 2 is a clinically similar disease affecting males, but there is a mutation in the same gene that causes Lowe syndrome, although Dent type 2 patients do not have the brain or eye involvement seen in Lowe syndrome.[17]

Etiology and Pathogenesis

Most of these disorders are caused by a mutation in the *CLCN5* gene leading to inactive ClC-5 chloride channel function (see Fig. 50-2). The ClC-5 chloride channel spans the membrane of pre-endocytic vesicles just below the brush border of the proximal tubule. This channel plays a role in the acidification of these vesicles by a proton pump. Lack of this Cl^- channel interferes with protein reabsorption from the tubule through the megalin-cubilin receptor system and cell surface receptor recycling, which may explain the phosphaturia, glycosuria, and aminoaciduria.

The defective OCRL1 in Dent disease type 2 patients interferes with normal cell protein trafficking. The renal disease is similar to that seen in type 1 Dent disease. Although patients do not have the eye and brain disease seen in Lowe patients, a few Dent type 2 patients have a mild intellectual deficits, hypotonia, and subclinical cataracts.

Filtered PTH is also reabsorbed by the megalin-cubilin system for degradation in the lysosome. Decreased PTH reabsorption allows increased binding to luminal PTH receptors and increased endocytosis of luminal phosphate transporters, leading to increased phosphaturia.[1]

Mitochondrial Cytopathies

Definition

Mitochondrial cytopathies are a diverse group of diseases with abnormalities in mitochondrial DNA that lead to mitochondrial dysfunction in various tissues.[20]

Clinical Manifestations

Most of the mitochondrial cytopathies present with neurologic disorders such as myopathy, myoclonus, ataxia, seizures, external ophthalmoplegia, stroke-like episodes, and optic neuropathy. Other manifestations include retinitis pigmentosa, diabetes mellitus, exocrine pancreatic insufficiency, sideroblastic anemia, sensorineural hearing loss, pseudo-obstruction of the colon, hepatic disease, cardiac conduction disorders, and cardiomyopathy.

The most common renal manifestation associated with mitochondrial cytopathies is Fanconi syndrome, although a number of patients have been described with focal segmental glomerulosclerosis (FSGS) and corticosteroid-resistant nephrotic syndrome. All the patients with renal abnormalities have had extrarenal disorders, mainly neurologic disease. Most patients present in the first months of life and die soon afterward.

Diagnosis

A clue to mitochondrial cytopathies is elevated serum or cerebrospinal fluid lactate levels, especially in association with an altered lactate-pyruvate ratio, suggesting a defect in mitochondrial respiration. The presence of "ragged red fibers," a manifestation of abnormal mitochondria, in a muscle biopsy specimen is another clue, especially with large abnormal mitochondria on EM of muscle tissue.

Treatment

There is little to offer these patients in terms of definitive therapy. Low mitochondrial enzyme complex III activity can be treated with menadione or ubidecarenone. Deficient mitochondrial enzyme complex I activity may be treated with riboflavin and ubidecarenone. Ascorbic acid has been used to minimize oxygen free radical injury. High-lipid, low-carbohydrate diet has been tried in cytochrome *c* oxidase deficiency.

Idiopathic Fanconi Syndrome

A number of patients develop the complete Fanconi syndrome in the absence of any known cause. Traditionally called "adult" Fanconi syndrome because it was thought that only adults were affected, it is now clear that children may be affected, and a more proper designation is *idiopathic* Fanconi syndrome. Not all the features of Fanconi syndrome may be present when the patient is first seen, but do appear with time. Idiopathic Fanconi syndrome can be inherited in an autosomal dominant, autosomal recessive, or even X-linked pattern. However, most cases occur sporadically, with no evidence of genetic transmission. The prognosis is variable, and some patients develop chronic renal failure 10 to 30 years after onset of symptoms. A few patients have undergone renal transplantation; in some, Fanconi syndrome has recurred in the allograft without evidence of rejection, suggesting an extrarenal cause of the idiopathic form. In one family, the gene defect was localized to chromosome 15.[21]

Renal morphologic descriptions of such cases are scanty. In some reports, no abnormalities were found, and in others, tubular atrophy with interstitial fibrosis was interspersed with areas of tubular dilation. Greatly dilated proximal tubules with swollen epithelium and grossly enlarged mitochondria with displaced cristae have also been noted.

ACQUIRED CAUSES OF FANCONI SYNDROME

Numerous substances can injure the proximal renal tubule. Injury can range from an incomplete Fanconi syndrome to acute tubular necrosis or ESRD. The extent of the tubular damage varies depending on the type of toxin, amount ingested, and host. A careful history of possible toxin exposure and recent medications is important in patients with tubular dysfunction. Box 50-1 lists the more common causes of acquired Fanconi syndrome.

Heavy Metal Intoxication

A major cause of proximal tubular dysfunction is acute heavy metal intoxication, principally lead and cadmium. In lead poisoning, the renal tubular dysfunction, mainly aminoaciduria and mild glycosuria and phosphaturia, is usually overshadowed by the involvement of other organs, especially the central nervous system.[22] Fanconi syndrome associated with cadmium poisoning is associated with severe bone pain, giving rise to the name itai-itai ("ouch-ouch") disease for its occurrence in Japanese patients affected by industrial contamination of the soil.[23]

Tetracycline

Outdated tetracycline causes a reversible Fanconi syndrome even in therapeutic doses. Recovery is rapid when the degraded drug is stopped. The compound responsible for the tubule dysfunction is anhydro-4-tetracycline, formed from tetracycline by heat, moisture, and low pH.

Cancer Chemotherapy Agents

A number of cancer chemotherapy agents have been associated with Fanconi syndrome and renal tubular dysfunction, especially cisplatin and ifosfamide. Carboplatin has been associated with reduced GFR and magnesium wasting but not Fanconi syndrome. The nephrotoxicity of both cisplatin and ifosfamide is dose dependent and often irreversible. Besides the usual manifestations of Fanconi syndrome, cisplatin toxicity is characterized by hypomagnesemia, caused by hypermagnesuria, which can be extremely severe, persistent, and difficult to treat.[24] Ifosfamide is more often associated with hypophosphatemic rickets.[25] Chloroacetaldehyde, a metabolite of ifosfamide, appears experimentally to cause Fanconi syndrome. Both ifosfamide and cisplatin can cause an irreversible reduction in GFR.

Other Drugs and Toxins

Exposure to a wide range of toxins may give rise to Fanconi syndrome, often in association with a reduced GFR, including 6-mercaptopurine, toluene (glue sniffing), and Chinese herbal medicines containing *Aristolochia* species.[26] There have also been anecdotal reports associating Fanconi syndrome with valproic acid (valproate), suramin, cresol-based antiseptic (Lysol), gentamicin, and ranitidine. Antiviral medications, especially antiretroviral agents

such as tenofovir, are an increasingly common cause of Fanconi syndrome.[27]

Dysproteinemias

Dysproteinemia[28] from multiple myeloma, light-chain proteinuria,[29] Sjögren syndrome, and amyloidosis is sometimes associated with Fanconi syndrome, which appears to be correlated with urinary free light chains with specific physicochemical characteristics that crystallize within the tubular cells.

Glomerular Disease

Nephrotic syndrome has rarely been associated with Fanconi syndrome. Most of these patients have FSGS, and the occurrence of Fanconi syndrome heralds a poor prognosis.

After Acute Kidney Injury

Tubular dysfunction can occur during recovery from AKI from any cause, whether or not a known tubular toxin was originally implicated.

After Renal Transplantation

Fanconi syndrome has appeared rarely after renal transplantation. The pathogenesis probably is multifactorial, including sequelae of acute tubular necrosis, rejection, nephrotoxic drugs, ischemia from renal artery stenosis, and residual hyperparathyroidism.

FAMILIAL GLUCOSE-GALACTOSE MALABSORPTION AND HEREDITARY RENAL GLYCOSURIA

Definition

Renal glycosuria refers to the appearance of readily detectable glucose in the urine when the serum glucose concentration is in a normal range. When the serum glucose concentration is in a physiologic range, virtually all the filtered glucose is reabsorbed in the proximal tubule.[30] Filtered glucose enters the proximal tubule through two specific carriers (SGLT1 and SGLT2) coupled to sodium and exits the cell through the sugar transporters GLUT1 and GLUT2 (see Fig. 50-6). However, when the serum level exceeds the physiologic range, the filtered load exceeds the capacity of these carriers, and glucose begins to appear in the urine; this is termed the *renal threshold.*

Etiology and Pathogenesis

Familial glucose-galactose malabsorption is a rare autosomal disorder that is caused by mutations in the gene coding for the brush border sodium-glucose cotransporter SGLT1, which is found in the intestinal cell and the S_3 segment of the proximal renal tubule cell. The disorder is characterized by the neonatal onset of life-threatening diarrhea from the intestinal malabsorption of glucose and galactose, which resolves rapidly with the removal of glucose and galactose and its dipeptide, lactose, from the diet. These patients frequently also have a mild renal glycosuria.

Familial renal glycosuria occurs with an incidence of 1 in 20,000 live births and appears to be inherited as a codominant trait with variable penetrance.[31] This disorder is caused by mutations in the *SLC5A2* gene that codes for the SGLT2 glucose transporter found in the early portion of the proximal tubule. Inhibitors of SGLT2, which mimic this genetic defect, have been used recently in type 2 diabetes to lower hyperglycemia without causing weight gain or aggravating hyperinsulinism.

In the past, renal glycosuria was divided into three types based on the reabsorption patterns observed during glucose infusion studies, but this typing system has been questioned because clearance data suggest that patients with renal glycosuria have rates of glucose reabsorption that vary from virtually no reabsorption to near-normal rates, rather than three distinct types, probably reflecting different mutations in the *SLC5A2* gene.[31]

Natural History

Patients with familial glucose-galactose malabsorption appear to grow and develop normally with removal of the offending sugars from the diet. The clinical course of hereditary renal glycosuria is benign, except for a few patients with polyuria and salt wasting, and it is not a precursor to diabetes mellitus. Patients need to be aware of the condition in order not to receive unnecessary diagnostic investigations, or even treatment for presumed diabetes mellitus.

AMINOACIDURIAS

As with glucose, amino acids are almost completely reabsorbed in the proximal tubule by a series of specific carriers. Studies have described a number of inherited disorders resulting in the incomplete reabsorption of a specific amino acid or a group of amino acids[32,33] (Table 50-2).

Cystinuria

Definition

Cystinuria is characterized by the excessive urinary excretion of cystine and the dibasic amino acids ornithine, lysine, and arginine.[35]

Etiology and Pathogenesis

These four amino acids share a transport system on the brush border membrane of the proximal tubule. Because of the relative insolubility of cystine when its urine concentration exceeds 250 mg/l (1 mmol/l), patients with cystinuria have recurrent renal calculi.

Cystinuria is an autosomal recessive trait with a disease incidence of 1 in 15,000 births.[34] Initially, there appeared to be three genetic types on the basis of *in vitro* studies of intestinal transport and amino acid excretion in heterozygotes. More recently, two genes (*SLC3A1* coding for the protein rBAT and *SLC7A9* for the protein $b^{0,+}$AT) have been identified that are defective in cystinuria. *SLC3A1* heterozygotes have normal excretion rates for cystine. *SLC7A9* heterozygotes

Inherited Aminoacidurias

Disease	Clinical Findings	Urine Amino Acids
Cystinuria	Urolithiasis	Cystine, lysine, ornithine, arginine
Hartnup disease	Rash, neurologic disease	Neutral amino acids
Iminoglycinuria	None	Proline, hydroxyproline glycine
Lysinuric protein intolerance	Hyperammonemia, vomiting, diarrhea	Dibasic amino acids

Table 50-2 Inherited aminoacidurias.

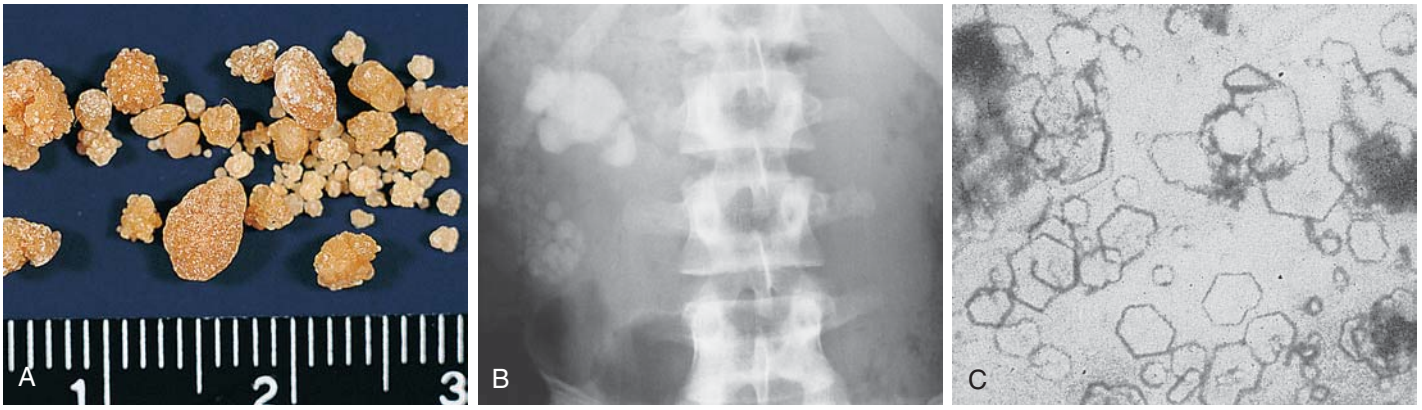

Figure 50-7 Cystinuria. A, Both rough and smooth cystine calculi. **B,** Plain radiograph of a cystine calculus in the right renal pelvis and further multiple parenchymal calculi. **C,** Urine microscopy showing characteristic flat hexagonal crystals (see also Fig. 4-4, *G*).

have cystine excretion rates that range from normal to almost that of homozygous patients. Based on these data, a newer classification proposed type A for mutations in both *SLC3A1* genes and type B for mutations in *SLC7A9*.[34] Type AB is compound heterozygote. Type A accounts for 38% of cystinuria patients, type B for 47%, and type AB for 14%.

Clinical Manifestations

Cystine stones (calculi) are typically yellow-brown (Fig. 50-7, *A*) and are radiopaque (Fig. 50-7, *B*). Cystine crystals appear as microscopic, flat hexagons in the urine (Fig. 50-7, *C*), and this is a clue to the diagnosis.

Diagnosis

Patients can be screened for cystinuria with the cyanide-nitroprusside test, but type B heterozygotes may also give a positive result. The definitive test is to quantify cystine and dibasic amino acid excretion in a 24-hour urine specimen. Homozygotes excrete more than 118 mmol cystine per mmol creatinine (250 mg/g).

Treatment

The aim of therapy in cystinuria is to lower the urine cystine concentration to below 300 mg/l (1.25 mmol/l). The first step is to increase fluid intake. However, because most patients with cystinuria excrete 0.5 to 1 g/day of cystine, a urine output of 2 to 4 l/day is needed to achieve this goal. Cystine solubility increases in alkaline urine, but the urine pH must be above 7.5 to be effective. In patients with recurrent stone disease, thiols, such as penicillamine, are extremely useful through the formation of a more soluble, mixed disulfide of the thiol and cysteine from cystine. Penicillamine should be started at 250 mg/day and gradually increased (maximum, 2 g/day) during 3 months to achieve a urine cystine concentration below 300 mg/l in conjunction with a high fluid intake. Tiopronin is equally effective and is better tolerated than penicillamine. Tiopronin should also be started at a low dose and slowly increased (maximum, 2 g/day). Captopril can be useful (an effect resulting from its thiol structure, not its angiotensin-converting enzyme inhibitor effect), but the dose range (75 to 150 mg/day) may be limited by its hypotensive effects.

Hartnup Disease

Hartnup disease is an autosomal recessive trait characterized by a neutral aminoaciduria that arises from a defect in a specific carrier for neutral amino acid transport present in both the intestine and the proximal renal tubule. The gene responsible for Hartnup disease is *SLC6A19*. It codes for the neutral amino acid transporter B^0AT1. From newborn screening programs, the genetic defect is more common than originally thought because most individuals with the aminoaciduria never manifest symptoms. Individuals who become symptomatic with Hartnup disease have pellagra-like clinical features, including a photosensitive dermatitis, ataxia, and psychotic behavior. These symptoms appear to be secondary to niacin deficiency partly caused by inadequate intestinal absorption of tryptophan, the precursor for niacin synthesis. However, most individuals who inherit the Hartnup transport defect do not have symptoms, so there must be other environmental or genetic factors that contribute to disease. Nicotinamide supplementation leads to clearing of the skin disease and occasionally some of the neurologic problems. The renal loss of neutral amino acids appears to have minimal clinical importance.

Iminoglycinuria

Iminoglycinuria is a benign heritable defect in the proximal tubule transporter PAT1, leading to incomplete reabsorption of proline, hydroxyproline, and glycine.

Lysinuric Protein Intolerance

Lysinuric protein intolerance is associated with recurrent bouts of hyperammonemia after a protein load, resulting from the decreased renal and intestinal dibasic amino acid transport.

Other Aminoacidurias

Rare individuals have been described with abnormalities in the excretion of other amino acids. These usually occur in association with mental retardation.

HEREDITARY DEFECTS IN URIC ACID HANDLING

Hereditary Renal Hypouricemia

Hereditary renal hypouricemia is a rare autosomal recessive disorder characterized by very low serum uric acid levels (<2.5 mg/dl; [<150 µmol/l] in adult men and <2.1 mg/dl [<124 µmol/l] in adult women) and increased uric acid clearance, ranging from 30% to 150% of the filtered load.[36] In the normal kidney, uric acid is both

reabsorbed and secreted in the proximal tubule by two different uric acid–anion exchange transporters and a voltage-sensitive pathway. In some patients, the defect is in the gene *SLC22A12* that codes for the protein URAT1; other patients have been found to have mutations in *SLC2A9 (GLUT9)*. Most patients do not have symptoms and are found incidentally when a low serum uric acid concentration is noted during routine serum chemistry evaluation. About one fourth of patients with renal hypouricemia have had renal stones, but only one third of these were uric acid stones. There may also be hypercalciuria, and a few patients have had exercise-induced AKI, thought to be caused by acute tubular injury by passage of uric acid "gravel" in association with volume depletion and reduced urine pH. Most patients require no treatment, but if forming uric acid stones, they should maintain a high fluid intake. Urine alkalinization and allopurinol can be used for patients with persistent uric acid stones.

Familial Juvenile Hyperuricemic Nephropathy and Medullary Cystic Kidney Disease Type 2

Familial juvenile hyperuricemic nephropathy (FJHN) is a rare autosomal dominant condition characterized by hyperuricemia associated with a tubular defect in uric acid excretion.[37] Children develop progressive chronic kidney disease (CKD) with interstitial fibrosis and glomerulosclerosis. The hyperuricemia is caused by renal underexcretion of uric acid. Diagnosis is suggested by a fractional excretion of uric acid of less than 5% (normal, 10% to 15%). Controversy exists as to whether lowering of serum uric acid slows the progression of CKD; the studies reporting benefit have usually involved starting of a xanthine oxidase inhibitor early in the course of the disease. Isosthenuria and hypertension are common, and some patients have renal salt wasting. Many of the features of FJHN are also seen in medullary cystic kidney disease type 2 (MCKD2).[38] Most of these patients have a defect in the gene *UMOD,* on chromosome 16p12, coding for the Tamm-Horsfall/uromodulin protein. This mutation may interfere with the function of the Na-K-2Cl transporter, leading to a secondary increase in proximal sodium and uric acid reabsorption. This mutation may also lead to deposition of abnormal protein in the endoplasmic reticulum and ultimately cell death.

CHAPTER 51

Sickle Cell Disease

Jan C. ter Maaten and Fatiu A. Arogundade

DEFINITIONS

Sickle cell disease is an autosomal recessive inherited disorder that predominantly affects persons of African, Mediterranean, Indian, and Middle Eastern descent. The gene for sickle hemoglobin (hemoglobin S, or HbS) results in the replacement of the normal glutamine by valine in the sixth position of the β-globin subunit, thereby changing the configuration of the hemoglobin molecule and enhancing the aggregation of hemoglobin molecules during cellular or tissue hypoxia, dehydration, or oxidative stress. This aggregation decreases the pliability of the erythrocytes and may distort their shape to a characteristic crescent or sickle, resulting in their premature destruction (hemolysis) and frequent, widespread vaso-occlusive episodes with subsequent acute and chronic organ damage. Sickle cell anemia occurs in those homozygous for HbS or in heterozygotes when HbS coexists with another abnormal hemoglobin (e.g., hemoglobin C, β-thalassaemia chains). *Sickle cell trait* occurs in those heterozygous for HbS when the other hemoglobin molecule is normal.

Sickle cell nephropathy describes the structural and functional abnormalities of the kidney in sickle cell disease.

SICKLE CELL DISEASE

Epidemiology

Sickle cell disease was first recognized in West Africa. The high prevalence of HbS in this region probably represents a survival benefit because the presence of sickle cell trait protects against malaria. At present, sickle cell disease is a worldwide health problem because HbS has spread throughout Africa, around the Mediterranean, and to the Middle East and India as well as to the Caribbean, North America, and northern Europe. The prevalence of the sickle cell gene is about 8% in African Americans and about 25% in adult Nigerians and in some areas in equatorial Africa, Saudi Arabia, and India.

Restriction enzyme techniques have identified several HbS haplotypes, mutations of the HbS molecule, that have probably arisen independently of each other. There are four major types in Africa—the Benin, Senegal, Cameroon, and Bantu (or Central African Republic)—and one Asian haplotype. Variations in these haplotypes determine disease severity; for example, the Senegalese haplotype is associated with a higher hemoglobin F (HbF) concentration and has a better prognosis than others. In a sample population of Nigerians, Benin haplotype was detected in 92.3%.[1] Gender influences disease severity; female HbSS patients with Benin haplotype have a higher HbF level than male patients.

Pathogenesis

Genetics

Sickle cell disease comprises a group of heterogeneous disorders that share the presence of the gene for HbS, either homozygous (i.e., sickle cell anemia, HbSS) or double heterozygous (i.e., combination of HbS with another abnormal hemoglobin).[2,3] Sickle cell anemia is the most common form. The most common double heterozygous disorders are the combinations of HbS with hemoglobin C (HbSC) and with β-thalassemia (HbS-thal). Patients with HbS-thal may produce reduced amounts of normal β chains (HbS–β^{+}-thal), but not always (HbS–β^{0}-thal). Those with a sickle cell trait or carrier state are heterozygous for HbS only.

Pathophysiology

The driving pathophysiologic factor is HbS polymerization. The mutated β-globin chains of the HbS molecule tend to crystallize to a polymer nucleus in the deoxygenated state. Polymerization disrupts the architecture and changes the shape of the red blood cell (RBC), increases its rigidity, and causes sickling (Fig. 51-1). Polymerization is dynamic and depends on three independent variables: degree of cellular hypoxia, intracellular hemoglobin concentration, and presence or absence of HbF (fetal hemoglobin).[4] The main determinant of disease severity is the rate and extent of HbS polymerization, which drives the two major pathophysiologic processes: vaso-occlusion with ischemia-reperfusion injury and hemolytic anemia (Fig. 51-2).[5]

Vaso-occlusion occurs in all patients, often triggered by inflammation and typically found in clinical states of infection, hypoxia, hypovolemia, hypothermia, acidosis, and hyperosmolality. Vaso-occlusion is probably caused by dynamic endothelial-leukocyte-erythrocyte adhesive interactions in the postcapillary venules and precapillary obstruction by rigid, deformed erythrocytes. Episodic microvascular occlusion and ischemia can be interrupted by restoration of blood flow and reperfusion, which further promote inflammatory stress and tissue injury.

Hemolysis has recently been shown to contribute to the development of progressive vasculopathy, characterized by endothelial dysfunction and proliferative changes in the intima and smooth muscle of blood vessels. The degree of hemolysis is associated with the development of pulmonary hypertension in sickle cell disease. An important role is ascribed to free hemoglobin, which inactivates nitric oxide and generates reactive oxygen species. Both these factors may further contribute to the hypercoagulability and vasculopathy.

Clinical Manifestations

The clinical manifestations of sickle cell disease are individualized and age dependent (Fig. 51-3). A chronic low-grade hemolytic anemia always occurs and predisposes to gallstones. The most prevalent clinical problem is periodic crises of bone pain. During the first years of life, bone pain presents as the hand-foot syndrome, and over the years it can result in avascular necrosis of the heads of the femur and humerus. Other disabling complications include cerebrovascular accident (stroke) resulting from occlusion of major cerebral

vessels, the acute chest syndrome, priapism, chronic leg ulceration, chronic pulmonary disease with pulmonary hypertension, and chronic kidney disease.[6,7]

Patients with sickle cell disease are prone to infections because of functional asplenia early in life as a result of splenic sequestration, recurrent splenic infarction, and consequent autosplenectomy. Common bacterial infections, especially with encapsulated organisms, can be fatal in these patients. Bacterial isolates during invasive bacterial infections show *Streptococcus pneumoniae* (38%), *Salmonella* spp. (33%), *Haemophilus influenzae* (14%), *Escherichia coli* (11%), and *Klebsiella* spp. (4%).[8] *S. pneumoniae* and *H. influenzae* occur predominantly before 5 years of age, *Salmonella* increases almost linearly with age, and *Klebsiella* and *E. coli* predominate in patients older than 10 years. Pneumococcal infections carry high morbidity and mortality rates in the early years of life, necessitating vaccination or prophylaxis.[2]

Fever is common in patients with sickle cell disease. Common complications accompanying fever are painful crisis and acute chest syndrome. Bacteremia is not always confirmed, and in some cases, the fever may be viral in origin or related to infections from atypical organisms. Nevertheless, early antibiotic treatment is recommended pending microbiologic information.

There are remarkable differences in clinical severity and outcome of disease. Sickle cell trait is a rather benign condition. Patients with HbSS tend to have more severe disease than those with HbSC. Likewise, patients with HbS–β^+-thal do better than those with HbS–β^0-thal. The Bantu haplotype is associated with the highest frequency of organ damage. However, the severity of disease may also differ among patients with an identical genotype. In part, these differences can be explained by the amount of HbF present because it protects against clinical severity. In addition, endothelial factors probably play an important role. Degree of adherence between sickle erythrocytes and endothelial cells has been shown to correlate with the clinical severity of disease. Also, an association has been found between circulating activated endothelial cells of microvascular origin and the onset of painful sickle cell crises.[9]

Natural History

Life expectancy is reduced in sickle cell disease, especially in patients with symptomatic disease. An increased risk for early death is associated with low levels of HbF, renal failure, the acute chest syndrome, and seizures.[7,10] Childhood survival to age 20 years has improved during the past decades. In the course of life, irreversible organ damage caused by arterial and capillary microcirculation obstructive vasculopathy gradually becomes more prevalent. The diagnosis of a clinically evident form of organ damage, such as leg ulcer, osteonecrosis, or retinopathy, predicts the development of a more lethal form of organ damage, such as chronic lung disease, renal failure, or stroke.[11] Overall, the primary causes of death in patients with sickle cell anemia are chronic lung disease in 20%, renal failure in 14%, and stroke in 10%. In younger patients, the primary cause of death is infection; in older patients, the primary cause of death is irreversible organ damage (Fig. 51-4).

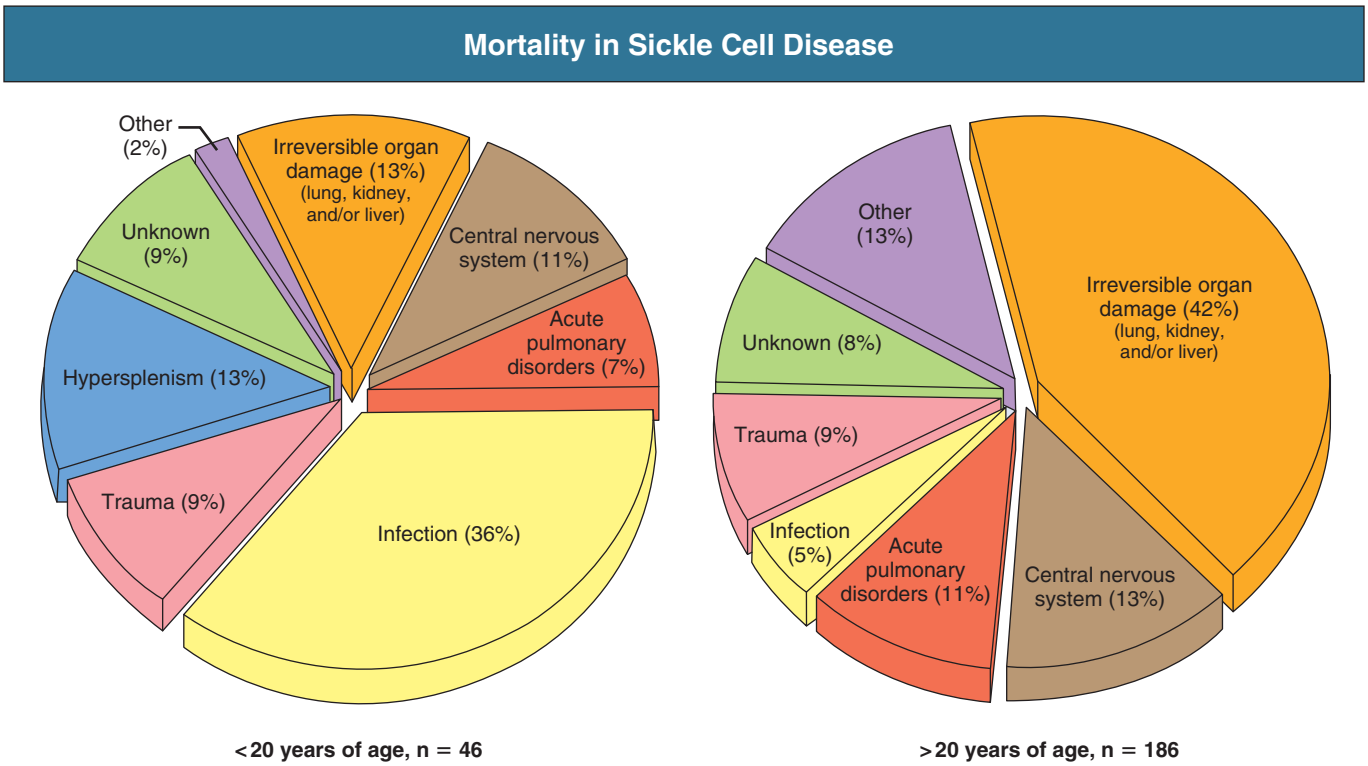

Figure 51-4 Mortality in sickle cell disease. Causes of death among 232 HbSS patients, comparing patients younger than 20 years (46 died) with patients older than 20 years (186 died). The infection category includes both bacterial and viral diseases. *(Modified from reference 11.)*

Treatment

Management of sickle cell disease is primarily directed at the relief of symptoms and prevention of complications, whereas newer treatments are being devised that target the pathophysiologic changes of the disease.[12] Daily oral penicillin for children 2 to 5 years of age is effective in reducing both the infection rate and the mortality related to pneumococcal infection.[13] Immunization against pneumococcus is recommended for children at 2 years of age, with booster doses at 5 years, although protection from current vaccines is imperfect. Immunization against influenza in children is also important.

Empiric broad-spectrum antibiotics effective against gram-positive and gram-negative organisms should be used in adults with fever pending microbiologic confirmation. A common antibiotic is amoxicillin.

Sickle cell crises are managed with oxygen therapy, rehydration with intravenous fluids, RBC transfusions, and analgesia. In severe cases, exchange RBC transfusions may be effective. Hydroxyurea treatment in patients with sickle cell anemia and recurrent vaso-occlusive events decreases the incidence of painful crises and acute chest syndrome and overall mortality. Butyrate compounds, deoxyazacytidine, and various combinations with erythropoietin are still being tried.[12,14] Hematopoietic stem cell transplantation is potentially curative in sickle cell patients, associated with 80% to 85% disease-free survival in several series.[15] Young and presymptomatic patients with high-risk features of severe disease benefit the most from hematopoietic stem cell transplantation.

PATHOGENESIS OF SICKLE CELL NEPHROPATHY

The hallmark of sickle cell nephropathy is the combination of impaired renal concentrating capacity and a normal diluting capacity.[16,17]

Concentrating Capacity

The defect in concentrating capacity results from loss of the countercurrent exchange mechanism in the inner renal medulla through loss of the vasa recta and long loops of Henle of the juxtamedullary nephrons (Fig. 51-5). The vasa recta of the juxtamedullary nephrons present an ideal setting for sickling. The renal medulla is relatively hypoxic and hyperosmotic, with increased blood viscosity in the medullary circulation and slow medullary blood flow. Studies in transgenic sickle cell mice have demonstrated distention and

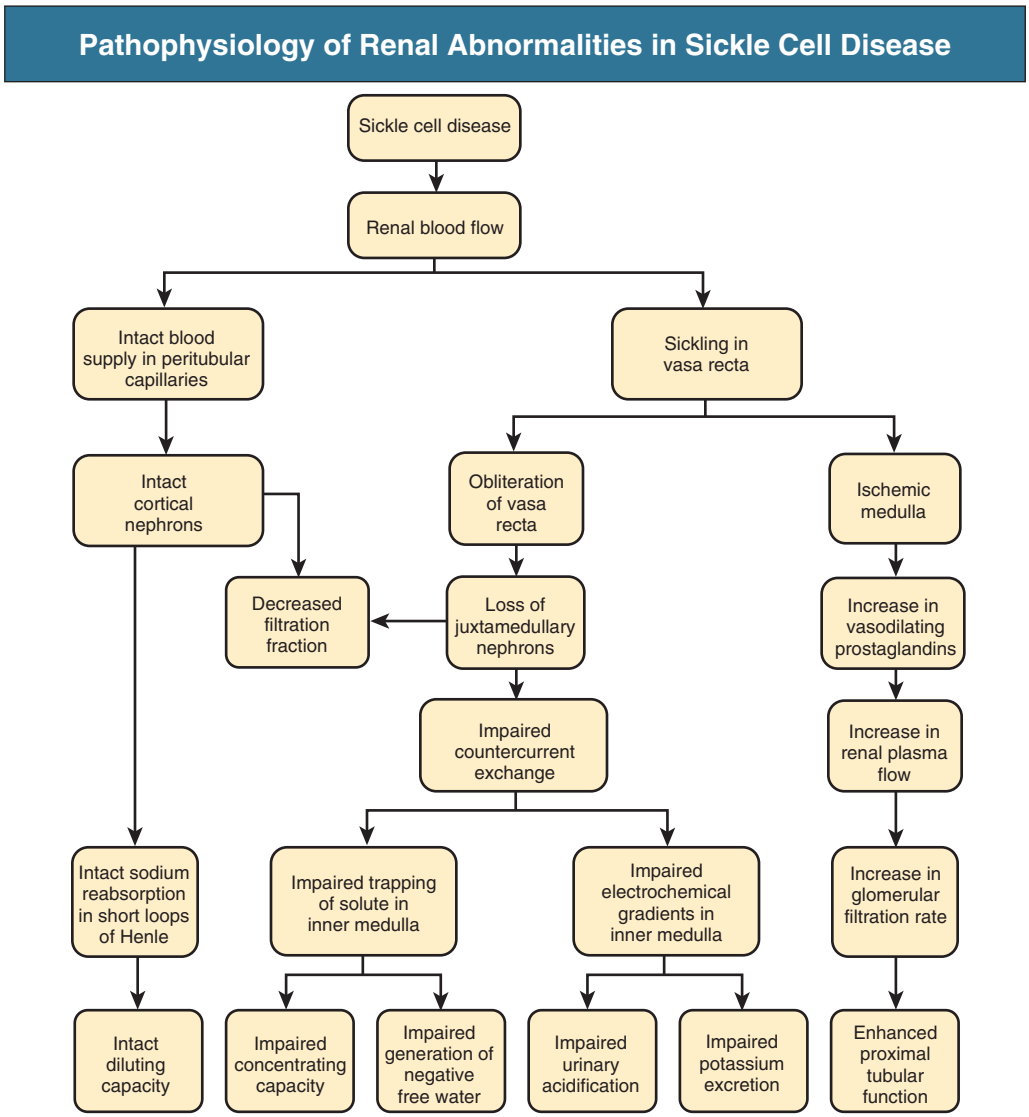

Figure 51-5 Pathophysiology of renal abnormalities in sickle cell disease.

Figure 51-6 Microradioangiography showing loss of vasa recta in sickle cell nephropathy. **A,** Kidney from control, with normal vasa recta. **B,** Patient with sickle cell anemia, with the absence of the vasa recta. *(From reference 18.)*

congestion of the vasa recta under hypoxic conditions. This environment facilitates the sickling of erythrocytes, formation of intravascular microthrombi, and obstruction of blood flow through the vasa recta. The loss of vasa recta has been confirmed by microradioangiographic studies[18] (Fig. 51-6).

Histologic examination of the medulla shows edema, focal scarring, and interstitial fibrosis resulting in tubular atrophy. Ischemic infarction in the vasa recta sometimes causes papillary necrosis. The concentration defect is found to be reversible in young children when sickling is prevented after multiple transfusions of normal blood, but it becomes irreversible thereafter. Adults with sickle cell anemia cannot concentrate the urine above 450 mOsm/kg H_2O. This relates to the interstitial osmolality at the transition of the outer and inner medulla, at the tips of the short loops of Henle of the cortical nephrons. Patients with sickle cell trait or hybrid sickling disorders show intermediate concentrating defects. Maximal osmolality varies from 400 to 900 mOsm/kg H_2O in sickle cell trait and from 400 to 700 mOsm/kg H_2O in HbSC and declines further with aging.

Diluting Capacity

The diluting capacity is normal as a result of the intact reabsorptive function of the superficial loops of Henle of the cortical nephrons. These are supplied by peritubular capillaries, which present a less ideal setting for sickling than the vasa recta. In contrast to the diluting capacity, the free water reabsorption, or capacity to generate negative free water balance, is impaired by defective trapping of solute in the inner medulla.

Urine volumes are typically higher than normal, a consequence of impaired concentrating ability. Response to a water deprivation test in sickle cell disease is usually positive with marked elevation of endogenous antidiuretic hormone, and response to desmopressin is poor. Because isosthenuria is typical, there is a susceptibility to normonatremic dehydration.

Other Tubular Abnormalities

Defects in urinary acidification and potassium excretion are other distal nephron function abnormalities.[17] These abnormalities may become overt only when there is an increased supply of acid and potassium, as during rhabdomyolysis. The exact causes are unknown, but these defects probably reflect failure to maintain the necessary energy-requiring hydrogen ion (H^+) and electrochemical gradients along the collecting ducts from the impaired medullary blood flow and hypoxia. The impaired potassium excretion is aldosterone independent.

In contrast to the functional abnormalities of the distal nephron, proximal tubular function is enhanced. Reabsorption of phosphate and β_2-microglobulin and secretion of uric acid and creatinine in the proximal tubule are increased. Therefore, creatinine clearance overestimates glomerular filtration rate (GFR) considerably. The cause of the enhanced proximal function is not clear, but it probably represents a secondary compensatory mechanism to correct for defects in medullary function.

Renal Hemodynamics

Renal hemodynamics show remarkable changes in the course of disease (Fig. 51-7). Young patients with sickle cell disease have increases in renal plasma flow (RPF) and renal blood flow and, to a lesser extent, in GFR. The increased RPF is ascribed to increased release of vasodilator prostaglandins as a result of medullary ischemia because prostaglandin inhibition significantly reduces RPF and GFR. It has been suggested that endothelial dysfunction from hemolysis can induce vasodilation in the cortex, including hyperfiltration and glomerular hypertrophy, in contrast to the prevailing vaso-occlusion in the medulla.[19]

The decrease in filtration fraction may be caused by selective damage of juxtamedullary nephrons, which have the highest filtration fractions.

Glomerular Injury

Glomerular hypertrophy is an early manifestation of sickle cell nephropathy. Histologic examination of the kidneys of young children shows glomerular enlargement and congestion, especially in the juxtamedullary glomeruli. Both afferent and efferent arterioles of these glomeruli may be dilated. Young adult patients with sickle cell

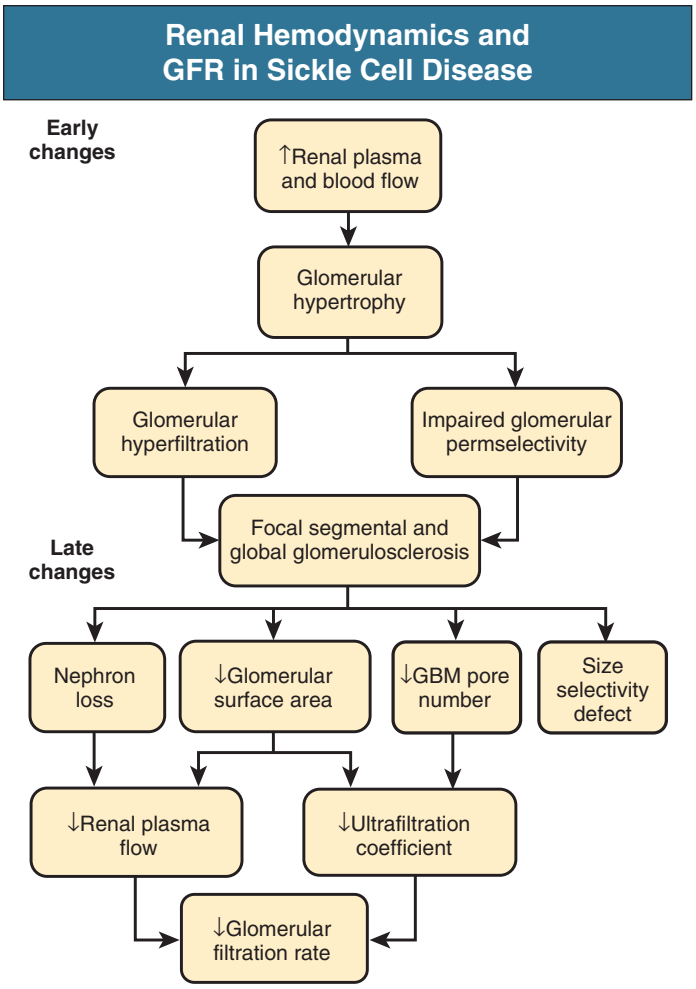

Figure 51-7 Renal hemodynamics and glomerular filtration in sickle cell nephropathy. *GBM,* Glomerular basement membrane; *GFR,* glomerular filtration rate.

anemia show a distinct pattern of glomerular dysfunction, with impaired glomerular permselectivity, increased ultrafiltration coefficient, glomerular hyperfiltration, and proteinuria.[20,21] Prolonged glomerular hyperfiltration may cause further glomerular injury. This is supported by the common histologic finding of focal segmental glomerulosclerosis (FSGS) in adult patients with sickle cell disease[22] (Fig. 51-8). Besides FSGS, other histopathologic variants are membranoproliferative glomerulonephritis, thrombotic microangiopathy, and specific sickle cell nephropathy.[23] Hypoxia did not seem to play a key role in the progression of glomerular lesions in histopathologic studies because immunohistochemistry did not reveal a specific induction of hypoxic markers at the time of renal biopsy.

In older patients, progressive ischemia and fibrosis with obliteration of glomeruli can be found. Glomerular studies show a decrease in glomerular basement membrane pore number and a size selectivity defect in patients with renal impairment.[24] Good correlation exists between tubular and glomerular dysfunction, with both contributing to nephropathy in patients with sickle cell disease.[25] Eventually, a combined decrease in ultrafiltration capacity and RPF can result in end-stage renal disease (ESRD).[20]

Hormones in Sickle Cell Nephropathy

There is relative erythropoietin (EPO) deficiency in sickle cell disease; that is, EPO levels do not increase to the expected level

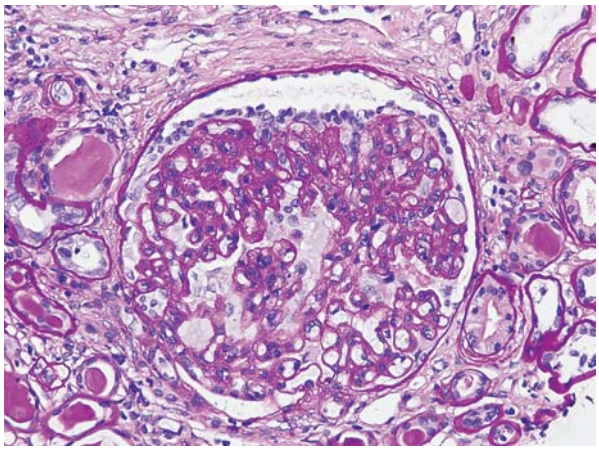

Figure 51-8 Focal segmental glomerulosclerosis in sickle cell nephropathy. There is segmental sclerosis in the upper half of the glomerulus. *(Courtesy Professor J. Weening.)*

for the degree of anemia, perhaps because of the right-shifted hemoglobin-oxygen dissociation curve. In addition, EPO levels fall with the decline in renal function, probably from renal damage caused by the sickling process.

Elevated serum renin and aldosterone levels have been reported in some studies, under standard and volume-depleted conditions, although in general normal values are found in sickle cell anemia.[16]

Hormone infusion studies have helped to localize sites of action in the kidney. Failure of low-dose infusion of atrial natriuretic peptide (ANP) to increase natriuresis in sickle cell anemia[26] suggests that ANP at this dosage exerts its natriuretic effect in the long Henle loops of the juxtamedullary nephrons, whereas insulin induces a similar sodium retention in patients with sickle cell anemia and normal individuals,[26] suggesting that its antinatriuretic effect is probably localized at a distal tubular site other than the long loops of Henle. Urinary endothelin-1 is elevated in asymptomatic sickle cell disease patients. It correlates with a urine-concentrating defect and microalbuminuria, which could be explained by a combination of functional resistance to vasopressin and fibrosis.[27]

CLINICAL MANIFESTATIONS OF SICKLE CELL NEPHROPATHY

The presentation of the clinical manifestations of sickle cell nephropathy shows an age-dependent pattern. In addition to age of the patient, duration of sickle cell disease and frequency of crises and hospitalizations are predictors of kidney disease.[28] Table 51-1 outlines the frequency and etiology of the renal abnormalities associated with sickle cell anemia, sickle cell trait, and the most common double heterozygous disorders (HbSC and HbS-thal).

Hematuria

Hematuria is a common clinical manifestation in sickle cell anemia and the hybrid sickling disorders and occurs in 3% to 4% of individuals with sickle cell trait at some time. Patients often have persistent microscopic hematuria with episodic gross hematuria. The hematuria may follow relatively minor trauma. Hematuria occurs more often in males and is usually unilateral, originating from the left kidney in 80% of patients. Urinary erythrocytes are typically isomorphic, but sickled erythrocytes are occasionally found in the urine.

Frequency and Etiology of Renal Abnormalities Associated with Sickle Cell Disease				
Type of Renal Disease	**Etiology**	**Sickle Cell Anemia**	**Sickle Cell Trait**	**HbSC and HbS-thal**
Impaired concentrating capacity	Loss of vasa recta of juxtamedullary nephrons	Irreversible defects in all adults	Intermediate defects in all adults' nephrons	Intermediate defects in all adults
Impaired urinary acidification	Incomplete form of distal renal tubular acidosis	Almost all, during acid loading	Rare	At least 30%, during acid loading
Impaired potassium excretion	Aldosterone independent	Almost all, during potassium loading	Rare	Unknown; probably at least 30%
Hematuria	Infarction, extravasation of blood in renal medulla	Common	3%-4%	Common
Proteinuria	Glomerular hyperfiltration plus impaired permselectivity	Up to 50%-60% with increasing age	Rare	20%-25%
Nephrotic syndrome	FSGS most common	About 4%	Rare	0%-4%
Chronic renal failure	See Fig. 51-7	4.2%-4.6%	Rare	About 2.4%
Renal medullary carcinoma	Possible genetic predisposition	Rare	Rare	Rare

Table 51-1 Frequency and etiology of renal abnormalities associated with sickle cell disease.

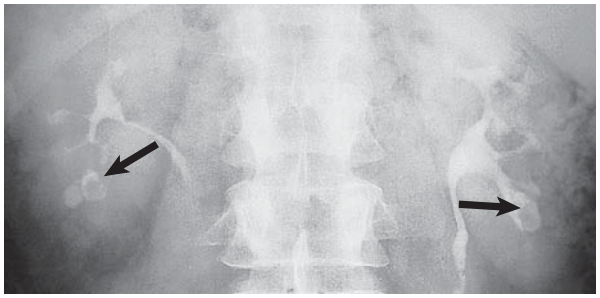

Figure 51-9 Papillary necrosis in sickle cell disease. Intravenous urography shows abnormal calyces with filling defects *(arrows)*.

Pathogenesis

Sickling The main mechanism of hematuria probably relates to sickling of erythrocytes in the vasa recta and microthrombotic infarction and extravasation of blood in the renal medulla. Histologic examination typically shows severe stasis in peritubular capillaries of the cortex and especially the medulla as well as extravasation of blood into the collecting system.

Papillary Necrosis Papillary necrosis is a frequent cause of hematuria in sickle cell anemia, hybrid sickling disorders, and sickle cell trait (Fig. 51-9). The incidence of papillary necrosis varies from 23% to 67% in studies of sickle cell disease.[17,29] This complication results from obliteration of the vasa recta, with medullary necrosis and fibrosis. Frequent analgesic use by these patients for their bone pain may also contribute to papillary necrosis. The most common presenting symptom is painless macroscopic hematuria. Other presentations are renal colic caused by the passage of blood clots or necrotic papillae, microhematuria, symptoms of urinary tract infection (UTI), and rarely acute kidney injury. Papillary necrosis may also be asymptomatic and is frequently an incidental finding during imaging.

Nutcracker Phenomenon The left-sided predominance of hematuria has been attributed to the so-called nutcracker phenomenon, with compression of the left renal vein between the aorta and the superior mesenteric artery increasing the pressure in the renal vein. This may especially contribute to the development of hematuria in sickle cell patients, because the increased renal vein pressure could worsen anoxia in the renal medulla, increasing the likelihood of sickling in the left kidney.

Clinical Manifestations

Painless macroscopic hematuria often presents after physical activity or minor renal trauma or is associated with hypoxic challenges (e.g., airplane flights). It usually is accompanied by a substantial decline in hematocrit. Bleeding typically remits spontaneously within a few days.

Diagnosis and Differential Diagnosis

Urinalysis can exclude the presence of myoglobinuria and rhabdomyolysis, which can mimic hematuria. Rhabdomyolysis can be provoked during strenuous exercise and dehydration and may also occur during severe sickle cell crises. The coexistence of hematuria with leukocyturia is not unusual and does not necessarily indicate UTI, even in combination with flank pain. Infection must be confirmed by examination of the urinary sediment and urine cultures.

Sickle cell trait has been reported in 50% of African Americans with ESRD caused by autosomal dominant polycystic kidney disease (ADPKD) but in only 7.5% of African American patients with other causes of ESRD. In addition, patients with ADPKD and sickle cell trait had an earlier onset of ESRD.[30] The prevalence of sickle cell disease in ADPKD has not been reported.

Renal medullary carcinoma has been recognized as a specific entity in sickle cell nephropathy.[17,31] It is an aggressive form of renal cell carcinoma that appears uniquely to affect patients with sickle cell hemoglobinopathies, particularly sickle cell trait or HbSC, especially in teenagers and young adults. Chronic medullary hypoxia is thought to contribute to its pathogenesis.[8] The tumors are resistant to chemotherapy and tend to be metastatic at diagnosis, with a reported postsurgical mean survival of only 15 weeks. It is not yet clear whether regular screening for renal medullary carcinoma in young patients with sickle cell disease or trait could result in an early diagnosis and a better survival.[31] Gross hematuria, flank pain, and weight loss are ominous signs of malignancy, particularly in young patients with sickle cell trait. The tumor is typically located deep in the parenchyma, unlike Wilms tumor or renal cell carcinoma. Immunohistochemical analysis for epithelial cell markers (e.g., CAM 5.5), epithelial membrane antigen, and cytokeratin may assist in diagnosis.

Von Willebrand disease has occasionally been described in patients with sickle cell trait and gross hematuria.

Further evaluation is indicated for patients with severe or prolonged hematuria who are resistant to conservative therapeutic measures. Ultrasound examination will be normal unless there is

papillary necrosis or a coincidental cause of hematuria, such as polycystic kidney disease, renal calculus, or tumor. Intravenous urography used to be the method of choice for diagnosis of papillary necrosis, but it does not distinguish reliably between papillary necrosis and other causes of filling defects in the pyelogram, including blood clots, neoplasm, calculus, and hemangioma. Ultrasound is therefore preferred, although it is suggested that contrast-enhanced computed tomography may better depict a full range of typical features.[32] The role of magnetic resonance imaging in this setting has not yet been sufficiently evaluated.

Cystoscopy is not routinely required but is indicated if the episode of hematuria is atypical, such as a first episode of macroscopic hematuria in a patient older than 40 years or an episode that persists for more than 2 weeks. Cystoscopy may also be required to lateralize the source of the bleeding if surgical intervention is considered (see later).

Renal angiography rarely identifies the bleeding source, but when identified, embolization can follow. However, the optimal approach in any institution depends on local experience with specific techniques.

Treatment

The therapeutic strategy for hematuria depends on the severity and duration of a specific bleeding episode. Bleeding will stop in most patients spontaneously or after bed rest, although it may occasionally last for weeks or months. About half of patients will have recurrent episodes.

Initial therapeutic measures include bed rest and interventions aimed at retardation of the sickling process in the anoxic renal medulla. A high urine flow rate should be induced by intravenous fluid administration and diuretics to further reduce medullary tonicity and the urine alkalinized by administration of sodium bicarbonate by mouth or by vein, with a target urine pH of 8. Blood transfusion with normal HbA is indicated if anemia becomes severe; this may also decrease the sickling process. If necessary, bladder irrigation is performed for removal of blood clots.

Hyperbaric oxygen therapy may be helpful but has not been formally evaluated. Irrigation of the pelvicalyceal system with silver nitrate has also been described. The antifibrinolytic agent ε-aminocaproic acid, although effective, may be associated with adverse renal outcomes and is not recommended.

Unilateral nephrectomy has occasionally been necessary in patients with persistent, life-threatening hematuria refractory to conservative approaches. Full evaluation for another cause of hematuria, including cystoscopy to exclude a bladder lesion and to establish which kidney is the source of bleeding, is required before proceeding with nephrectomy.

Urinary Tract Infection

Subjects with sickle cell disease have an increased susceptibility to bacterial infections; even low-grade bacteremia with a common organism may be fatal. In addition to the impaired immunity resulting from autosplenectomy, there is opsonic antibody deficiency, which predisposes to bacterial infections. The precise incidence of UTIs is not well defined. However, the incidence of asymptomatic bacteriuria during pregnancy and the puerperium appears to be twice as high in women with sickle cell disease or trait as in women without sickle cell disease and requires appropriate therapy (see Chapter 44).

Pyelonephritis and urosepsis, as with any infection, may precipitate a sickle cell crisis. The clinician should especially be aware of this possibility in young children, who often do not complain of urinary tract symptoms. Most common organisms isolated include *E. coli, Klebsiella* species, and other gram-negative *Enterobacteriaceae*. Invasive bacterial infections with *E. coli* occur especially in females after age 15 years, suggesting a greater chance of UTIs in relation to sexual activity.

Acute Kidney Injury

People with sickle cell disease sometimes present with features of acute kidney injury (AKI). Defined as a doubling of serum creatinine, AKI is reported in 10% of hospitalized patients with sickle cell anemia.[33] A potentially reversible renal dysfunction with significant reduction in GFR could occur during vaso-occlusive crises.[34]

Etiology

A pre-renal cause of AKI will be found in more than half of patients, especially volume depletion in the setting of sickle cell crisis. Patients with sickle cell disease are prone to AKI caused by volume depletion because of impaired urine-concentrating capacity; it is therefore typically nonoliguric. A less frequent pre-renal cause is congestive heart failure.

Typical intrinsic renal causes of AKI are rhabdomyolysis, sepsis, and drug nephrotoxicity. Less common are renal vein thrombosis and hepatorenal syndrome (caused by hemosiderosis-induced hepatic failure). Both exertional and nontraumatic rhabdomyolysis have been reported in patients with sickle cell disease; the latter especially occurs during a sickle cell crisis and has been ascribed to intravascular sickling and muscle ischemia. Rhabdomyolysis is a common finding in patients who develop multiorgan failure during severe sickle cell crises, in addition to the acute chest syndrome, which further contributes to AKI. The most common post-renal cause of AKI is urinary tract obstruction by necrotic papillae or blood clots.

Treatment

Treatment and recovery of renal function depend on the specific underlying pathologic process. Metabolic acidosis may be prominent and should be actively corrected with sodium bicarbonate. Patients with volume depletion have a favorable outcome after fluid replacement.[33] Renal function may recover in patients with sepsis and rhabdomyolysis, although temporary renal replacement therapy (RRT) may be necessary. AKI as a part of multiorgan failure during a severe sickle cell crisis may show a dramatic improvement with aggressive RBC transfusion therapy, although some renal function loss may persist.

Proteinuria and Nephrotic Syndrome

Microalbuminuria has been reported in 19% to 26% of children with sickle cell anemia.[35,36] The presence of microalbuminuria is directly related to age and inversely related to hemoglobin levels.[36] Proteinuria has been reported in 17% to 33% of patients with sickle cell disease by semiquantitative or dipstick measurement.[7,28] The prevalence of proteinuria is lower in patients with coinheritance of sickle cell anemia and α-thalassemia than in those with sickle cell anemia and intact α-globin genes (13% vs. 40%).[37] The "renoprotective" effect of α-globin gene microdeletions could be related to a lower mean corpuscular volume or lower erythrocyte hemoglobin concentration in sickle erythrocytes. The frequency of proteinuria increases with age (56% in patients 40 years or older), and its presence is associated with renal impairment.

The nephrotic syndrome has been estimated to occur in 4% of patients with sickle cell anemia. The eventual development of renal failure appears virtually inevitable once the patient has nephrotic syndrome.

Pathology

The most common pathologic lesion is FSGS,[22,23] which is also the major lesion in patients who develop renal failure (see Fig. 51-8). Another specific pathologic lesion is a form of membranoproliferative glomerulonephritis (MPGN) with mesangial expansion and basement membrane duplication.[3] The absence of immune complexes and electron-dense deposits discriminates this entity from idiopathic MPGN type I. It has been proposed that this form of MPGN is caused by intracapillary red cell fragmentation. Fragments of erythrocytes become lodged in isolated capillary loops and are continuously phagocytosed by mesangial cells. As a result, the mesangium expands and lays down new basement membrane material.

Patients may become hepatitis C positive from multiple blood transfusions, which may also be associated with MPGN, although it is rare with appropriate screening procedures before transfusion. In our series, hepatitis C positivity was observed in only one patient (0.26%), a reflection of the generally low seroprevalence rate in the environment.[28] On occasion, other causes have been reported, such as poststreptococcal glomerulonephritis, minimal change disease, and immune complex–mediated glomerulonephritis. Glomerulonephritis has also been described in association with aplastic crises in parvovirus infection. Renal vein thrombosis should be considered when nephrotic syndrome develops in sickle cell disease, but its incidence is not exactly known.

Treatment

Theoretically, dietary protein restriction may reduce hyperfiltration and retard the development of renal failure in those with FSGS, but this has not been evaluated specifically in sickle cell disease.

Short-term treatment with angiotensin-converting enzyme (ACE) inhibitors significantly reduces the degree of proteinuria without affecting blood pressure (BP) or renal hemodynamics. More prolonged ACE inhibition reduces proteinuria with a slight decrease in BP. Short-term angiotensin receptor blocker (ARB) use has led to regression of microalbuminuria, overt proteinuria, and improvement in GFR in sickle cell patients with nephropathy.[38] However, it remains to be established whether long-term treatment with ACE inhibitors or ARBs delays the development of progressive renal failure. Combinations of ACE inhibitor and hydroxyurea have been found to be useful in retarding progression of microalbuminuria to overt proteinuria.[35,39]

Prevention of hyperfiltration theoretically also can be obtained with nonsteroidal anti-inflammatory drugs (NSAIDs), but these drugs reduce RPF and GFR in sickle cell anemia and are thus contraindicated.

Sodium and Acid-Base Disturbances

Distal Tubular Function

Impaired potassium excretion and impaired urinary acidification are caused by an incomplete form of distal tubular acidosis. However, hyperkalemia and metabolic acidosis are not present under normal circumstances and may become manifested only during potassium or acid loading, with mild renal impairment or volume depletion, and during rhabdomyolysis.[16,17] Hyperkalemia may also develop more readily during treatment with NSAIDs, ACE inhibitors, β-blockers, potassium-sparing diuretics, or heparin.

Urine pH does not fall below 5 during acid loading tests unless maximal acidifying stimuli are used. The titratable acid and H^+ excretion is reduced, whereas the ammonium excretion is either normal or decreased. Metabolic acidosis that develops during renal impairment or intercurrent diseases in sickle cell disease requires active treatment with sodium bicarbonate because acidosis stimulates the sickling process. Plasma bicarbonate should be monitored routinely and oral sodium bicarbonate supplements given to keep it within the reference range.

Proximal Tubular Function

Proximal tubular function abnormalities modify solute handling, producing increased reabsorption of phosphate and increased secretion of uric acid. Hyperphosphatemia may develop easily when renal function declines, necessitating dietary phosphate restriction and the use of phosphate binders early in renal impairment. The increased uric acid secretion protects patients with sickle cell disease against hyperuricemia, with elevated uric acid production resulting from hemolysis. However, the incidence of hyperuricemia and risk for gout increase with age as renal function declines.

Hypertension

Epidemiology

The prevalence of hypertension in patients with sickle cell anemia is about 2% to 6%, which is significantly lower than in age- and gender-matched controls.[16,28,40] However, BP in patients with sickle cell anemia is higher than in matched patients with β-thalassemia and similar degrees of anemia. Hypertension in sickle cell anemia especially occurs in the presence of advanced renal failure.

Pathogenesis

It is not yet clear whether the relative hypotension in sickle cell patients compared with controls relates to the pathologic renal medullary condition in sickle cell disease or to other mechanisms. The kidney in sickle cell disease has a normal overall capacity for sodium conservation, despite a tendency to lose sodium and water through the medullary defect.[16,40] This sodium conservation in sickle cell disease may follow stimulation of the renin-angiotensin system, which has been described in some but not all studies. The relative hypotension may be related to general vasodilation, because skeletal vascular resistance is reduced in sickle cell patients. Increased production of vasodilatory prostaglandins or nitric oxide may be involved. Systemic vasodilation and increased flow is a compensatory mechanism for microcirculatory flow disturbances and intermittent microvascular occlusion.[41] In addition, reduced vascular reactivity has been demonstrated in sickle cell patients and may protect against BP elevation.[40]

Treatment

The antihypertensive treatment of choice is an ACE inhibitor or ARB because of the potential beneficial effects on the progression of proteinuria and renal failure and because of the reported increments in plasma renin activity. However, the risk for hyperkalemia is increased. There are no specific recommendations on target BP in sickle cell disease, and the targets for other nondiabetic nephropathies are appropriate.

An alternative therapeutic option is a calcium channel blocker, but CCBs recognized to worsen proteinuria, such as the short-acting dihydropyridines, should be avoided. Loop diuretics are less effective in patients with sickle cell disease because of the specific medullary defect.

Chronic Kidney Disease

Epidemiology

In a prospective, 25-year longitudinal study, chronic kidney disease (CKD) developed in 4.2% of 725 patients with sickle cell anemia and in 2.4% of 209 patients with HbSC.[42] The patients with sickle cell

anemia were much younger at the diagnosis of renal failure than those with HbSC (median age, 23.1 and 49.9 years, respectively). However, in another study of 368 patients with sickle cell anemia with an overall prevalence of CKD of 4.6%, the prevalence of CKD clearly increased with age.[43] The prevalence of CKD will probably increase even more in the future with further improved medical care and longer life expectancy. In our series, younger age at diagnosis and higher duration of sickle cell disease were found to strongly predict the development of nephropathy.[28]

Predictors of CKD are hypertension, proteinuria, hematuria, increasingly severe anemia, the nephrotic syndrome, and inheritance of the Bantu or Central African Republic β-globin gene cluster haplotype.[42] In addition to an apparent genetic predisposition, glomerular capillary hypertension and prolonged glomerular hyperfiltration seem to be important in the development of renal failure.

Natural History

Patients with sickle cell anemia and CKD have increased mortality compared with patients without renal failure (Fig. 51-10). Patients with renal failure are also prone to other manifestations of sickle-induced vasculopathy, such as cerebrovascular diseases, chronic restrictive lung disease, and leg ulcers, leading to frequent hospitalizations.[42] Adults with sickle cell disease and ESRD have an increased mortality risk (hazard ratio 2.80; 95% confidence interval 2.31 to 3.38) compared to those without sickle cell disease but with ESRD.[44] Patients with sickle cell disease and ESRD receiving predialysis care had lower mortality than those with sickle cell disease and ESRD who did not receive predialysis care (hazard ratio 0.67; 95% CI 0.45 to 0.99).

As nephropathy progresses in sickle cell disease, strategies aimed at retarding progression and preparations for eventual RRT should be initiated. Table 51-2 summarizes the changing profile of renal

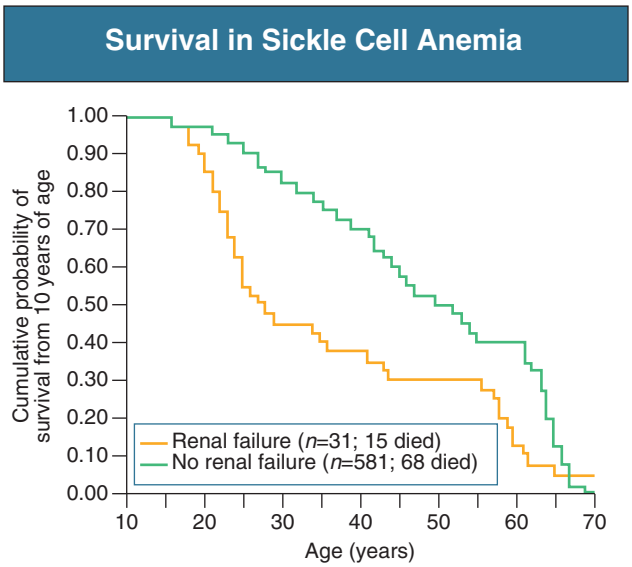

Figure 51-10 Survival in sickle cell anemia in the presence and absence of renal failure. *(Modified from reference 43.)*

Changing Profile of Renal Dysfunction in Sickle Cell Disease with Age and Available Treatment Options

Average Age (yr)	Clinical Observations	Process	Modifiers*	Treatment Options
1	Anemia, pain	Sickling	HbF level (+)	Hypertransfusion, hydroxyurea, zinc supplements
			Level of aberrant β-globin (±)	β-globin gene therapy
			Increased HbA level (+)	Bone marrow transplantation
5-10	Hematuria	Medullary congestion	Increased WBC adhesion, resultant RBC adhesion (–)	Hydration
			High blood oxygen level (+)	
	Increased GFR, decreased serum creatinine	Hyperperfusion	High prostaglandin E production (+)	ACE inhibitor Avoid NSAIDs
		Hypertrophy	Hypoxia (–)	Somatostatin analogue
		Papillary necrosis	High NO synthesis (+)	Hydration
			High caspase-3 level (+)	
			High HSP-70 level (+)	
			Increased COX-2 production (+)	
			High CRP level (–)	
			High HO-1 level (+)	
		Hyperfiltration	Increased angiotensin II production (+)	ACE inhibitor or ARB
			High prostacyclin level (+)	Prostacyclin analogue
15	Microalbuminuria	Hyperperfusion	High prostaglandin E production (+)	ACE inhibitor
20	High urinary NAG and β_2-microglobulin	Tubular damage	Unknown	No specific treatment
30	Proteinuria	Glomerular hypertension, FSGS	Increased angiotensin II production (+)	ACE inhibitor or ARB
35	Low GFR	Loss of glomerular function	Unknown	Strategies to retard CKD progression
40	Falling GFR	Further loss of glomerular function	Unknown	Strategies to retard CKD progression, preparation for RRT

Table 51-2 Changing profile of renal dysfunction in sickle cell disease with age and available treatment options. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *CKD,* chronic kidney disease; *COX-2,* cyclooxygenase-2; *CRP,* C-reactive protein; *FSGS,* focal segmental glomerulosclerosis; *GFR,* glomerular filtration rate; *HbA,* hemoglobin A; *HbF,* fetal hemoglobin; *HO-1,* heme oxygenase 1; *HSP-70,* heat shock protein 70; *NAG, N*-acetylglucosamine; *NO,* nitric oxide; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *RBC,* red blood cell; *RRT,* renal replacement therapy; *WBC,* white blood cell. *(+), Ameliorating factor; (–), risk factor. *(Modified from reference 17.)*

dysfunction in sickle cell disease with age and available treatment options.[17]

Treatment

For the development of progressive renal failure to be delayed, it is important to control hypertension and to avoid the use of nephrotoxic drugs, especially NSAIDs. Although plausible, it remains to be established whether the reduction of the degree of proteinuria with ACE inhibitors or a low-protein diet retards the progression of renal failure.

The response to EPO therapy is poor, even when high doses are used during long treatment periods. EPO treatment predominantly results in the release of HbS-containing reticulocytes, with only a modest increase in the more stable HbF. A marked increase in hemoglobin levels, although unexpected, may precipitate sickle cell crisis. Routine use of EPO is therefore not recommended, but it can be tried on an individual basis with higher doses than needed in other forms of ESRD. As an alternative, supportive RBC transfusion may be necessary. Excessive iron accumulation should be prevented in patients undergoing regular transfusions, who are at risk for hemochromatosis, although organ dysfunction caused by tissue iron overload seems less predictable in sickle cell disease than in thalassemia major. Metabolic acidosis is also prominent and requires correction with sodium bicarbonate supplements.

In patients with sickle cell disease, ESRD has been treated successfully with hemodialysis, peritoneal dialysis, and transplantation. Hemodialysis has been used more frequently than peritoneal dialysis. Sickle cell crises are not common despite the potential for hypotension, hypoxemia, and cytokine release during hemodialysis. The 30-month survival of 77 patients predominantly treated with hemodialysis was 59%, comparable to survival in other patient groups with multisystem disorders receiving dialysis.

TRANSPLANTATION

Transplantation is an appropriate form of RRT in sickle cell nephropathy. Patient survival in sickle cell disease after kidney transplantation has recently improved. Survival at 6 years was lower among sickle cell disease patients in the early era (1988-1999) compared with other diagnoses (56% vs. 78%; $P < .001$).[45] In the more recent era (2000-2011), patient survival at 6 years in sickle cell disease improved (70%) and was no longer significantly lower than for other diagnoses (80%; $P = .07$).[45] Patient survival among sickle cell recipients in the recent era is comparable to survival in matched diabetic kidney transplant recipients.[45]

In sickle cell disease patients, perioperative risks such as severe crisis and massive sickling can be reduced by preoperative transfusions of normal blood, thereby reducing the proportion of HbS. After transplantation, hematocrit increases and may even be higher than in patients with sickle cell disease and normal renal function. Sickle cell crisis may occur after transplantation, but it is not yet clear whether the increase in hematocrit enhances the risk for a crisis. Standard immunosuppressive therapy does not increase the risk for sickle cell crisis. However, caution is warranted with the use of antilymphocyte antibodies because the onset of a crisis has been related to this therapy in a few patients, perhaps because of increased cytokine release. The recurrence of hyposthenuria and sickle cell nephropathy after transplantation has occasionally been described.

Hematopoietic cell transplantation is the only curative treatment for sickle cell disease. However, this therapy has been used only on a very limited scale thus far, when patients have serious complications of sickle cell disease, such as cerebrovascular disease in children who are dependent on transfusions.[5]

CHAPTER 52

Congenital Anomalies of the Kidney and Urinary Tract

John O. Connolly and Guy H. Neild

Congenital anomalies of the kidney and urinary tract can result in renal problems and renal failure. Almost half of children who develop end-stage renal disease (ESRD) have asymmetric, irregularly shaped kidneys.[1,2] This appearance, often referred to as "bilateral renal scarring," is frequently associated with lower urinary tract anomalies that include vesicoureteral reflux (VUR). The most serious conditions involve bladder outflow obstruction, and many anomalies are now detected antenatally.

These cases were previously described as *reflux nephropathy* or *chronic pyelonephritis.* With advances in genetics and developmental biology, however, it is becoming clear that many anomalies are caused by primary renal malformations, or *renal dysplasia,* often associated with congenital malformations of the ureter, bladder, and urethra. This is a change from the view that renal scarring and damage are secondary to the outflow problem and ureteral reflux. Although still somewhat debatable, the British Association for Pediatric Nephrology has stated that the clinical distinction between reflux nephropathy and renal dysplasia is arbitrary and unnecessary.[1]

CLINICAL PRINCIPLES

Congenital renal tract abnormalities may present in one of five settings:

1. *Antenatal diagnosis by fetal ultrasound screening*
2. *Failure to thrive in an infant or young child*
3. *Investigation of urinary tract infection (UTI)*
4. *An incidental finding in a child or adult*
5. *An adult with abnormal urinalysis, stones, hypertension, or renal impairment*

The identification of these problems always poses the following questions:

- What is the cause?
- What is the natural history?
- Is surgical intervention required?

Such patients fall into two broad groups. The first group of patients appear to have normal bladders without outflow obstruction and normal-caliber ureters when not micturating, described as having either primary VUR or primary renal dysplasia. The second group has some form of bladder outflow dysfunction that causes secondary VUR and dilated upper urinary tracts, the most common cause of which is posterior urethral valves in males.

As predicted by the Brenner hypothesis,[3] small asymmetric kidneys with reduced glomerular filtration rate (GFR) develop all the features of glomerular hyperfiltration, with the onset of progressive renal failure signaled by increasing proteinuria. This can now be significantly modified by treatment with renin-angiotensin blockade.[4,5] The details of antenatal and pediatric management of these patients are beyond the scope of this chapter, which focuses on management in adolescence and adult life.

DEVELOPMENT OF THE URINARY TRACT

The urinary tract develops from the cloaca and intermediate mesoderm in parallel with the early differentiation of the metanephric blastema (future kidney)[6-8] (Fig. 52-1). At the fifth week of gestation, the mesonephric (wolffian) duct connects to the allantois and the cloaca. By the sixth week, the urorectal fold appears and divides this cavity, which separates the future urinary system (urogenital sinus) from the rectum (hind gut). Growth of the anterior abdominal wall between the allantois and the urogenital membrane is accompanied by an increase in size and capacity of this bladder precursor. The allantois remains attached to the apex of the fetal bladder and extends into the umbilical root, although it loses its patency and persists as the urachal remnant, the median umbilical ligament, which connects the bladder to the umbilicus. By the seventh week, there is a separate opening of the mesonephric duct into the bladder at what will become the vesicoureteral opening and the area known as the *trigone.* The distal part of the primitive urogenital sinus will form the definitive urogenital sinus. In females, this gives rise to the entire urethra and the vestibule of the vagina. In males, it gives rise to the posterior urethra, whereas the anterior urethra is formed from the closure of the urethral folds.

In the 6-week embryo, the mesonephric and paramesonephric (müllerian) ducts run in parallel. By 7 weeks, in the male, the müllerian duct starts to regress, and the wolffian duct will eventually develop into the epididymis and the caudal part of the vas deferens. In the female, the müllerian ducts fuse to become the uterovaginal cord, which opens into the urogenital sinus and will develop into the vagina.

As the urogenital tract develops, there is simultaneous development of the fetal kidney (Fig. 52-1). The ureteric bud arises from the distal end of the wolffian duct as an unbranched diverticulum (day 28) and invades the adjacent metanephric mesenchyme, initiating the branching collecting duct system within the primitive kidney. In the absence of the ureteral bud, the metanephric kidney does not form. Fetal urine reaches the bladder by 8 to 10 weeks and makes a significant contribution to the amniotic fluid by 16 weeks. Nephron formation is complete by 34 weeks' gestation.

Renal development is orchestrated by the expression of transcription factors, growth and survival factors, and adhesion molecules.[6,8,9] Mutations of genes encoding all classes of these molecules cause

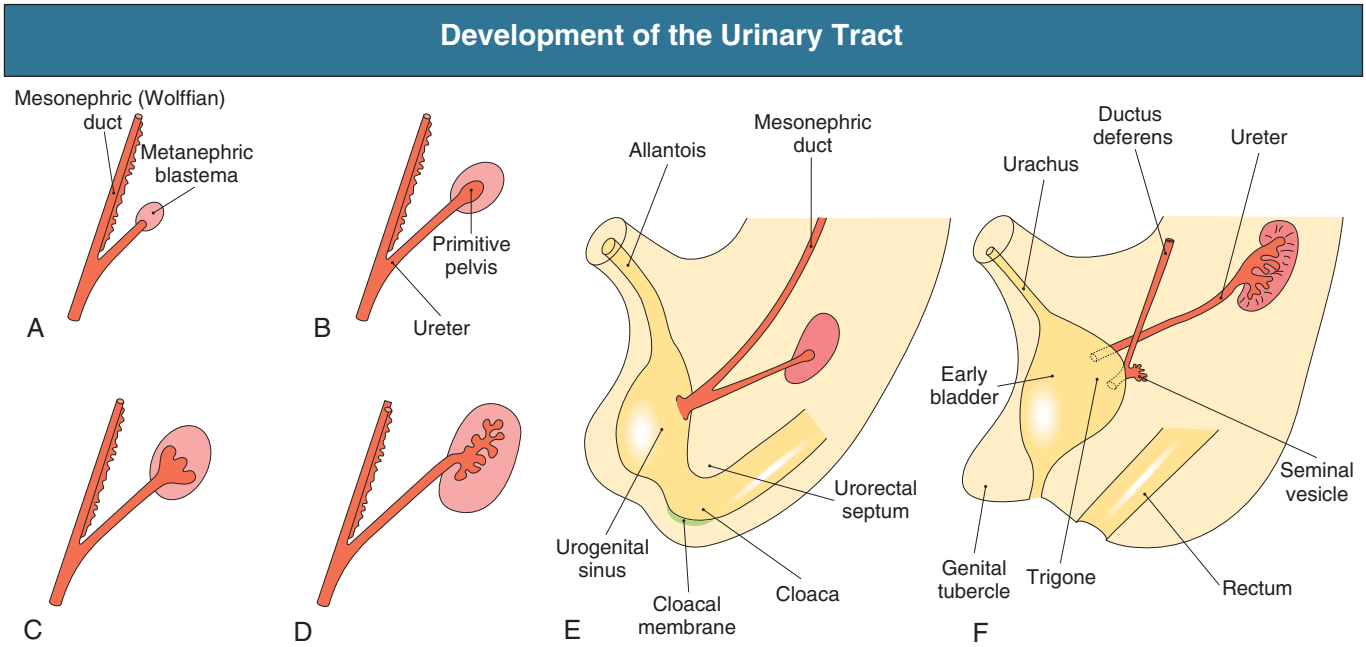

Figure 52-1 Development of the urinary tract. Growth and development of the ureter, pelvis, and calyces are shown in parts **A** to **D. A,** The metanephric kidneys first become detectable as small areas in the mesoderm close to the aorta. The primitive epithelial ureter buds off from the mesonephric duct and makes contact with the metanephric mesenchyme. **B,** Under the influence of signals from the ureter, the mesenchyme condenses and proliferates around the ureteral tip, with simultaneous elongation and branching of the ureteral tip. **C** and **D,** A primitive pelvis appears, then branches to form the divisions of the calyces. The branching process continues, with the epithelial system eventually differentiating into the nephrons of the renal parenchyma. As the fetus grows, the kidney ascends because of the continuous rostral growth. **E,** Growth and development of the cloaca during weeks 5 to 6 of gestation. **F,** Growth and development of the urogenital sinus into bladder and outflow tract during weeks 8 to 9.

urinary tract malformations in mice.[8-10] One family of transcription factor proteins contains the paired DNA-binding domain and is encoded by the *PAX* genes. Studies in mice show that these *PAX* genes regulate the development of brain, eyes, lymphoid system, musculature, neural crest, and vertebrae.[11,12] *PAX2* is expressed in the metanephros and in cell lineages that are forming nephrons and also in those that are destined to differentiate into the ureter, renal pelvis, and branching collecting duct system. The ablation of a single *PAX2* allele in knockout mice causes impaired metanephric growth and fewer nephrons than normal as well as megaureter, a finding consistent with gross VUR.[12] *WT1,* which is mutated in a proportion of Wilms tumors, is another transcription factor whose mutation is associated with abnormal urinary tract development.

Normal development appears to depend on urine flow from the fetal kidney. This requires peristalsis and no anatomic obstruction to flow. A number of diverse defects can now be unified as it becomes clear they play some key role in peristalsis. This may be caused by defects in smooth muscle development or innervations in the ureter. For example, mice lacking the transcription factor "teashirt 3" fail to develop normal smooth muscle in the ureter and have congenital hydronephrosis without anatomic obstruction.[13] Angiotensin plays a key role in initiating the peristalsis, and mice in whom the angiotensin type 1 receptor is knocked out fail to develop a renal pelvis and die of renal failure.[9]

Angiotensin type 2 receptor gene null mutant mice display congenital anomalies of the kidney and urinary tract. These include unilateral agenesis, unilateral megaureter and hydronephrosis, and pelviureteral junction (PUJ) obstruction and mimic a range of abnormalities found in humans.[9] Administration of angiotensin-converting enzyme (ACE) inhibitors throughout pregnancy in humans can cause hypotension and anuria in the baby with histologic features of renal tubular dysplasia. This phenotype is also caused by mutations in genes encoding renin, angiotensinogen, ACE, and angiotensin II receptor type 1. Little is yet known about the genetics of congenital bladder outlet obstruction.[13]

Other syndromes associated with dysplasia and agenesis in which the mutation is now known include branchio-oto-renal syndrome (*EYA1* mutation, transcription factor–like protein), Fraser syndrome (*FRAS1* mutation, putative cell adhesion molecule), Kallmann syndrome (X-linked form, *KAL1* mutation, cell adhesion molecule; autosomal form, *FGFR1* mutation, growth factor receptor), and renal cysts and diabetes syndrome (*HNF1* mutation, transcription factor).[14]

RENAL MALFORMATIONS

Congenitally abnormal kidneys may be large or small, cystic or irregular in outline, and absent or misplaced. These conditions were traditionally discussed on the basis of findings on intravenous urography (IVU), but the findings on computed tomography (CT) and magnetic resonance imaging (MRI) are now increasingly being emphasized.

Large Kidneys

Enlarged kidneys resulting from congenital problems are usually hydronephrotic or cystic. Wilms' tumor must also be considered. The differential diagnosis in adults of enlarged kidneys, both congenital and acquired, is shown in Chapter 5 (see Fig. 5-1), and the differential diagnosis of cystic kidney disease is discussed further in Chapters 46 and 47.

Definitions of Renal Dysplasia and Malformation	
Term	**Characteristics**
Renal agenesis	Absence of the kidney or an identifiable metanephric structure
Renal aplasia	Severe dysplasia with extremely small kidney, sometimes identifiable only by histologic examination
Renal dysplasia	Abnormal differentiation of renal parenchyma with development of abnormal structures, including primitive ducts surrounded by collars of connective tissue, metaplastic cartilage, variety of nonspecific malformations such as preglomeruli of fetal type, and reduced branching of collecting ducts with cystic dilations and primitive tubules
Renal hypoplasia	Significantly reduced renal mass and nephron number without evidence of maldevelopment of parenchyma
Renal multicystic dysplasia	Severe cystic dysplasia with extremely enlarged kidney full of cystic structures; occurs as an isolated renal lesion in response to ureteral atresia and urethral obstruction; 10% of patients have a family history.

Table 52-1 **Definitions of renal dysplasia and malformation.**

Irregular Kidneys

Irregularity of the renal outline may result from fetal lobulation or a "dromedary hump," neither of which has any functional implications. Much more important is the diagnosis of renal dysplasia.

Renal Dysplasia

Table 52-1 presents the range of dysplastic and other malformations of the kidney. Clearly, abnormalities of the ureter, bladder, and urethra are often associated with renal dysplasia.[15,16] All types of renal dysplasia can also occur as isolated developmental anomalies. Renal dysplasia, although typically producing small, irregular kidneys, may be cystic or multicystic renal dysplasia.

Renal Hypoplasia (Oligomeganephronia)

Renal hypoplasia is defined as a congenitally small kidney (two standard deviations below the expected mean) that lacks evidence of either parenchymal maldifferentiation (renal dysplasia) or acquired disease sufficient to explain the reduced size. The term is often used loosely, however, and most patients with a small kidney and other malformations will have *oligomeganephronia.* This is a type of renal hypoplasia resulting from a congenital reduction in the number of nephrons. It results from arrested development of the metanephric blastema at 14 to 20 weeks of gestation with subsequent hypertrophy of glomeruli and tubules in the kidney. The hypertrophy and hyperfiltration result in progressive nephron injury and sclerosis later in life. Oligomeganephronia is recognized on renal biopsy by the large size of the glomeruli and tubules and the small number of glomeruli seen in a good core of renal cortex. It is reported in congenital syndromes caused by mutations in *PAX2* and hepatocyte nuclear factor 1β *(HNF1β).*

Differential Diagnosis of Scarred Kidneys

Dysplasia Versus Reflux Progressive scarring and renal failure were once considered to be caused by chronic parenchymal infection (so-called chronic pyelonephritis) and were regarded as a consequence of VUR. The 1980s, however, saw a retreat from the paradigm of the primary role of infection, and emphasis was placed on scarring as a result of reflux and the progressive nature of the glomerular lesion associated with glomerular hypertension (or hyperfiltration), so-called reflux nephropathy.[3,17,18] The emphasis is changing again to the concept that scarring is often a consequence of renal dysplasia, and that the reflux is a secondary or incidental feature (Fig. 52-2). Thus, irregular kidneys with normal-caliber ureters are more likely to be caused by primary dysplasia, and no evidence of VUR may be seen.

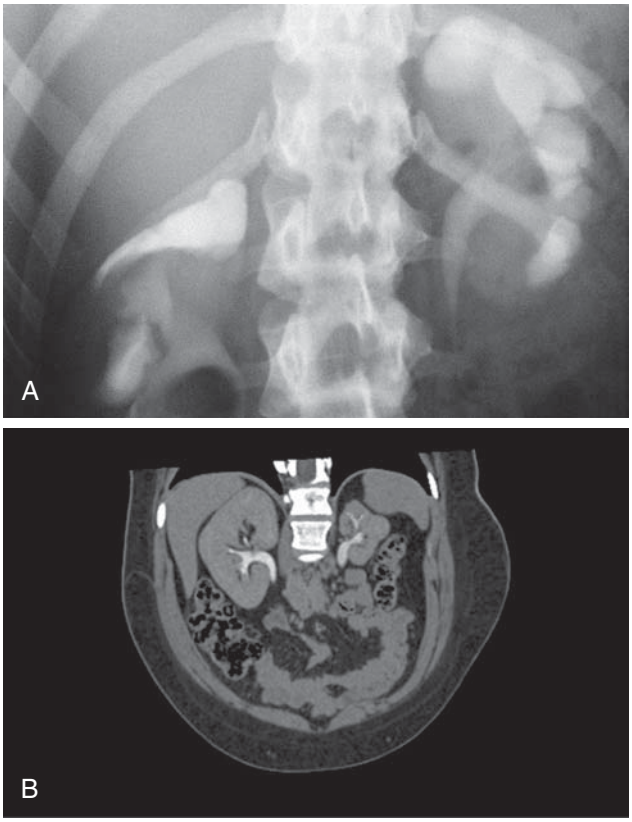

Figure 52-2 **Renal dysplasia. A,** Intravenous urogram (IVU) shows gross bilateral scarring in a 20-year-old woman who has been assessed since age 2 years. Progressive scarring has been observed in the absence of urinary tract infections and obstruction. This probably represents primary renal dysplasia. **B,** Computed tomography (CT) IVU shows gross scarring of right kidney. *(Courtesy Dr. A. Kirkham, University College Hospitals, London.)*

Renal Scarring in Adults A practical clinical problem is the differential diagnosis of scarred, asymmetric kidneys. With older patients, the differential diagnosis of scarred or "lumpy bumpy" kidneys widens. Often attributed to analgesic nephropathy in the 1970s, this appearance now is often designated "reflux nephropathy." In older patients, multiple scarring from atheromatous arterial disease and embolization of the kidney is an increasingly important cause of renal failure. The diagnosis has historically been made by the radiologic features on IVU, but in practice, patients often have advanced renal impairment and are unable to excrete enough radiocontrast to delineate the anatomy of the calyces and pelvis and their relationship to the scarring. Newer techniques that include CT and MR urography have supplanted the IVU.[19] With urologic conditions, there will be distortion and clubbing of calyces; with other conditions, the calyceal pattern should be normal, except for examples of papillary necrosis (Fig. 52-3). Scarring is best demonstrated by technetium 99m–labeled dimercaptosuccinic acid (^{99m}Tc-DMSA) scintigraphy.

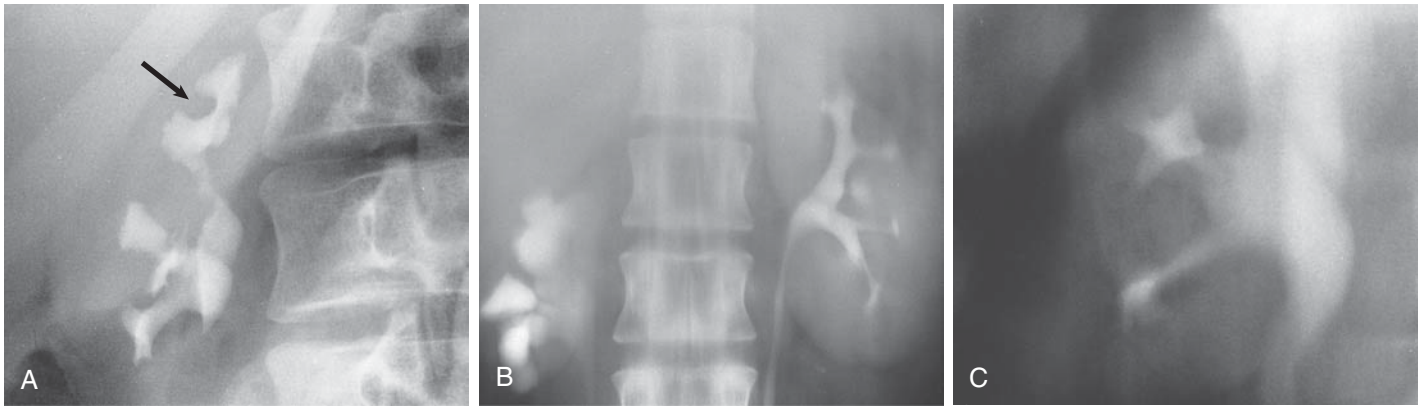

Figure 52-3 Differential diagnosis of "lumpy bumpy" kidneys from appearances on intravenous urography. A, Sickle cell disease: papillary necrosis. Missing papillae leave a round hole in the medulla *(arrow)* and give a clubbed appearance. Otherwise, the calyceal architecture is relatively well preserved. **B,** Reflux nephropathy. There is gross scarring and distortion of the calyceal pattern of the right kidney, giving rise to clubbed appearance of the dilated calyces. With reflux, there is a predilection for scarring of the upper and lower poles; with papillary necrosis or analgesic nephropathy, changes are less predictable. **C,** Analgesic nephropathy. The uniformly small shrunken kidney has relative preservation of the calyceal pattern. A plain film showed areas of calcification in both kidneys.

Absent Kidneys

Unilateral Renal Agenesis

Complete absence of one kidney occurs in 1 in 520 to 1000 births. It can be familial, and the term *hereditary renal aplasia* is used by pediatricians. It is an autosomal dominant trait with incomplete penetrance and variable expression and can be associated with bilateral renal agenesis or severe dysplasia. In some families, mutations in uroplakin-IIIa are found.[20]

Typically, there is no ureter, and the ipsilateral half of the bladder trigone is missing. The remaining kidney is usually hypertrophic, but it may be ectopic, malrotated, or hydronephrotic with a megaureter. The more severe the dysplasia of the remaining kidney, the earlier is the presentation. The ipsilateral testis and seminal tract are usually absent, and in 10% of cases, the adrenal gland is also missing. Girls can have an absent fallopian tube or ovary or malformation of the vagina or uterus. Other associations include imperforate anus and malformations of the vertebrae and cardiovascular system. Agenesis could result from failure in formation of the metanephros or the ureteral bud; however, in association with cloacal abnormalities, the ureteral bud is more likely.

Normality of the single kidney should be confirmed by ^{99m}Tc-DMSA scintigraphy, normal isotopic GFR, and absence of proteinuria. If the remaining kidney is not normal, lifelong follow-up is necessary. Ultrasound of the kidneys is recommended in first-degree relatives in all families in whom there is an individual with unilateral or bilateral renal agenesis.

Bilateral Renal Agenesis

Bilateral renal agenesis is lethal. It is associated with pulmonary hypoplasia and a characteristic facial appearance (Potter facies) caused by intrauterine compression, which is a consequence of oligohydramnios. The prevalence is about 1 in 10,000 births, with risk for occurrence in siblings of about 3%, unless there is a family history of agenesis, when risk rises to 15% to 20%.

Misplaced Kidneys

Renal Ectopia, Malrotation, and Crossed Fused Kidneys

The starting position of the fetal kidney is deep in the pelvis. Kidneys that fail to ascend properly and therefore remain lower than usual occur in 1 in 800 births (Fig. 52-4; see also Fig. 5-16). During development and ascent of the kidney, the renal pelvis comes to face more medially. The most common anomaly is for the pelvis to face forward. The more ectopic the kidney, the more severe is the rotation and more abnormal the appearance. In more than 90% of ectopia, there is fusion of both kidneys. This is now best visualized on CT or MR urography (Fig. 52-5). Symptoms and complications, if any, are caused by associated reflux or PUJ obstruction.

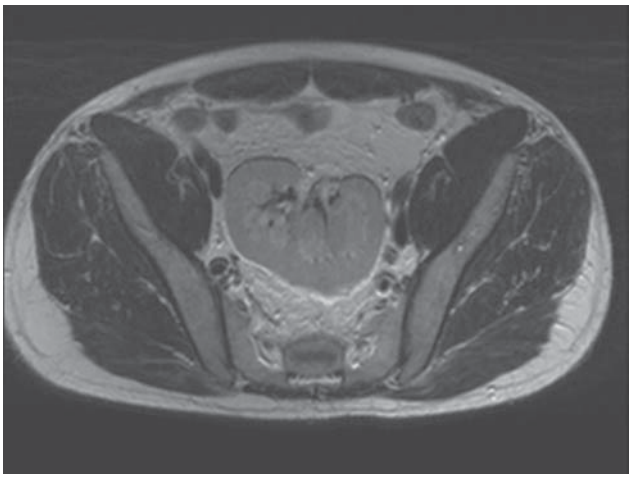

Figure 52-4 Single pelvic kidney. Magnetic resonance (MR) scan, transverse section, shows single midline pelvic kidney. *(Courtesy Dr. A. Kirkham, University College Hospitals, London.)*

Horseshoe Kidney

If both kidneys are low, they may join at the lower pole and are usually drained by two ureters (Fig. 52-6). The kidneys lie lower than normal, and further ascent is prevented by the root of the inferior mesenteric artery. Horseshoe kidney occurs in 1 in 400 to 1800 births and is more common in males (2:1). Patients present, if at all, with complications of reflux, obstruction, or stone formation.

Calyceal Abnormalities

Hydrocalyx and Hydrocalycosis

Dilated calyces are usually caused by obstruction. Focal dilation can also be caused by congenital infundibular stenosis, extrinsic compression from vessel or tumor, stones, or tuberculosis. If obstruction

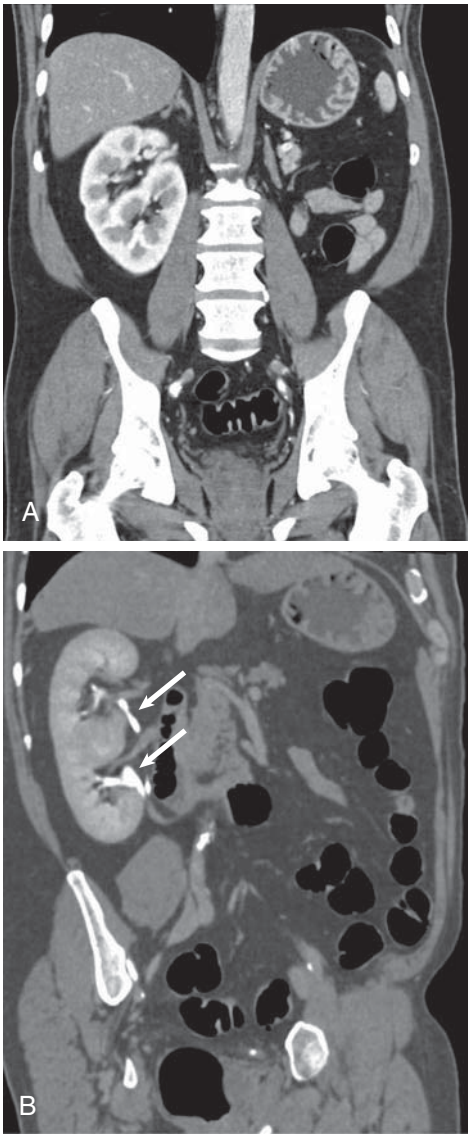

Figure 52-5 Crossed fused ectopia. A, MR scan shows fused kidneys on right. **B,** There are two ureters *(arrows). (Courtesy Dr. A. Kirkham, University College Hospitals, London.)*

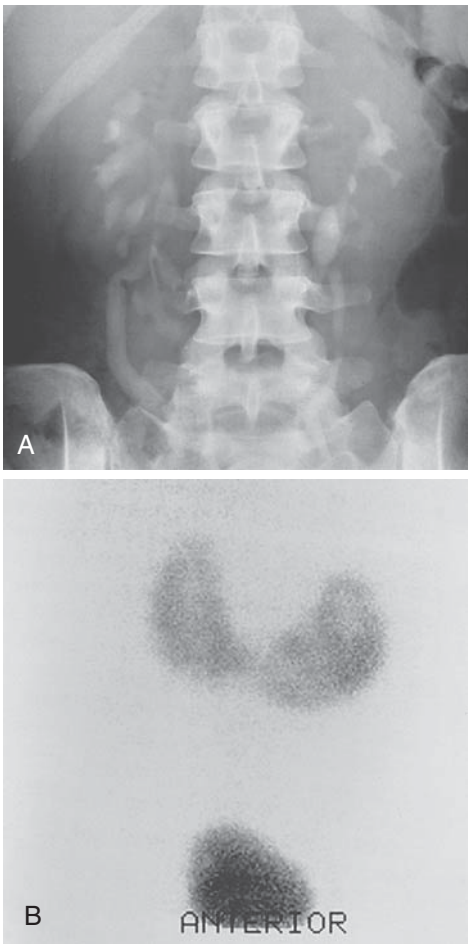

Figure 52-6 Horseshoe kidney. A, IVU soon after pregnancy in a 25-year-old woman shows not only the horseshoe kidney joining in the midline but also dilated ureters as a transient effect of pregnancy. **B,** Dimercaptosuccinate scan shows a horseshoe kidney.

is excluded, the appearance is likely to be a congenital abnormality and can be an incidental finding. Moreover, if the GFR is normal and the divided function of the kidneys is 50:50, surgery to "improve" the anatomy should not be attempted.

Megacalycosis

In megacalycosis, there is bizarre dysplasia of the calyceal system with an increase in the number of calyces. There is no obstruction, and the cause is malformation of renal papillae. Megacalycosis is congenital, usually unilateral, and an incidental finding. It is much more common in males (6:1) and occurs only in Caucasians. Bilateral disease is confined to males, and segmental, unilateral disease to females, which suggests an X-linked partially recessive gene with reduced penetrance in females. There may be an associated ipsilateral segmental megaureter, usually affecting the distal third.

Calyceal Diverticulum (Calyceal Cyst)

A calyceal diverticulum is a cavity peripheral to a minor calyx that is not a closed cyst but rather is connected to the calyx by a narrow channel. It is usually an incidental finding in 5 per 1000 IVUs and is best seen on a delayed film (Fig. 52-7). If a calyceal diverticulum is present, symptoms relate to stones or infection within the cavity.

Bardet-Biedl Syndrome

Multiple calyceal clubbing and calyceal diverticula are the characteristic features of the renal dysplasia seen in Bardet-Biedl syndrome (formerly known as Laurence-Moon-Biedl syndrome).[21] This autosomal recessive condition is characterized by retinitis pigmentosa, dysmorphic extremities (sometimes with polydactyly), obesity, and hypogonadism. Calyceal malformation is associated with parenchymal dysplasia; renal failure in early adult life is common. Since it was shown that Bardet-Biedl syndrome was caused by a defect of the basal body of ciliated cells,[22] mutations in 15 genes coding for different proteins located in the basal body and cilia of the cell have been reported, making the syndrome an archetypal ciliopathy.

Pelviureteral Junction Obstruction

In children, PUJ obstruction is one of the most frequent causes of obstructive uropathy. The condition is usually congenital but can have an acquired mechanical basis caused by stenosis or external compression from adhesions, aberrant lower pole vessels, or kinking of the most proximal ureter. Associated abnormalities are common, and up to 50% of infants have another urologic abnormality, such as

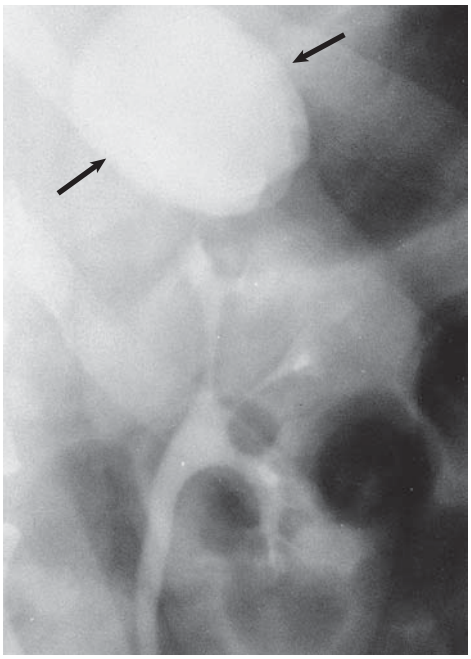

Figure 52-7 Calyceal cyst. IVU shows an upper pole calyceal cyst filled with contrast *(arrows)*. Plain abdominal radiograph showed a group of stones in the floor of the cyst.

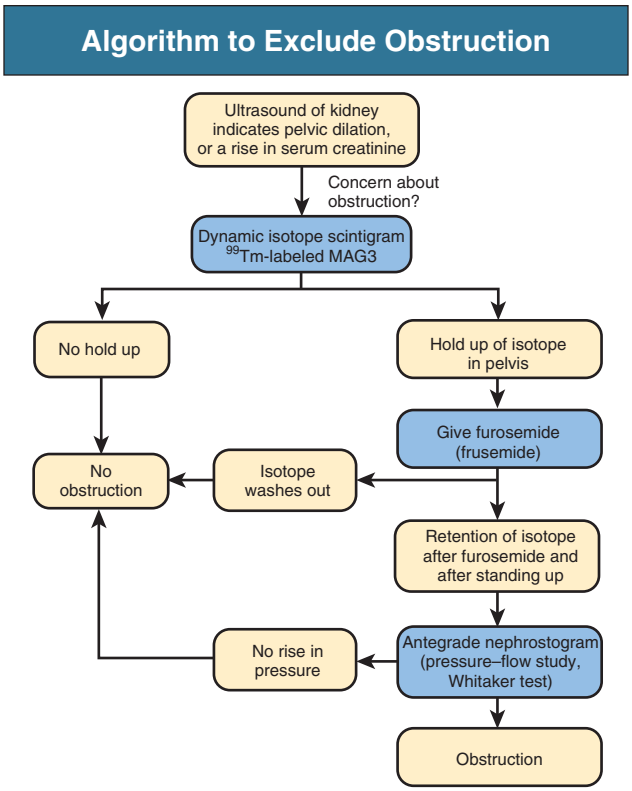

Figure 52-8 Algorithm to exclude pelviureteral junction (PUJ) obstruction. Diagnostic path used to differentiate between significant PUJ obstruction and congenital ectasia of renal pelvis.

contralateral PUJ, contralateral renal dysplastic and multicystic kidney, minor degrees of VUR, and contralateral renal agenesis.

Older children can present with an abdominal mass or with pain in the flank, hematuria secondary to mild trauma, or UTI. Hypertension is unusual but can occur temporarily after surgical correction.

Diagnostic procedures need to differentiate between significant obstruction that requires surgical correction and congenital ectasia of the renal pelvis, in which case surgery is not indicated (Fig. 52-8). Indications for surgical intervention include impairment of renal function, pyelonephritis, renal stones, and pain. Kidneys with good function can generally be left alone, and surgery is indicated only when function is clearly shown to deteriorate.[23]

Gonadal Dysgenesis

The problems of intersex, gender identity, and micropenis are beyond the scope of this chapter and rarely encountered in adult practice. Patients will be met, however, with ESRD who are phenotypically female but are genotype XY and have mutations of *WT1* (Denys-Drash and Frasier syndromes). They have gonadal dysgenesis and must have their streak ovaries removed; otherwise, gonadoblastomas will develop.

URETERAL ABNORMALITIES

The Ureter

The ureter is lined by a multilayered, watertight epithelium (urothelium) surrounded by smooth muscle that generates peristaltic waves distally from pelvis to bladder. The molecular mechanism and growth factors initiating and regulating ureteric budding and branching are increasingly understood, and some genes already implicated in ureteric dysplasia include *PAX2, HNF1β, GATA3, ROBO2,* and *UPK3A*.[24]

Duplex Ureters

Duplication of the ureter and the renal pelvis is a common anomaly, with an incidence of about 1 in 150 births; unilateral duplication is six times more frequent than bilateral. It is more common in girls. If duplication has been detected in a patient, the likelihood of another sibling with duplication rises to 1 in 8.

Pathogenesis

If the ureteral bud bifurcates after its origin from the mesonephric duct but arises at a normal site, an incomplete ureteral duplication with a Y ureter will develop.[7] Complete ureteral duplication occurs if there are two ureteral buds, one in the normal location and the other in a low position. The normal bud ends in a correct site on the trigone in the bladder and is nonrefluxing. The lower bud, representing the ureter of the lower pole of the kidney, ends in the bladder as a lateral orifice with a short submucosal tunnel. The lower pole ureter is therefore often associated with VUR, and scarring of the lower pole can result.

If there are two ureteral buds, one with a normal location and one with a high position, the upper ureter is incorporated into the developing bladder, ending more distally and medial to the normal one. Thus, the upper pole ureter ends ectopically, and because of obstruction or dysplasia, there is often severe scarring of the upper pole moiety.

Clinical Manifestations

In most adult patients, ureteral reduplication is asymptomatic and causes no long-term problems. Children with ureteral duplication often have VUR. The spontaneous disappearance of reflux is less common in duplex ureters than in patients with a single ureter.[25]

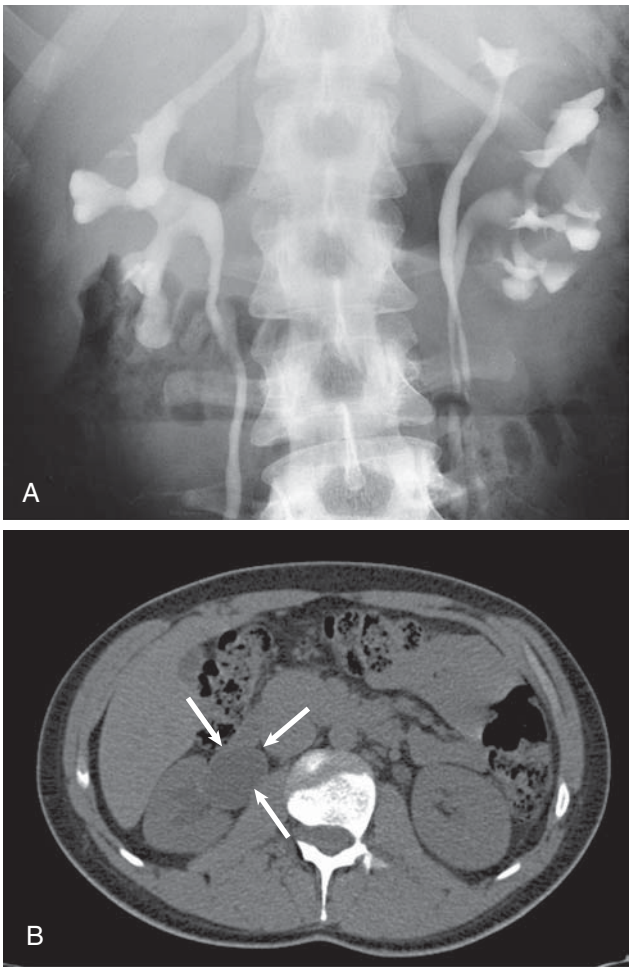

Figure 52-9 Duplex kidney. A, IVU shows a duplex left kidney. The lower pole is scarred and shows evidence of reflux damage. The two ureters entered the bladder separately, with the lower pole ureter in the abnormal location. The right kidney also shows features of reflux, with clubbing of the calyces and some scarring. **B,** CT scan shows an isolated right-sided megaureter *(arrows)*.

Duplex ureters are best diagnosed by CT urogram. PUJ obstruction of the ureter draining the lower pole of the kidney can occur.

Associated conditions, such as ectopic ureters and ureterocele (see later discussion), usually cause problems in early life and therefore have been addressed by adolescence. Upper pole scarring is associated with an ectopic ureter, and lower pole scarring with VUR (Fig. 52-9, *A*).

Ectopic Ureters

Ectopic ureters are almost always associated with ureteral reduplication, and 10% are bilateral. There is a female-male ratio of 7:1. The ectopic ureter comes from the upper pole and inserts into the bladder more distally and toward the bladder neck, or it opens into the upper urethra. In females, the ureter may end in the urethra, vagina, or vulva, and patients present with incontinence, UTIs, or a persistent vaginal discharge, particularly if the external sphincter is damaged, as during labor.

Ectopic ureters are rare in males and present as UTI. Usually, there is a single ureter associated with a dysplastic kidney, which ends in the posterior urethra, ejaculatory duct, seminal vesicle, or vas. Males are usually continent because the ureter is proximal to the external sphincter.

Ectopic ureters are best visualized by CT or MR urography. A voiding cystourethrogram shows reflux into the lower pole of the kidney in 50% of patients.

Ureterocele

Ureteroceles are cystic dilations of the terminal segments of the ureter and are caused by maldevelopment of the caudal ureter. Ureteroceles affect females more than males (4:1) and almost exclusively affect Caucasians, and 10% are bilateral. Ectopic ureters and ureters with ureteroceles frequently (80%) drain the upper pole and are often associated with dysplastic or nonfunctional renal tissue. These usually present in childhood with infection; when large, they can obstruct the bladder neck or even the contralateral ureter. In adults, ureteroceles typically present with stones in the lower ureter.

The treatment of simple ureteroceles is surgical excision with reimplantation of the ureter or simple incision if they subtend a well-functioning moiety. There are usually no medical sequelae.

Megaureter

Isolated dilation of the ureter does not necessarily imply obstruction. There are three broad groups of conditions with widely dilated ureters, as follows:

1. Obstruction of the ureter itself. This may be intrinsic (e.g., stone) or extrinsic (e.g., retroperitoneal fibrosis); it is not associated with reflux.
2. Bladder outflow obstruction, with secondary ureteral obstruction. Examples include a neuropathic bladder and posterior urethral valves; this may or may not be associated with reflux.
3. A dilated but nonobstructed ureter. This often occurs without reflux, and there can be normal renal function; this may be caused by an adynamic segment of the lower ureter (Fig. 52-9, *B*).

Pathogenesis

In the normal ureter, there is a characteristic helical orientation of muscle fibers. When the megaureter is secondary to bladder outflow obstruction, there is muscle hyperplasia and hypertrophy of the ureteral wall. In megaureters with no apparent cause, a variety of abnormalities of muscle orientation are described, or there may even be absence of muscle fibers at the proximal end of the undilated segment.

Electron microscopy shows an increase in collagen between the muscle bundles at the level of the obstructing segment. Obstruction appears to be caused by a failure of peristalsis through the distal ureteral segment.

Clinical Manifestations

Most cases of megaureter associated with obstruction present in childhood with severe infections, often complicated by septicemia. These patients have a high incidence of other congenital abnormalities. In less severe cases or with no obstruction, patients can present with abdominal pain, loin pain, hematuria, and UTI. Renal stones can form easily in the dilated systems. The exclusion of obstruction is often established only by an antegrade pressure-flow study (Whitaker test), in which a nephrostomy is placed in the renal pelvis and contrast material infused at 10 ml/min.[26]

Treatment

A definitive diagnosis must be made on whether an obstruction exists (see Fig. 52-8). The current view is that patients with asymptomatic nonobstructed disease should be managed conservatively, and most do well with this approach.

BLADDER AND OUTFLOW DISORDERS

Prune-belly Syndrome

The prune-belly syndrome occurs in males and consists of absence of the muscles of the anterior abdominal wall, bizarre malformations of the urinary tract with gross dilation of the bladder and ureters, and bilateral undescended testes.[27-29] When the disorder is diagnosed early, renal outcome is related to the degree of renal dysplasia. There are incomplete forms of prune-belly syndrome (pseudo-prune). Rarely, a similar megacystis or megaureter may be seen in a male or female patient.

Pathogenesis

No gene defect or unifying hypothesis has emerged to explain these features. The incidence of prune-belly syndrome varies from 1 : 30,000 to 1 : 52,000 births. There are a few familial cases, and the condition has been reported in twins, but there is 100% discordance reported in identical twins, which is a powerful argument against a genetic basis. There is evidence for a primary, localized arrest of mesenchymal development. This is supported by the lack of prostatic differentiation; the epithelial element in the prostate is absent or hypoplastic. Ultrastructural studies of the ureter show massive replacement of smooth muscle with fibrous and collagen tissue and the absence of nerve plexuses. An almost identical syndrome can result from fetal urethral obstruction, including urethral atresia.

Clinical Manifestations

The prognosis depends on the degree of renal dysplasia and injury. Three prune-belly groups can be distinguished. In group I (20%), complete urethral obstruction causes stillbirth or neonatal death. In group II (20%), acute, early presentation requires diversion and reconstruction. In group III (60%), good health and renal function continue despite urologic appearances.

There is complete absence or incomplete formation of the rectus abdominis and other muscles, which leads to the wrinkled abdominal wall of the prune infant (see Fig 52-11, C). This gives way to a fairly smooth "pot belly" in later life (Fig. 52-10). Reconstructive surgery is not normally required. The patients grow up physically active and strong but cannot sit up directly from a supine position. Abnormalities of the thoracic cage, such as pectus excavatum, are common.

Although true outflow obstruction may be present, the gross and irregular dilation of the urinary tract characteristic of prune-belly syndrome is primarily caused by a developmental defect with a variable degree of smooth muscle aplasia leading to aperistaltic ureters (Fig. 52-11). Urodynamic studies are often difficult to interpret because of gross VUR, but typically there is a low-pressure bladder. With late presentation, some patients have detrusor instability.

Differential Diagnosis

In severe cases of megacystis or megaureter with gross impairment of renal function (often with dysplastic kidneys), the differential diagnosis of prune-belly syndrome includes posterior urethral valves, renal dysplasia with or without multiple congenital defects, neuropathic bladder, and nephrogenic diabetes insipidus.

Natural History

Once any outflow obstruction is addressed, usually in infancy, the renal function should remain stable despite the frightening radiologic appearances. In prune-belly patients observed in our unit for up to 40 years, renal deterioration and hypertension have been rare. In the small number who have progressed, recurrent infection, hypertension, and proteinuria have been warning signs of impending trouble. Renal scarring should be assessed by isotopic DMSA scintigraphy and renal function followed by serial isotopic GFR measurements. Lifelong attention to blood pressure, UTIs, and stones is necessary.

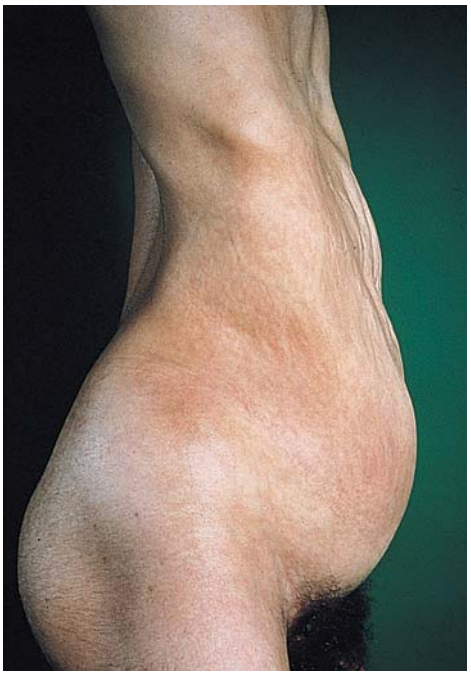

Figure 52-10 Prune-belly syndrome. Note the lax abdominal musculature leading to a pot-bellied appearance. There is also marked thoracic cage deformity. *(Courtesy Prof. C. R. J. Woodhouse, University College Hospital, London.)*

Treatment

In all children with prune-belly syndrome, even with good renal function, a careful search for obstruction should begin with the urethra and work up to the PUJ. Often, however, no obstruction is found, and no surgery is required. In many other patients, the floppy bladder is not anatomically obstructed, but bladder emptying is improved by urethrotomy ("functional obstruction"). In infancy, there is debate about the need for reconstructive surgery. Certainly, a group of patients born with severely compromised renal function do require reconstruction after stabilization by early diversion.[30]

The current view is that the testes should be brought down to the scrotum in infancy. It is hoped that earlier surgery will produce proper germ cell development and thus preserve fertility. Thus far, however, no prune-belly patient has been shown to be fertile.

Bladder Exstrophy (Ectopia Vesicae)

Classic exstrophy is the failure of the anterior abdominal wall and bladder to close. However, these defects range from epispadias of an otherwise normal penis to major cloacal abnormalities (Fig. 52-12).

Pathogenesis

Failure of growth of the lower abdominal wall between the allantois and the urogenital membrane coupled with breakdown of the urogenital membrane leaves a small, open bladder plate, a low-placed umbilical root, and diastasis of the pubic bones (Fig. 52-13, *B*). The genital tubercle is probably placed lower in these patients, and the cloacal membrane ruptures above it, leading to a penis with an open

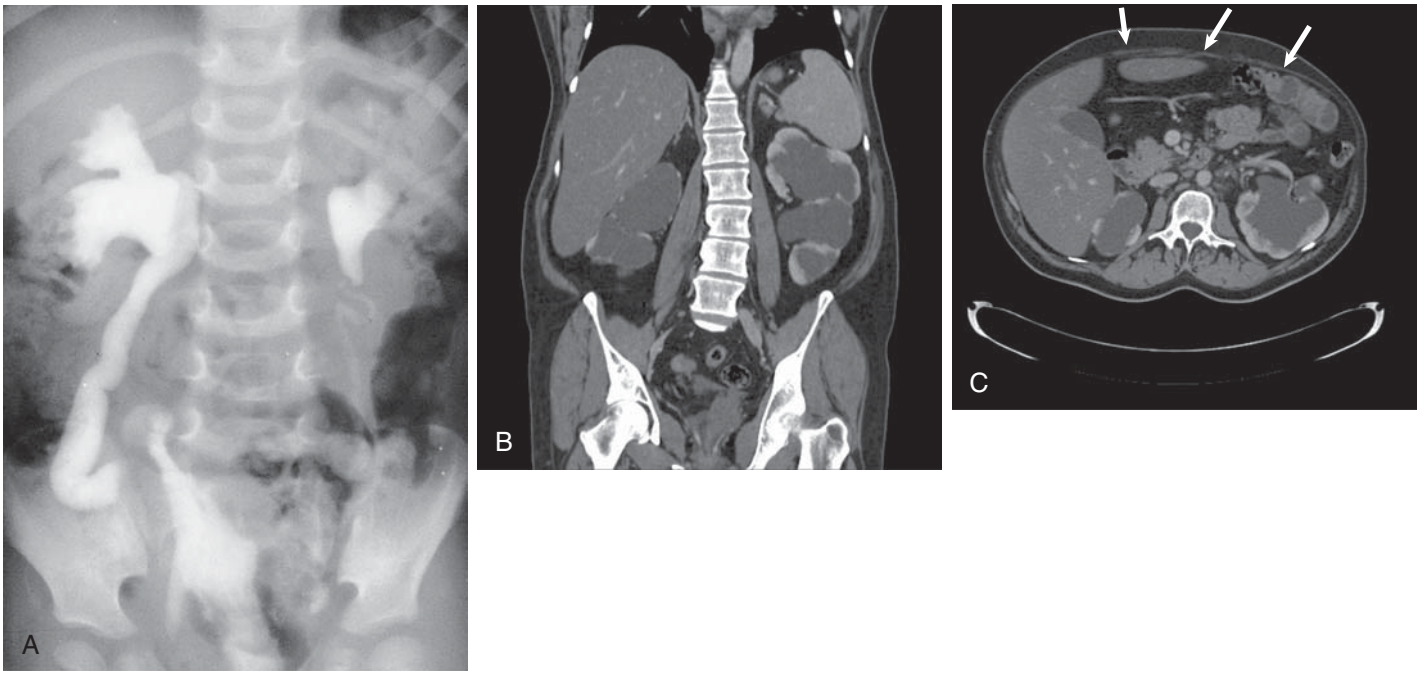

Figure 52-11 Prune-belly syndrome. A, Typical IVU appearance of a patient with prune-belly syndrome and good renal function. Often, the ureters are extremely dilated and tortuous. **B,** CT urogram showing gross bilateral hydronephrosis. **C,** Absence of anterior abdominal wall musculature *(arrows)*.

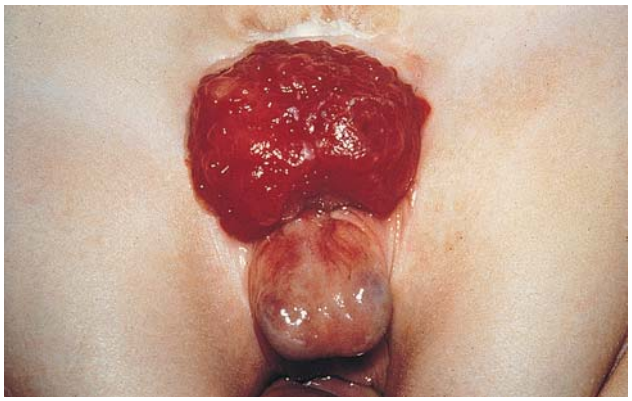

Figure 52-12 Bladder exstrophy. The entire length of the penis is also open (epispadias). *(Courtesy Prof. C. R. J. Woodhouse, University College Hospital, London.)*

dorsal surface that is continuous with the bladder plate. A midline closure defect causes a failure of fusion of the lower anterior abdominal wall, including the symphysis pubis, lower urinary tract, and external genitalia. There are rare reports of a familial incidence. The condition occurs in 1 in 10,000 to 52,000 births. The male-female ratio is 2:1.

Clinical Manifestations

In severe cases, the bladder mucosa lies exposed on the lower abdominal wall, with the bladder neck and urethra laid open. The prostate and testes are normal. Most patients have normal kidneys at birth, although many reports do not record the state of the kidneys at birth. In one series, 33% had dilated ureters at presentation, but IVU was usually normal after diversion. In another series, however, one third of patients were said to have "unilateral renal agenesis."[31] Renal function may be preserved after the diversion, although reflux is common (Fig. 52-13).

Other congenital abnormalities are only rarely present. More severe cloacal abnormalities are associated with imperforate anus and high or low rectal atresia.

Natural History

Long-term renal outcome depends on the bladder. Up to 25 years, the kidneys survive much better with a well-functioning bladder; 13% of those with a good bladder had significant renal damage compared with 82% with ileal conduits, 22% with nonrefluxing colonic conduits, and 33% with ureterosigmoidostomy.[32] Currently, the bladder is usually augmented (enterocystoplasty, ileocystoplasty, cecocystoplasty) or replaced by bowel (intestinal reservoir). In a study of 53 such patients monitored more than 10 years, renal function deteriorated (GFR decrease ≥20%) in only 10 patients (~20%).[33]

Treatment

When the infant is born, the three urologic treatment goals are to close the abdominal wall, to establish urinary continence and preserve renal function, and to reconstruct cosmetically acceptable genitalia. The aim of initial surgery is to convert the defect to a complete epispadias (Fig. 52-14). At 4 years of age, reconstruction of the bladder neck and correction of the epispadias can be performed. If the bladder is small, intestinal augmentation is required. Patients may be able to void, but many have to use catheters. Incontinence may be a long-term problem.

Neuropathic Bladder

In childhood, the most common cause of a neuropathic bladder is myelomeningocele, although with antenatal diagnosis, it is becoming less common. A neuropathic bladder may also be seen without associated neurologic or other obvious causes (Table 52-2). The principal consequences are incontinence, infection, and reflux with upper tract dilation and subsequent renal failure. Early urodynamic assessment is essential (Fig. 52-15). Three different patterns of bladder behavior are seen: contractile, intermediate, and acontractile.

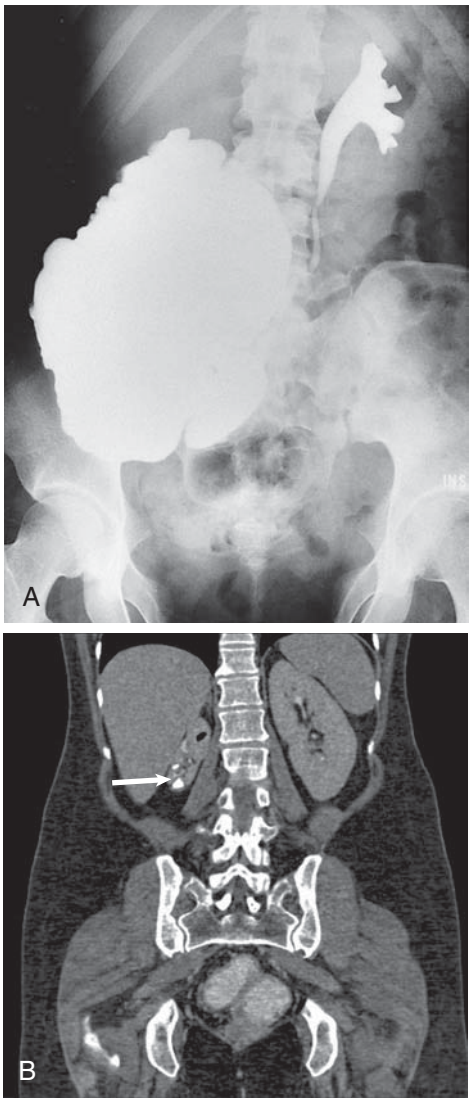

Figure 52-13 Cystography in bladder exstrophy. A, A 26-year-old woman with bladder exstrophy who has a continent Mitrofanoff system (see Fig. 52-19) with use of the colon to create a reservoir. There is reflux into the left kidney. Reflux also occurs into the right kidney, but the kidney is obscured by the full reservoir. Glomerular filtration rate is 130 ml/min. **B,** MR scan of a patient with bladder exstrophy shows scarred, small left kidney with several renal calculi *(arrow)*. Note widely splayed symphysis pubis.

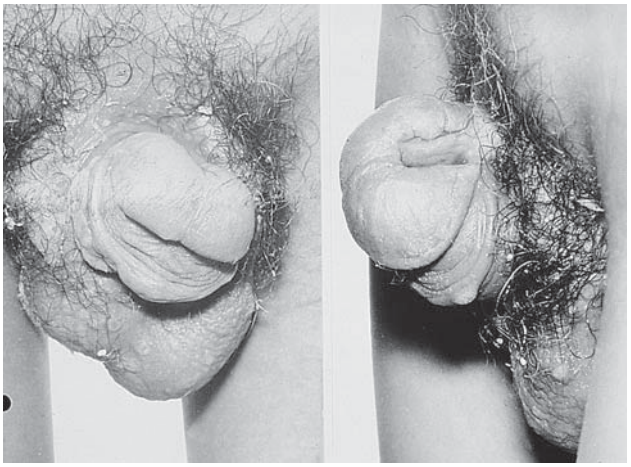

Figure 52-14 Epispadias. Result of multiple surgeries to close the epispadias and to lengthen the penis. *(Courtesy Prof. C. R. J. Woodhouse, University College Hospital, London.)*

Causes of Neuropathic Bladder	
Site of Lesion	**Causes**
Cerebral	Cerebrovascular accident/cerebral palsy, encephalopathy, trauma, Parkinson disease, dementia
Spinal	Isolated (no other neurologic features), trauma, multiple sclerosis, compression, spina bifida, spinal dysraphism, tethered cord, sacral agenesis, sacral teratoma
Peripheral nerve	Pelvic surgery, diabetes

Table 52-2 Causes of neuropathic bladder.

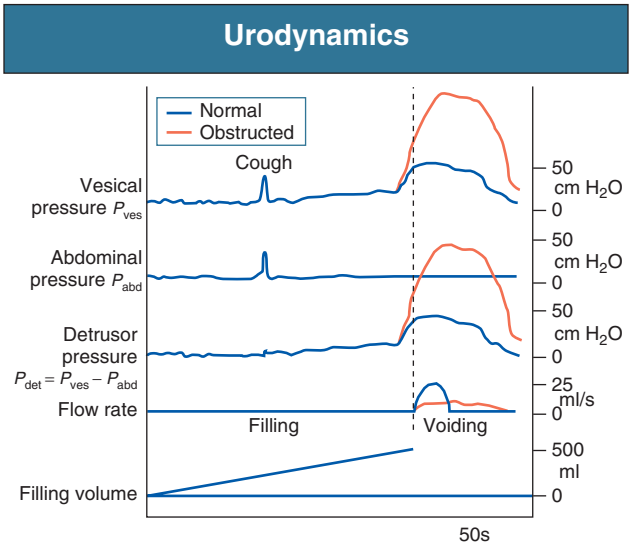

Figure 52-15 Urodynamic assessment by cystometrography. The vesical pressure is measured simultaneously with the abdominal pressure through the rectum; the detrusor pressure is the difference. A cough is used as a marker to show that the system is working. During filling, the first desire to void is normally at a detrusor pressure of less than 10 cm H_2O. This point is noted. The voiding pressure should normally be less than 40 cm H_2O (and is lower in women). Detrusor instability is an unstable (spontaneous) contraction occurring with a detrusor pressure above 15 cm H_2O. Higher pressure can cause incontinence. In combination with radiologic imaging (videocystometrography), the following are recorded: bladder neck, closed or open; bladder pressure, end filling; voiding detrusor pressure; bladder stability; compliance; flow rate, maximum; sensation, first; volume, voided and residual. *(Courtesy Prof. M. Craggs, University College London.)*

Contractile Behavior

An overactive detrusor (hyperreflexia) can produce some bladder emptying (incontinence). Unfortunately, 95% of patients have sphincter dyssynergia (inability to relax urethral sphincter), which results in no relaxation and incomplete emptying of the bladder. Patients with incomplete lesions may have some control of the distal sphincter and normal anal and sacral reflexes. Ironically, although this latter group has the least neurologic deficit, they have the worst bladder situation, generating high pressures and great risk for renal injury. The bladder becomes progressively hypertrophic, fibrotic, and poorly compliant.

Intermediate Behavior

These patients have some detrusor activity, but not sufficient to empty the bladder. These intermediate bladders are poorly compliant, and patients have no voluntary control of their sphincters. Any

rise in bladder pressure tends to cause incontinence, or the high intravesical pressures lead to renal injury.

Acontractile Behavior

About 25% of patients have no detrusor activity, and the bladder overflows when it is sufficiently full. This acontracile bladder is not usually associated with renal failure.

Myelodysplasia

Myelodysplasia refers to a group of neural tube anomalies that primarily affect the lumbar and sacral segment of the spinal cord and are the most common cause of neurogenic bladder dysfunction in children. *Spina bifida* reflects defective fusion of the posterior vertebral arches. *Meningocele* implies that the meninges extend beyond the confines of the vertebral canal with no neural elements contained inside. A *myelomeningocele* has neural tissue protruding with the meningocele. *Spinal dysraphism* (symptomatic spina bifida occulta) defines a group of structural anomalies of the caudal end of the spinal cord that do not result in an open vertebral canal but are associated with incomplete fusion of the posterior vertebral arches.

Sacral agenesis is a rare anomaly in which part or all of two or more vertebral bodies is absent. It occurs early in fetal development when there is failure of ossification of the lowest vertebral segments. The only known teratogen is insulin. Sacral agenesis occurs in 1% of children born to insulin-dependent mothers. Partial sacral agenesis can be associated with an anterior meningocele.

Pathogenesis

The neural tube normally forms as the neural folds close over and fuse, starting in the cervical region and progressing caudally. It is believed that the embryologic defect is an incomplete tubularization of the neural tube, with inadequate mesodermal invagination and subsequent arrest of vertebral arch formation.

The incidence of myelodysplasia varies from 1 to 5 in 1000 live births, but there are wide geographic variations. Monozygotic twins are often discordant for spina bifida, but siblings are at increased risk (1:10 to 1:20), and children of affected parents have a 4% chance of having a similarly affected child. Myelomeningocele accounts for more than 90% of myelodysplastic infants. Folic acid supplements taken during the last trimester reduce the incidence of myelodysplasia by 52%.

Clinical Manifestations

All causes of tethered cord can produce a variable neurologic deficit. During development, some children develop progressive neurologic disturbance with bladder dysfunction, bowel dysfunction, scoliosis, and a syndrome of pes cavus and limb growth failure.

Bladder Dysfunction Neuropathic bladder can be an isolated problem with abnormal urodynamic studies but a normal neurologic examination.[34]

Bowel Dysfunction Bowel dysfunction is often present and needs to be treated accordingly. There may be severe constipation and overflow incontinence. The antegrade continent enterostomy procedure has been developed to improve the management. The appendix is brought out to the abdominal surface, and thus the colon can be irrigated antegrade with saline.

Cognitive Impairment Patients with myelomeningocele may have some intellectual impairment, especially those who have required ventriculoperitoneal shunting for associated hydrocephalus. Manual dexterity may also be affected. These are crucial issues in long-term management.

Natural History

About 14% of patients have renal complications at birth and are at high risk in the next few years. Ultimately, about 52% will develop upper tract problems, although these can take up to 30 years to occur (Fig. 52-16). In one prospective study, renal outcome could be predicted by the urodynamic findings, with worst outcomes related to increased bladder wall thickness, degree of reflux, urethral pressures above 70 cm H_2O, and reduced bladder capacity. VUR occurs in 3%

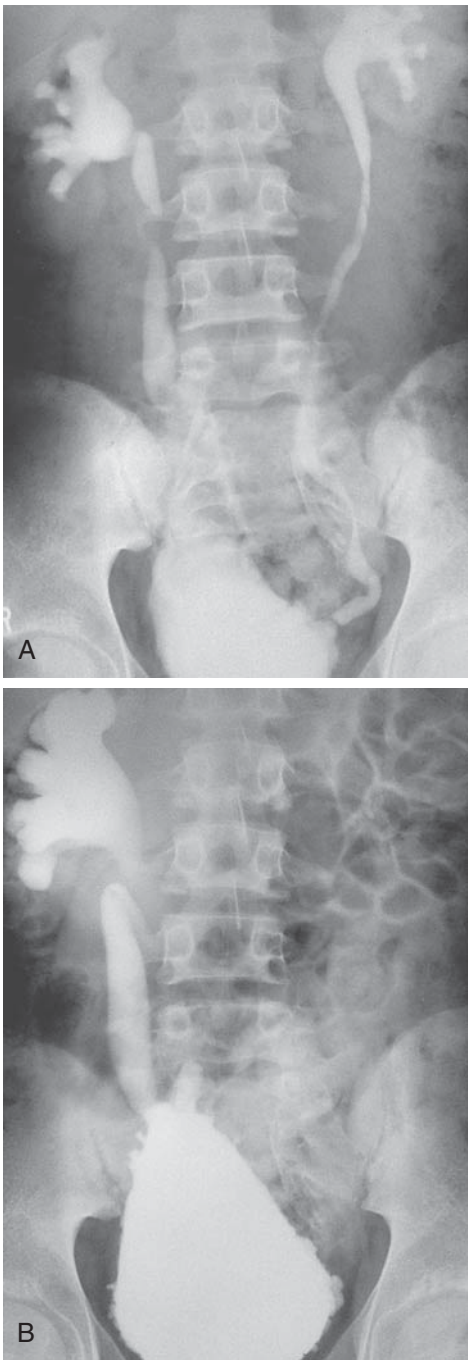

Figure 52-16 Sacral spina bifida with neuropathic bladder. A, IVU shows evidence of a previous hydronephrosis and subsequent scarring of the right kidney. The architecture of the left kidney is well preserved. **B,** Micturating cystogram. The typical tapering, hypertrophied, trabeculated bladder gives the characteristic fir (pine) cone appearance. Note the gross reflux on the right side. This is probably helping to protect the left kidney by acting as a "pop-off" mechanism. This is analogous to the protection that can occur in boys with posterior urethral valves.

to 5% of newborns with detrusor hypertonicity or dyssynergia. Without treatment, this increases to 30% to 40% by age 5 years.[35]

Treatment

The management of the bladder depends on the urodynamic findings. In the 1970s, clean intermittent self-catheterization (CISC) was introduced,[36] but before that time, urinary diversion was the usual treatment. Currently, when reflux and hydroureter are present, the management is principally with CISC and antimuscarinic drugs that increase bladder compliance. With persisting symptoms related to bladder storage or hyperreflexia, bladder wall injection with botulinum toxin type A1 is offered. In the presence of deteriorating renal function or intractable symptoms, continent bladder augmentation or sometimes ileal conduit is required.[37]

Bladder Neck Obstruction

Congenital bladder neck obstruction is rare and is usually caused by a neuropathic bladder, posterior urethral valves, or an ectopic ureterocele.

Posterior Urethral Valve

Posterior urethral valves are the most common cause of severe subvesical obstruction in the male infant (but account for only 10% of neonatal hydronephrosis). As a result, bilateral hydronephrosis and megaureter occur. Obstruction is caused by a diaphragm that extends from the floor to the roof of the urethra at the apex of the prostate. Valves appear as mucosal folds in the posterior urethra below the verumontanum. There is dilation of the proximal urethra and bladder wall hypertrophy and trabeculation. Above the valves, the prostatic urethra dilates, undermining the bladder neck. The valves obstruct flow only in one direction, and therefore a catheter can be passed without difficulty.

Pathogenesis

The urethra develops in two parts: differentiation of the urogenital sinus part (posterior urethra) and tubularization of the urethral plate (anterior urethra). Early obstruction during renal development can result in severe renal dysplasia.

Clinical Manifestations

Most cases of posterior urethral valves are now detected antenatally by ultrasound. Half of all patients present before age 1 year. Infants present with a palpably distended bladder and enlarged kidneys, abnormal urine stream, or failure to thrive due to renal failure. At diagnosis, 30% to 52% of children also have VUR. Children with less severe disease present with poor stream, hematuria, incontinence, acute UTI, or renal failure. However, late presentation is also associated with worse outcome.[38]

Three abnormal features can help protect the kidney, reducing the high pressures generated during voiding: massive unilateral reflux, usually with ipsilateral renal dysplasia (thereby protecting the other kidney); large bladder diverticulum; and urinary extravasation, often with urinary ascites. These protective mechanisms are referred to as "pop-off" mechanisms[39] (Fig. 52-16, *B*). Ultrasound can show the bladder thickening, dilated system, and dilation of the posterior urethra. A specific diagnosis should be documented by videocystometrography (see Urodynamics).

Natural History

In the 1960s, 25% of children with posterior urethral valves died within the first 12 months, and 25% died later in childhood, including "renal death" (i.e., ESRD). By the late 1990s, early mortality was less than 5%, and after 15 years of follow-up, only 15% to 20% of patients had reached ESRD.[40]

The bladder may become stretched, resulting in poor emptying, or unstable, leading to poor compliance, unsuppressed detrusor contractions, and high storage pressure. Both these situations are exaggerated by progressive polyuria. Such patients may have a daily urine volume of 5 liters. Urodynamic follow-up studies suggest that instability decreases with time; bladder capacity increases, but there are unsustained voiding contractions. The prognosis correlates with the nadir serum creatinine value once obstruction has been relieved. Despite adequate early treatment, chronic kidney disease (CKD) caused by renal dysplasia develops in many children.[38,41]

Treatment

All children have had transurethral resection of their valves in infancy. Bladder diversion should be avoided. The question of "undiversion" of ileal conduits previously created is discussed later. Bladder instability and poor bladder compliance must be treated, regardless of whether symptoms result. Boys with substantial residual volumes can be managed by CISC, but compliance is often poor because of urethral discomfort or because previous urethral surgery has made the passage of catheters difficult. Compliance is a particular problem with adolescents who are continent and for whom renal failure is too abstract a concept. Continence often improves spontaneously at puberty but can be helped by imipramine. Deterioration in renal function will require further examination of urine flow rate and exclusion of urethral stricture.

Urethral Diverticulum

Urethral diverticulum usually occurs in boys and is rare. It may present with UTI, obstruction, or stones. The two types are anterior and posterior. The anterior type can be associated with anterior urethral valves and obstruction.

Other Congenital Causes of Bladder Outflow Obstruction

Non-neurogenic neurogenic bladder, or Hinman syndrome, has been used to describe a group of patients with severe bladder dysfunction, urodynamically consistent with a neurogenic bladder, but in whom no neurology defect can be demonstrated. The genetic background to some of these disorders has been discovered.

Urofacial Syndrome

Urofacial syndrome, or Ochoa syndrome, is a rare autosomal recessive disease characterized by facial grimacing when attempting to smile and failure of the urinary bladder to void completely, despite a lack of anatomic bladder outflow obstruction or overt neurologic damage. Patients present with enuresis and UTI and all the features of a neuropathic bladder together with dilated upper tracts. They are at risk of renal failure. Some but not all families have mutations of *HPSE2* (heparanase-2), which is expressed in the fetal and adult central nervous system, and also in bladder smooth muscle, consistent with a role in renal tract morphology and function.[42]

Prune-belly–like Syndrome

A prune-belly–like syndrome, or "pseudo-prune," can result from mutation of *CHRM3* (muscarinic acetylcholine receptor M3). A similar bladder problem can be modeled in mice by knocking out this gene. In males, this syndrome can masquerade as posterior urethral valves.[43]

Management of Congenital Renal Tract Abnormalities

- Educate and explain to encourage compliance
- Review urologic status
- Find cause of urinary tract obstruction and treat
- Control blood pressure
- Monitor renal function and proteinuria
- Treat acidosis
- Prevent bone disease
- Check for stones
- Clean intermittent self-catheterization for chronic retention
- Maintain bladder storage pressure below 40 cm H_2O
- Maintain bladder volume below 400 ml

Box 52-1 General principles of management of congenital renal tract abnormalities.

GENERAL MANAGEMENT OF CONGENITAL TRACT ABNORMALITIES

The principles of management of congenital tract abnormalities are shown in Box 52-1. The most important part of the management is ensuring that the patient, family, and primary care physician know what can and must be done. First, they must understand the necessity of long-term follow-up at least annually. ESRD often occurs when a patient is lost to follow-up, often presenting later with accelerated hypertension and rapid loss of renal function.

Clinical Evaluation

By the time the adolescent requires an adult physician, it is assumed that the urinary tract is not obstructed and that further surgery is not required. Nevertheless, it is the responsibility of the nephrologists and urologists who care for these young people to review this aspect periodically.

Symptomatic UTI is common and must be treated promptly. Increase in frequency or severity of infections must lead to investigations to find the cause.[44] The blood pressure must be monitored regularly and kept normal. Finally, renal function must be monitored, proteinuria assessed, and the cause of any deterioration identified. As in any renal condition, the remnant kidney function may decline inexorably, which is associated with increasing proteinuria and hypertension. As with other renal conditions, kidney function is usually stable when proteinuria is minimal or absent. Deterioration in the absence of proteinuria must alert the physician to the likelihood of obstruction or the adverse effect of a nephrotoxic drug.

The routine investigations performed to document the current situation act as a reference point for the future (Table 52-3). If the bladder empties completely with an adequate flow rate (15 ml/s), no problems should arise. If there is any doubt about the condition of the bladder, urodynamic investigations are necessary. If the clinical situation changes, further investigations are required. An increase in UTIs might suggest a stone or increase in residual urine. With an unexpected decline in renal function, obstruction again must be excluded.

The patient should keep a 24-hour urine volume diary every 6 to 12 months, recording the time of voiding and volume passed. It is best to ask patients to do this on 2 consecutive days, to determine the maximum bladder capacity and the total 24-hour urine volume. This should be done before urodynamic investigations, because results can be misleading if bladder is not filled to capacity.

Monitoring Patients with Congenital Renal Tract Abnormalities

Baseline Measurements	Reason for Test
Radiology	
Abdominal x-ray film	Exclude stones
Ultrasound	
Ultrasound of kidneys	Baseline
Ultrasound of bladder after micturition	Assess residual volume
Urine flow rate	Ensure adequacy
Scintigraphy	
Glomerular filtration rate: ^{51}Cr-labeled EDTA	Baseline
Dynamic isotope scan: ^{99}Tc-labeled MAG3 or DTPA	Assess outflow obstruction/ holdup
Static isotope scan: ^{99}Tc-labeled DMSA	Assess scarring and divided function
Biochemistry	
Urine protein-creatinine ratio	Baseline

Table 52-3 Monitoring patients with congenital renal tract abnormalities. Routine investigations for assessment of clinical status. *^{51}Cr,* Chromium 51; *DMSA,* dimercaptosuccinic acid; *DTPA,* diethylene triamine pentaacetic acid; *EDTA,* ethylenediaminetetraacetic acid; *MAG3,* mercaptoacetyltriglycine; *^{99}Tc,* technetium 99.

Exclude Obstruction

Obstruction must always be excluded if there is a change in renal function. The possibility of obstruction may be raised by a routine ultrasound (see Fig. 52-8) and should be pursued with mercaptoacetyltriglycine (MAG3) scintigraphy to exclude obstruction (Fig. 52-17).

In patients with conduits, obstruction can be excluded by infusion of contrast material into the loop (loopogram) and demonstration of reflux up the ureter.

Rarely, in patients with large bladders or in transplant recipients, the kidney may become obstructed when the bladder reaches a certain volume. This can be investigated by filling the bladder by a catheter and performing ^{99m}Tc-labeled MAG3 scintigraphy, initially with the bladder full. If there is no excretion, the bladder volume can be reduced in 100-ml increments until there is flow down the ureter (Fig. 52-18).

Urodynamics

Any urodynamic investigation should start with a free urine flow rate. Provided the flow rate is normal and the bladder empties completely (leaving no residual volume on postmicturition ultrasound), it can be assumed that there is no significant bladder outflow obstruction.

Complete investigation of abnormalities of bladder and urethral function requires synchronous recordings of intravesical and intrarectal pressures taken during bladder filling and emptying (see Fig. 52-15). Combined with radiologic imaging, the study is known as videocystometrography (VCMG).

Surgical Correction of the Urinary Tract

A normal bladder acts as a low-pressure, good-volume urine reservoir that is continent, is sterile, and empties freely and completely. Any other form of urine reservoir aims to recreate such an

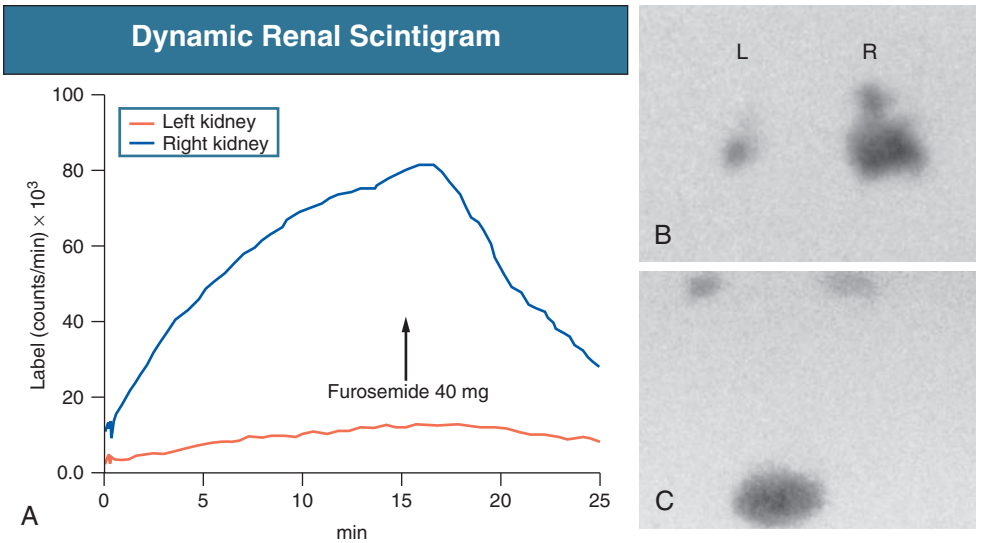

Figure 52-17 Dynamic ^{99m}Tc-labeled MAG3 renal scintigram. A, Time-activity curve showing accumulation of isotope in right kidney that washes out after furosemide, thus excluding significant obstruction. **B** and **C,** Images from the same study showing holdup of isotope in dilated right *(R)* renal pelvis (**B**) that washes out into the bladder after furosemide (**C**), excluding significant obstruction.

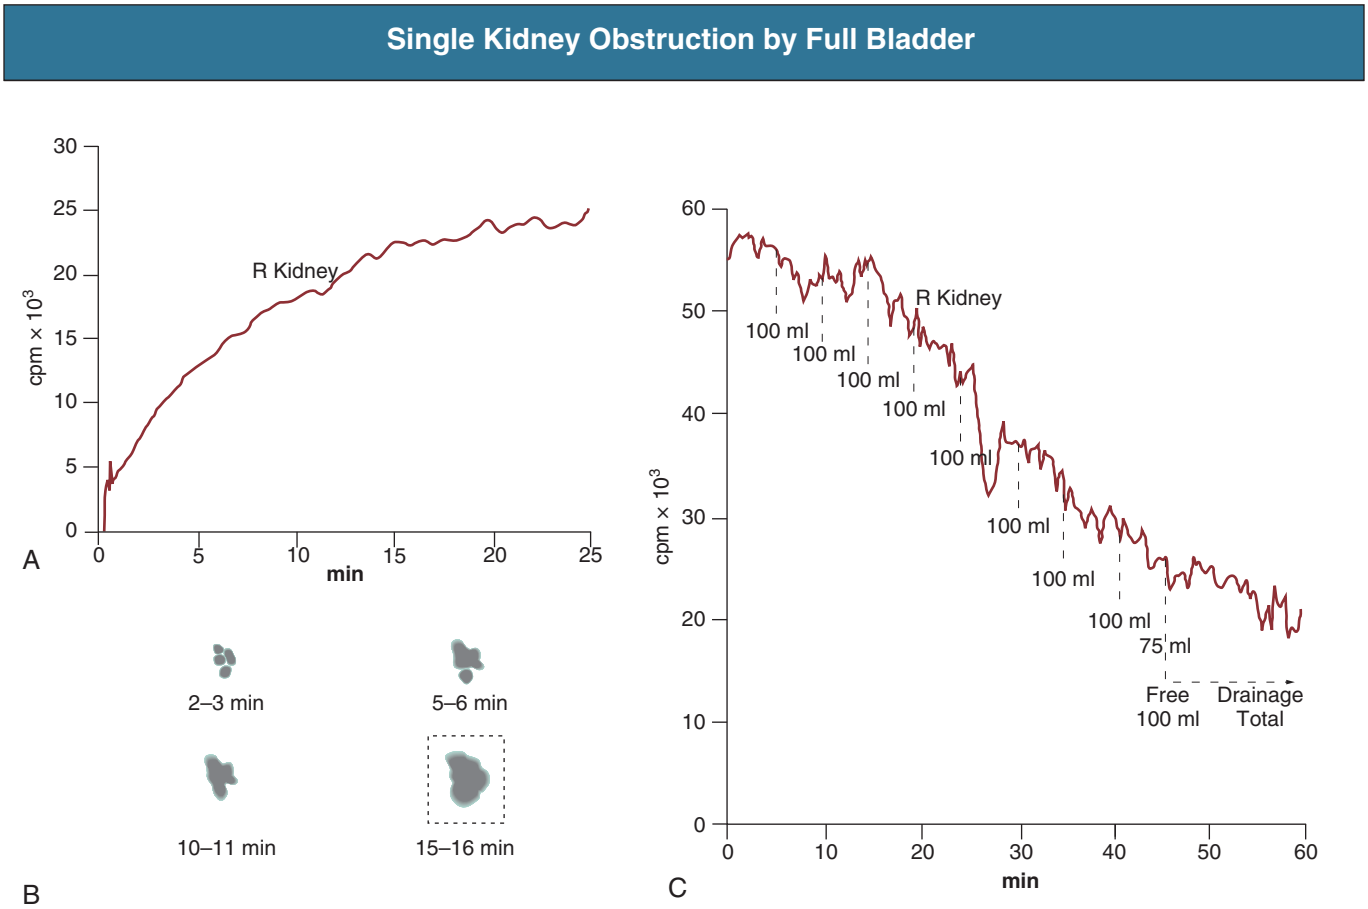

Figure 52-18 Dynamic isotope scan (MAG3) starting with bladder full in a patient with solitary right kidney. A, Rising curve of tracer accumulating in kidney and showing no excretion. *cpm,* Counts per minute. **B,** Accumulation of isotope in hydronephrotic pelvis without excretion to bladder. **C,** The 100-ml increments of fluid removed from bladder result in eventual free drainage of the kidney.

environment. When this is not achieved in either a natural or a reconstructed bladder, complications such as sepsis and renal dysfunction can occur.

A variety of conduits and continent reservoirs have been developed to replace unusable bladders. Ileal conduit diversion has been most widely used for native kidneys, although deterioration in renal function frequently results from long-term complications, including urosepsis, renal calculi, and most often stenosis, leading to obstruction or to reflux with ureteral dilation. There is an overall complication rate of 45%, but with a high index of suspicion and an aggressive diagnostic and therapeutic approach, many of these problems can be detected and treated early, with resultant good long-term function

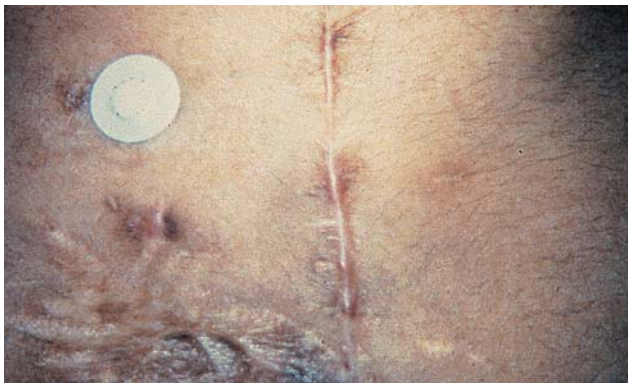

Figure 52-19 Mitrofanoff stoma. This patient was born with bladder exstrophy and has had a successful renal transplant for 22 years. Her kidney is plumbed into a colonic reservoir, and she catheterizes herself through a continent Mitrofanoff stoma, which is covered by a small piece of plaster in the photograph.

of native kidneys. Similar results may be obtained when renal transplantation is performed in these patients.[45] Other forms of urinary diversion that are continent and therefore more socially acceptable to patients are now widely used in general urologic practice and are being encountered in renal transplantation (Fig. 52-19; see also Fig. 52-13). These forms include augmented bladders draining through the urethra and augmented or intestinal bladders draining through continent stomas.

Undiversion of Conduits

The only certain improvement with undiversion is cosmetic. Initially, undiversion was undertaken because of poor results or complications from conduits. Current indications are convenience and cosmetic appearance (see Fig. 52-19). Before undiversion is considered, the following four questions must be answered:

1. Is there residual obstruction?
2. What is the function of the bladder?
3. What is the function of the sphincters?
4. What is the normal 24-hour urine volume?

In particular, the bladder storage pressure must be considered because a low-pressure reservoir must be achieved. This is a particular problem when patients are polyuric. The potential capacity of the bladder will often need to be reassessed after a period of bladder cycling, when the bladder is repeatedly filled through a suprapubic catheter and the volume, voiding capacity, and residual volume are determined. If the native bladder is not of sufficient volume and compliance, some form of augmentation will be required.

COMPLICATIONS

Urinary Tract Infections

Symptomatic UTIs are common.[44] Risk factors include stagnation of urine, stones, foreign bodies (stents, catheters), previous infections, and renal scarring. UTIs must be treated promptly after a urine culture specimen (midstream or catheter specimen) has been taken. Recurrent UTIs, particularly after a period of stability, must lead to further investigations to exclude stones or obstruction, including abdominal radiography, renal ultrasound, and postmicturition bladder ultrasound.

Asymptomatic UTIs often do not require treatment (except during pregnancy). For patients with urinary diversions, it is important to obtain a catheter specimen of urine because urine taken from a bag is invariably infected.

It is sometimes appropriate to give prophylactic antibiotics, such as trimethoprim or nitrofurantoin, to eradicate infection. Many patients believe that cranberry juice helps them; it reduces the incidence of *Escherichia coli* infection but will not treat a symptomatic infection. Tetracycline and oxytetracycline are contraindicated because they cause acute or chronic deterioration in renal function, but doxycycline can be used. Nitrofurantoin and nalidixic acid are avoided if GFR is reduced below 50 ml/min, because both are renally excreted and toxic in renal failure. Quinolones should not be used for prophylaxis, if possible, because of the risk for inducing resistance. When foreign bodies such as stones remain, attempts to sterilize the urinary tract are unlikely to be successful.

If prophylactic antibiotics are no longer effective at preventing infection, it is advisable to stop all antibiotics and to give the patient a supply of antibiotics to treat symptoms arising at home.

Hypertension and Glomerular Hyperfiltration

If renal function is declining with proteinuria and hypertension, glomerular hyperfiltration is likely, although all other causes of renal dysfunction must be excluded. Patients should be treated with renin-angiotensin blockade with ACE inhibitors and angiotensin receptor blockers (ARBs).[4]

Proteinuria and Progressive Renal Failure

Can progression to ESRD be predicted, and does treatment with ACE inhibitors delay or prevent this?[4] We investigated this in a retrospective review of patients with scarred irregular kidneys caused by primary renal dysplasia or abnormal bladder function. All patients had at least 5 years of follow-up, and when ACE inhibitors were started, estimated GFR (eGFR) was below 60 ml/min/1.73 m^2 (mean, 41 ml/min), with mean proteinuria of 1.7 g/24 h. ESRD developed in 46% of patients but in none with proteinuria less than 0.5 g/24 h and in only 2 of 18 patients with eGFR above 50 ml/min. The renal outcome of the two groups was similar whether there was primary renal dysplasia or abnormal bladder function. There was a watershed GFR of 40 to 50 ml/min above which ACE inhibitor treatment improved renal outcome.[4] The similar outcome of the two groups indicates that progressive renal failure in young men born with abnormal bladders is caused by intrinsic renal pathophysiologic processes, in contrast to the view that it is a result of poor bladder function.

Hypertension

Hypertension is common in the presence of scarred kidneys, but it is usually controlled easily with one or two drugs. Patients in whom CKD is secondary to obstruction tend to have volume contraction and therefore often have normal blood pressure or only mild hypertension. ACE inhibitors or ARBs are preferred for patients with proteinuria and progressive renal failure. Diuretics should not be used if the patient is volume-contracted.

Stones

Stones that form in the presence of infected urine are typically magnesium ammonium phosphate (struvite) or calcium phosphate (hydroxyl apatite, carbonate apatite, calcium hydrogen phosphate [brushite], tricalcium phosphate [whitlockite]). These salts are poorly soluble in alkaline urine. In 90% of patients, the infecting

organism is *Proteus* spp.,[46] but other urea-splitting organisms (including some staphylococci and *Pseudomonas* spp.) also generate ammonia.[42]

Stones, usually calcium phosphate, are common in conduits because of the alkaline environment and occur in 5% to 30% of ileal conduits. Stones must be suspected if UTIs recur or become more frequent, if renal function suddenly deteriorates, or if there is an unexplained sterile pyuria.

Tubular Dysfunction

Patients whose renal failure is secondary to obstruction have significant tubular injury. This may cause problems, in particular with urinary concentration, acidification, and sodium reabsorption.

Polyuria

Nocturia is one of the most significant symptoms in the assessment of patients in whom obstruction or tubular dysfunction is suspected. Overfilling of the bladder or reservoir is an important cause of intermittent upper tract obstruction and deteriorating function. The 24-hour urine volume diary is a simple way to assess this.

Salt Depletion

Patients with tubular damage may have a salt-losing tendency. Patients typically have a cool periphery and constricted hand veins with no peripheral edema. Increasing salt intake can relieve cramps, improve renal function, and reduce hyperuricemia, but at the cost of increasing blood pressure. With patients who are salt depleted, it is important to give sodium chloride because it is the chloride anion that is deficient and responsible for the reduction in circulating volume.

Acidosis

There is often a metabolic acidosis disproportionate to the degree of renal impairment. This is secondary both to a proximal tubular failure of bicarbonate reabsorption and to a distal tubular failure to secrete hydrogen ions. It is our practice to give sufficient sodium bicarbonate to correct the plasma bicarbonate into the normal range.

Bone Disease

In addition to the typical bone disease of progressive CKD, acidosis contributes significantly to osteomalacia. Growing children are particularly vulnerable to osteomalacia, and great care must be taken to correct acidosis and actively manage bone disease.

Urinary Diversions

Ureterosigmoidostomy

Fortunately, it is now rare to meet a patient who still has a ureterosigmoidostomy, which was widely used as a technique for urinary diversion until the 1970s. The ureters were anastomosed directly into the sigmoid colon with no disruption of bowel continuity. This technique was most often used in patients with bladder exstrophy. Although patients start with normal renal function, there is frequently deterioration in function. In one series of 25 patients, significant renal damage occurred in 50%. Stones, infection, and ureteral strictures are common, and patients remain at risk for colonic carcinoma, with a 10% incidence of carcinoma at 20-year follow-up. However, this diversion is probably best known for the hyperchloremic, hypokalemic acidosis that occurs. Once the urine is in contact with the colonic mucosa, the urinary sodium exchanges for potassium and the chloride for bicarbonate, and large quantities of ammonium ions are produced by the action of the fecal bacteria on urinary ammonia. Ammonium ions are absorbed both with chloride and in exchange for sodium. The severe acidosis is caused by ammonium ion retention and stool loss of bicarbonate. Patients are managed with large doses of oral sodium bicarbonate, which is titrated to keep the plasma bicarbonate in the normal range (>22 mmol/l).

Ileal Conduits

Unlike the sigmoidostomy, in which urine enters a reservoir, the ileal conduit is free flowing, with rapid urinary transit and no reservoir. Therefore, metabolic complications are much less common, although again the bowel can exchange sodium and chloride for potassium and bicarbonate.[47,48] A number of other complications of ileal and colonic conduits can lead to progressive loss of renal function (Box 52-2).

Enterocystoplasty and Intestinal Urinary Reservoirs

In 53 patients with bladder exstrophy monitored more than 10 years with serial isotopic GFRs, renal function deteriorated (GFR decrease ≥20%) in only 10 (~20%).[33] Loss of function was caused principally by chronic retention with or without infection in poorly compliant patients who did not catheterize regularly. Patients must also be checked regularly to ensure that anastomotic stenoses and high-pressure reservoirs do not occur. Stones are common and occur in up to 52% of patients.[49]

END-STAGE RENAL DISEASE AND TRANSPLANTATION

This group of patients presents two important problems at ESRD. First, because of multiple abdominal surgeries, continuous ambulatory peritoneal dialysis (CAPD) is often impossible, although if there is any doubt, CAPD should be attempted. Second, the bladder and urinary reservoir must be suitable for renal transplantation. If a bladder has just destroyed two good native kidneys, it is likely to do the same to a transplant kidney. Most patients will be maintained on hemodialysis, but it is frequently difficult to establish a good arteriovenous fistula because of chronic hypovolemia and venoconstriction. Patients receiving dialysis often continue to pass 1 liter or more of

Long-term Complications of Urinary Diversion

- Pyelonephritis and scarring
- Calculi
- Obstruction
- Strictures
- Bladder mucus causing obstruction
- Cancer at intestinal-ureteral anastomosis
- Hyperchloremic acidosis
- Delayed linear growth in children
- Effects of intestinal loss from gastrointestinal tract (e.g., vitamin B_{12} deficiency)
- Complications related to abnormal pelvic anatomy (e.g., in pregnancy)
- Psychological and body image problems

Box 52-2 Long-term complications of urinary diversion.

urine per 24 hours, and they also remain at risk for serious UTI and pyelonephritis.

Pretransplantation Assessment

Transplantation into the abnormal lower urinary tract requires careful evaluation and follow-up. Thorough preoperative assessment of bladder function is essential. Patients considered to have normal bladders require at least postmicturition bladder ultrasound and urinary flow rate.

All patients with abnormal bladders or reservoir must have a full videocystometrogram to ensure that the bladder reservoir is large and adequately compliant. If the bladder is small or has not been used for some time, *bladder cycling,* which involves periodically filling and distending the bladder through a suprapubic catheter, may be required. A urodynamic study before transplantation indicated that poor bladder function, as shown by small bladder volumes, is a predictor of graft loss even in patients with previously normal bladder function.[50]

Intermittent self-catheterization is safe and effective for a patient with a poor flow rate who fails to empty the bladder. This, however, is possible only with a normal urethra and a cooperative patient. When this is not practical, we attempt to establish suprapubic drainage through a continent stoma, such as a Mitrofanoff stoma (see Fig. 52-19). If a conduit is to be used, a loopogram and endoscopy must ensure that it is in good condition. We do not remove native kidneys unless they are causing recurrent UTI.

Transplant Outcome

In an 18-year experience, we transplanted 65 patients with abnormal bladders, with a total of 72 renal transplants.[51] In 52 cases, the ureters were transplanted into unaugmented bladder; in 20 cases, there was some form of augmentation or diversion. Results were compared with 59 transplants in 55 patients who had renal failure from renal dysplasia and whose bladder function was considered normal. There was no difference in actuarial graft survival in the two groups at 10 years (abnormal bladders, 66%; normal bladders, 61%), although longer follow-up showed an advantage for normal bladders, with a kidney half-life of 29 to 33 years compared with 15 years for the abnormal bladders.[52] UTIs were relatively common in all patients but produced problems only in patients with abnormal bladders.

Management

A double-J ureteral stent should be placed routinely at the time of transplant surgery. Adequacy of urinary drainage must be assessed frequently, even when graft function seems to be good. Two months after transplantation, when the ureteral stent has been removed, we perform as a baseline the following tests:

- Chromium 51–labeled ethylenediaminetetraacetic acid (^{51}Cr-EDTA) GFR
- Postmicturition ultrasound of kidney and bladder
- Dynamic ^{99m}Tc-MAG3 scintigraphy
- Static ^{99m}Tc-DMSA scintigraphy (baseline for renal scarring)

The GFR is repeated at 6 months and then annually. Ultrasound and ^{99m}Tc-MAG3 scintigraphy are repeated at 1 year and then when indicated. The protein-creatinine ratio is measured on a random urine sample at every outpatient visit. If there is renal dysfunction, imaging tests are repeated, and if there is a change from baseline, renal biopsy is performed to exclude an immunologic cause of graft dysfunction. If there is a documented deterioration in renal function in the absence of rejection or calcineurin inhibitor toxicity, the DMSA scan is repeated (to see whether there has been new scarring) and the bladder reassessed urodynamically.[52]

Complications

Urinary tract infections must be detected and treated early, and recurrent UTIs may require long courses of antibiotics or even removal of the native tracts. Symptomatic UTIs are common in the first 3 months after transplantation (63%); fever and systemic symptoms occur in 39% of patients with normal bladders and 59% with abnormal bladders. UTI directly contributes to graft loss in patients with abnormal bladders but causes no consequences in those with normal bladders.[44] Prophylactic administration of antibiotics for the first 6 months reduces significantly the subsequent incidence of UTI. When UTIs recur, a cause must be sought with ultrasound of kidney and bladder. A plain abdominal radiograph is essential to look for stones in native or transplant kidneys and the bladder or urinary diversion. If there is a residual volume after double micturition, the patient must be instructed to perform CISC. With these measures, good results are obtained.

SECTION IX

Infectious Diseases and the Kidney

CHAPTER 53

Bacterial Urinary Tract Infections

Thomas Hooton

DEFINITION

Urinary tract infection (UTI) in adults can be categorized into six groups: young women with acute uncomplicated cystitis, young women with recurrent cystitis, young women with acute uncomplicated pyelonephritis, adults with acute cystitis and conditions that suggest occult renal or prostatic involvement, complicated UTI, and asymptomatic bacteriuria (Box 53-1).[1] Chapter 44 discusses UTI in pregnancy, and Chapter 63 describes vesicoureteral reflux (VUR) in children.

Complicated urinary tract infection is defined as UTI that increases the risk for serious complications or treatment failure. Patients with various conditions, such as those presented in Box 53-1, are at increased risk for complicated UTI. Complicated UTIs may require different pretreatment and post-treatment evaluation and type and duration of antimicrobial treatment than for uncomplicated UTI. On occasion, complicated UTIs are diagnosed only after a patient has a poor response to treatment.

EPIDEMIOLOGY

Acute uncomplicated UTIs are extremely common, with several million episodes of acute cystitis and at least 250,000 episodes of acute pyelonephritis occurring annually in the United States. The incidence of cystitis in sexually active young women is about 0.5 per 1 person-year.[2] Acute uncomplicated cystitis may recur in 27% to 44% of healthy women, even though they have a normal urinary tract.[3] The incidence of pyelonephritis in young women is about 3 per 1000 person-years.[4] The self-reported incidence of symptomatic UTI in postmenopausal women is about 10% per year.[5] The incidence of symptomatic UTI in adult men younger than 50 years is much lower than in women, ranging from 5 to 8 per 10,000 men annually.

Complicated UTIs encompass an extraordinarily broad range of infectious entities (see Box 53-1). Nosocomial UTIs are a common type of complicated UTI and occur in 5% of admissions in the university tertiary care hospital setting; catheter-associated infections account for most of the infections. Catheter-associated bacteriuria is the most common source of gram-negative bacteremia in hospitalized patients.[6]

Asymptomatic bacteriuria is defined as two separate consecutive clean-voided urine specimens, both with 10^5 or more colony-forming units per milliliter (cfu/ml) of the same uropathogen in the absence of symptoms referable to the urinary tract.[7] Asymptomatic bacteriuria is found in about 5% of young adult women,[8] but rarely in men younger than 50. The prevalence increases up to 16% of ambulatory women and 19% of ambulatory men older than 70 and up to 50% of elderly women and 40% of elderly men who are institutionalized.[7] Asymptomatic bacteriuria may be persistent or transient and recurrent, and many patients have had previous symptomatic infection or develop symptomatic UTI soon after having asymptomatic bacteriuria. Asymptomatic bacteriuria is generally benign, although it may lead to serious complications in some clinical settings.

PATHOGENESIS

Uncomplicated Infection

Most uncomplicated UTIs in healthy women result when uropathogens (typically *Escherichia coli*) present in the rectal flora enter the bladder through the urethra after an interim phase of periurethral and distal urethral colonization. Colonizing uropathogens may also come from a sex partner's vagina, rectum, or penis. Hematogenous seeding of the urinary tract by potential uropathogens such as *Staphylococcus aureus* is the source of some UTIs, but this is more likely to occur in the setting of persistent bloodstream infection or urinary tract obstruction.

Many host behavioral, genetic, and biologic factors predispose healthy young women to uncomplicated UTI (Table 53-1). Risk factors include sexual intercourse, use of spermicide products, and a history of previous recurrent UTI.[2,9] Nonsecretors of ABO blood group antigens are at increased risk for recurrent cystitis, the P_1 blood group phenotype is a risk factor for recurrent pyelonephritis in women, and mutations in the gene for CXCR1, the interleukin-8 receptor, are more frequent and expression of CXCR1 is lower in children prone to pyelonephritis compared with controls.[10] Factors protecting individuals from UTI include the host's immune response; maintenance of normal vaginal flora, which protects against colonization with uropathogens; and removal of bladder bacteriuria by micturition.[11] Uropathogenic *E. coli*, the predominant pathogens in uncomplicated UTI, are a specific subset of extraintestinal pathogenic *E. coli* that have the potential for enhanced virulence[12] (Table 53-1). P-fimbriated strains of *E. coli* are associated with acute uncomplicated pyelonephritis, and their adherence properties may stimulate epithelial and other cells to produce proinflammatory factors that stimulate the inflammatory response. Other virulence determinants include adherence factors (type 1, S, and Dr fimbriae), toxins (hemolysin), aerobactin, and serum resistance. Bacterial virulence determinants associated with cystitis and asymptomatic bacteriuria have been less well characterized. Triggers for development of urinary symptoms are not entirely clear.

Factors affecting the large difference in UTI prevalence between men and women include the greater distance between the usual source of uropathogens (anus and urethral meatus), the drier environment surrounding the male urethra, and the greater length of the male urethra. Risk factors associated with UTIs in healthy men include intercourse with an infected female partner, anal intercourse, and lack of circumcision, although these factors are often not present in men with UTI. Most uropathogenic strains infecting young men are highly virulent, suggesting that the urinary tract in healthy men is relatively resistant to infection.

Categories of Urinary Tract Infection in Adults

- Acute uncomplicated cystitis in young women
- Recurrent acute uncomplicated cystitis in young women
- Acute uncomplicated pyelonephritis in young women
- Acute uncomplicated cystitis in adults with a following condition suggesting possible occult renal or prostatic involvement but without other known complicating factors:
  - Male sex
  - Elderly
  - Pregnancy
  - Diabetes mellitus
  - Recent urinary tract instrumentation
  - Childhood urinary tract infection
  - Symptoms for more than 7 days at presentation
- Complicated urinary tract infection*
  - Obstruction or other structural factor: urolithiasis, malignancies, ureteral and urethral strictures, bladder diverticula, renal cysts, fistulas, ileal conduits, other urinary diversions
  - Functional abnormality: neurogenic bladder, vesicoureteral reflux
  - Foreign bodies: indwelling catheter, ureteral stent, nephrostomy tube
  - Other conditions: renal failure, renal transplantation, immunosuppression, multidrug-resistant uropathogens, health care–associated (includes hospital-acquired/nosocomial place) infection, prostatitis-related infection, upper tract infection in an adult other than a healthy young woman, other functional or anatomic abnormality of urinary tract)
- Asymptomatic bacteriuria

Box 53-1 Categories of urinary tract infection in adults. *This is a selected list of complicating factors. Some factors complicate urinary tract infections through several mechanisms. *(Data for complicating factors from reference 1.)*

Complicated Infection

The initial steps leading to uncomplicated UTI discussed earlier probably also occur in most individuals who develop a complicated UTI. Factors that predispose individuals to complicated UTI generally do so by causing obstruction or stasis of urine flow, facilitating entry of uropathogens into the urinary tract by bypassing normal host defense mechanisms, providing a nidus for infection that is not readily treatable with antimicrobials, or compromising the host immune system (see Box 53-1).[1] UTIs are more likely to become complicated in the setting of impaired host defense, as occurs with indwelling catheter use, VUR, obstruction, neutropenia, and immune deficiencies. Diabetes mellitus is associated with several syndromes of complicated UTI, including renal and perirenal abscess, emphysematous pyelonephritis and cystitis, papillary necrosis, and xanthogranulomatous pyelonephritis.[13] Uropathogen virulence determinants are less important in the pathogenesis of complicated UTIs compared with uncomplicated UTIs. However, infection with multidrug-resistant uropathogens is more likely with complicated UTI.

ETIOLOGIC AGENTS

Uncomplicated upper and lower UTI are most often caused by *E. coli*, present in 70% to 95%, and *Staphylococcus saprophyticus*, present in 5% to more than 20% (Table 53-2).[1] *S. saprophyticus* only rarely causes acute pyelonephritis.[14] Less common causes of uncomplicated UTI include other *Enterobacteriaceae* (e.g., *Proteus mirabilis, Klebsiella* spp.) and rarely *Pseudomonas aeruginosa*, *Citrobacter* species (spp.), or other uropathogens. Among otherwise healthy nonpregnant women, the isolation of organisms such as lactobacilli, enterococci, group B streptococci, and coagulase-negative staphylococci other than *S. saprophyticus* most often represents contamination of the urine specimen.[15] However, such organisms should be considered a likely causative agent in symptomatic women when found in voided midstream urine in high counts and pure growth.

A broader range of bacteria can cause complicated UTI, and many are resistant to broad-spectrum antimicrobial agents. Although

Factors Modulating Risk for Acute Uncomplicated Urinary Tract Infections in Women

Host Determinants	Uropathogen Determinants
Behavioral: sexual intercourse, use of spermicidal products, recent antimicrobial use, suboptimal voiding habits	*Escherichia coli* virulence determinants: P, S, Dr, and type 1 fimbriae; hemolysin; aerobactin; serum resistance
Genetic: innate and adaptive immune response, enhanced epithelial cell adherence, antibacterial factors in urine and bladder mucosa, nonsecretor of ABO blood group antigens, P1 blood group phenotype, reduced CXCR1 expression, previous history of recurrent cystitis	
Biologic: estrogen deficiency in postmenopausal women, glycosuria (including from SGLT-1 inhibitors)	

Table 53-1 Factors modulating risk for acute uncomplicated urinary tract infections in women.

Bacterial Etiology of Urinary Tract Infections

Organisms	Urinary Tract Infection (%)	
	Uncomplicated	*Complicated*
Gram-Negative Organisms		
Escherichia coli	70-95	21-54
Proteus mirabilis	1-2	1-10
Klebsiella spp.	1-2	2-17
Citrobacter spp.	<1	5
Enterobacter spp.	<1	2-10
Pseudomonas aeruginosa	<1	2-19
Other	<1	6-20
Gram-Positive Organisms		
Coagulase-negative staphylococci (*Staphylococcus saprophyticus*)	5-20 or more	1-4
Enterococci	1-2	1-23
Group B streptococci	<1	1-4
Staphylococcus aureus	<1	1-2
Other	<1	2

Table 53-2 Bacterial etiology of urinary tract infections. *(Data for complicated infections from reference 1.)*

E. coli is the most common, *Citrobacter* spp., *Enterobacter* spp., *P. aeruginosa*, enterococci, and *S. aureus* account for a relatively higher proportion of cases compared with uncomplicated UTIs (Table 53-2).[1] The proportion of infections caused by fungi, especially *Candida* species, is increasing (see Chapter 55). Patients with chronic conditions, such as spinal cord injury and neurogenic bladder, are more likely to have polymicrobial (multiorganism) and multidrug-resistant infections.

CLINICAL SYNDROMES

Acute Uncomplicated Cystitis in Young Women

Women with acute uncomplicated cystitis generally present with acute onset of dysuria, frequency, urgency, or suprapubic pain. Acute dysuria in a sexually active young woman is usually caused by acute cystitis; acute urethritis from *Chlamydia trachomatis, Neisseria gonorrhoeae*, or herpes simplex virus infections; or vaginitis caused by *Candida* spp. or *Trichomonas vaginalis*.[6] These three entities can usually be distinguished by the history, physical examination, and simple laboratory tests. Pyuria is present in almost all women with acute cystitis as well as in most women with urethritis caused by *N. gonorrhoeae* or *C. trachomatis,* and its absence strongly suggests an alternative diagnosis. Hematuria (microscopic or gross) is common in women with UTI but not in women with urethritis or vaginitis.

Definitive diagnosis of UTI requires the presence of significant bacteriuria, the traditional standard for which is 10^5 or more uropathogens per milliliter of voided midstream urine. Studies have shown, however, that up to half of women with cystitis have lower colony counts, which are missed with use of the traditional definition. The Infectious Diseases Society of America (IDSA) consensus definition of cystitis is 10^3 cfu/ml or more.[16] Urine cultures are generally not indicated in women with uncomplicated cystitis, because the patient's history has been shown to be highly reliable in establishing the diagnosis,[17] the causative organisms are predictable, and the culture results usually become available only after therapeutic decisions have been made.

E. coli in uncomplicated UTI is often resistant to sulfonamides and amoxicillin, and increasing resistance is also being observed for trimethoprim and trimethoprim-sulfamethoxazole (TMP-SMX, cotrimoxazole) in outpatient urinary strains in the United States and Europe.[18,19] In the United States, cotrimoxazole resistance rates among *E. coli* strains causing uncomplicated UTI range from 15% to 42% in different regions,[18] with a similar range among European countries and Brazil.[19] Many drug-resistant *E. coli* organisms are clonal and have been hypothesized to enter new environments by contaminated products ingested by community residents.[20] The prevalence of *E. coli* resistance to nitrofurantoin is generally less than 5%, although nitrofurantoin is inactive against *Proteus* spp. and some *Enterobacter* and *Klebsiella* spp. Fluoroquinolones remain active against most *E. coli* strains causing uncomplicated cystitis, although resistance is increasing in certain areas of the world.[18,19] In a recent antimicrobial susceptibility study of more than 12 million *E. coli* isolates from U.S. outpatients, fluoroquinolone resistance increased from 3% to 17% over 10 years.[21] In addition, infections caused by extended-spectrum β-lactamase (ESBL)–producing strains are increasing in number, even in the setting of uncomplicated UTI.

Recommended management of acute uncomplicated cystitis is summarized in Figure 53-1 and Table 53-3. Updated IDSA guidelines emphasize the importance of considering ecological adverse effects of antimicrobial agents (i.e., selection for colonization or infection with multidrug-resistant organisms—so-called "collateral damage") when selecting a treatment regimen.[22] Short-course regimens are recommended as first-line treatment for acute uncomplicated cystitis because of comparable efficacy, better compliance, lower cost, and fewer adverse effects than with longer regimens.[23] Given the benign nature of uncomplicated cystitis along with its high frequency, the IDSA guidelines give equal weight to the risk of ecological adverse effects and drug effectiveness in the recommendations.

Nitrofurantoin is well tolerated and has good efficacy when given twice daily for 5 days, and it has a low propensity for ecological adverse effects.[24] Despite concern about the high prevalence of resistance to TMP-SMX, this combination remains very effective and is inexpensive and well tolerated. Fosfomycin is also considered a first-line regimen because of its low propensity for ecological adverse

Oral Regimens for Acute Uncomplicated Cystitis

Drug	Dose (mg)	Interval*	Comment
Trimethoprim-sulfamethoxazole (TMP-SMX)	160/800	q12h	If used in pregnancy (not approved use), avoid in first trimester.
Trimethoprim	100	q12h	If used in pregnancy (not approved use), avoid in first trimester.
Nitrofurantoin			Less active against *Proteus* spp.
Monohydrate/macrocrystals	100	q12h	
Macrocrystals	50	q6h	
Cefpodoxime proxetil	100	q12h	Comparable to TMP-SMX, inferior to ciprofloxacin in 3-day regimen[28]
Fosfomycin	3000	Single dose	Less effective than fluoroquinolone or TMP-SMX
Amoxicillin-clavulanate	500/125	q12h	Inferior to ciprofloxacin in 3-day regimen[27]
Amoxicillin	500	q12h	Used only when causative pathogen is known to be susceptible or for empiric treatment of mild cystitis in pregnancy
Fluoroquinolones			
Ciprofloxacin	100-250	q12h	Avoid fluoroquinolones if possible in pregnancy, nursing mothers, or persons <18 years old. Although highly effective, should be considered second-line treatment to preserve their usefulness for other infections.
Ciprofloxacin extended release	500	q24h	
Levofloxacin	250	q24h	
Ofloxacin	200	q12h	

Table 53-3 Oral antimicrobial agents for acute uncomplicated cystitis or cystitis in patients with possible occult renal or prostatic involvement. *Duration of therapy depends on the clinical setting (see text and Fig. 53-1); *q6h, q12h, q24h,* every 6, 12, or 24 hours.

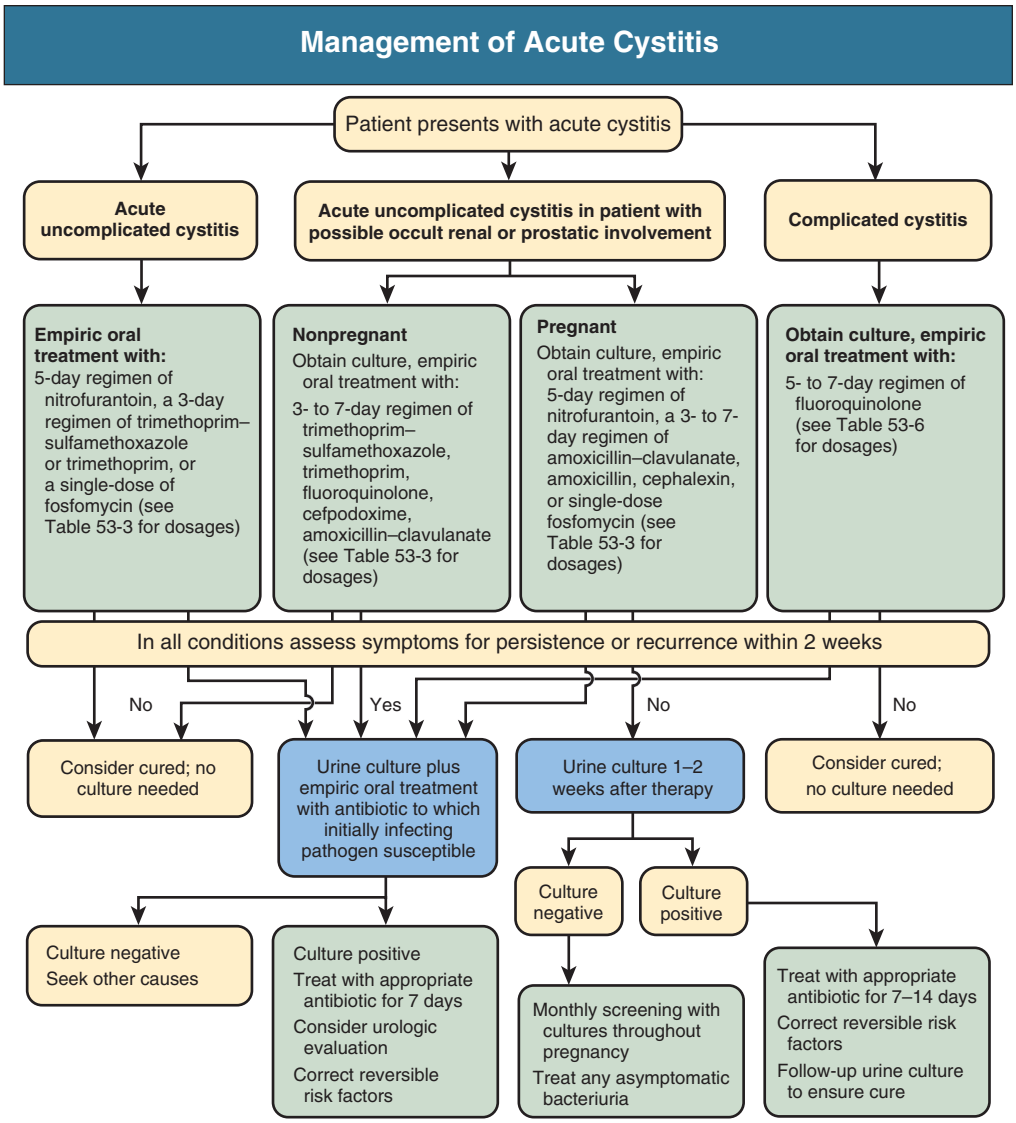

Figure 53-1 Algorithm for management of acute cystitis.

effects, even though it appears to be clinically inferior to TMP-SMX and fluoroquinolones.[22] Moreover, fosfomycin appears to have a role as a therapeutic agent effective against ESBL *E. coli* UTIs.[25]

The choice of an antimicrobial agent should be individualized based on the patient's allergy and compliance history, local practice patterns, prevalence of resistance in the local community (if known), availability, cost, and patient and provider threshold for failure.[22] If a first-line antimicrobial is not a good choice because of one or more of these factors, fluoroquinolones or β-lactams are reasonable alternatives, although it is preferable to minimize their use because of concerns about ecological adverse effects.[22] Thus, although fluoroquinolones (3-day duration) are highly effective in the treatment of cystitis, many experts recommend that they be considered as second-line therapy for uncomplicated cystitis, to help preserve their usefulness in the treatment of other infections.[22] In general, β-lactam antibiotics have been inferior to TMP-SMX or fluoroquinolones in regimens of the same duration.[26]

Although broad-spectrum oral β-lactams (e.g., cefixime, cefpodoxime, cefprozil, cefaclor, amoxicillin-clavulanate) demonstrate *in vitro* activity against most uropathogens causing uncomplicated cystitis, clinical data are sparse. Recent trials demonstrated that cure rates with 3-day regimens of amoxicillin-clavulanate[27] or cefpodoxime proxetil[28] were lower than a 3-day regimen of ciprofloxacin. Moreover, there are concerns about the possibility of ecological adverse effects with oral broad-spectrum cephalosporins, as has been observed with parenteral cephalosporins, although again few data exist. Given increasing antimicrobial resistance and the benign nature of cystitis, antimicrobial-sparing management strategies, such as the use of anti-inflammatory drugs (ibuprofen) or delayed treatment, neither of which is in common clinical use, are of increasing interest.[15]

Routine post-treatment cultures in women are not indicated unless the patient is symptomatic. If the patient remains symptomatic and has documented persistent infection, a longer course of therapy based on sensitivities, usually with a fluoroquinolone, should be used. The benefit of detecting and treating asymptomatic bacteriuria in healthy women has been demonstrated only in pregnancy and before urologic instrumentation or surgery.[7,29]

Recurrent Acute Uncomplicated Cystitis in Women

Most recurrent cystitis in healthy women is caused by repeated infection, which in many cases is caused by persistence of the initially

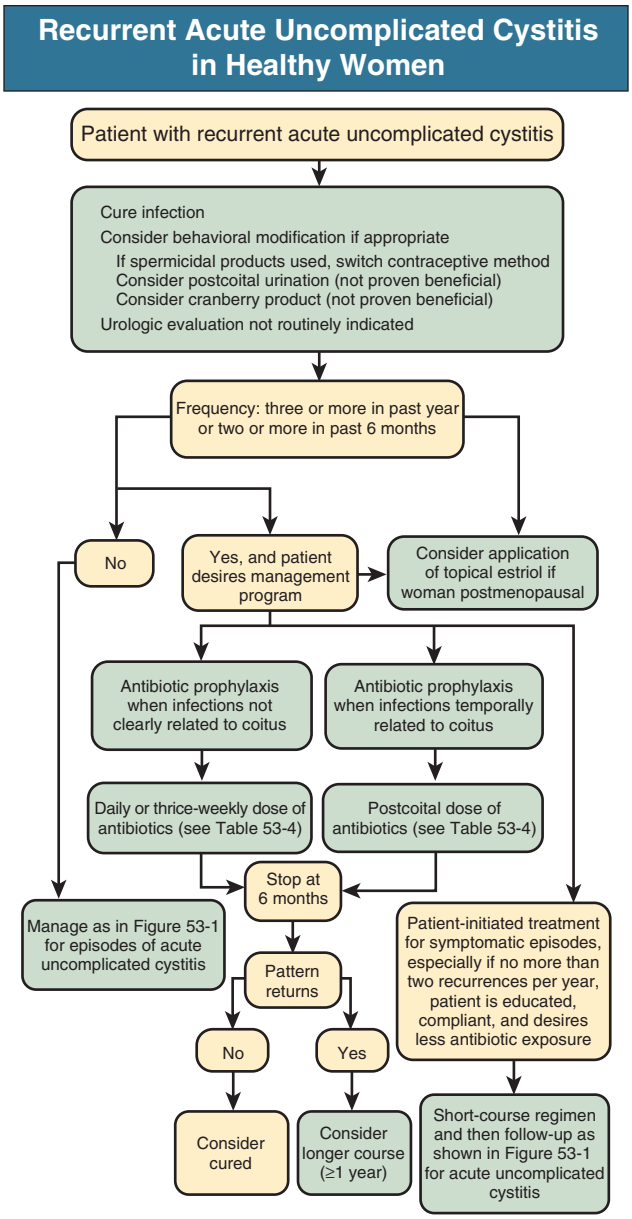

Figure 53-2 Management strategies for recurrent acute uncomplicated cystitis.

Prophylaxis for Recurrent Acute Uncomplicated Cystitis

Drug	Dose (mg)	Frequency
Continuous Prophylaxis		
TMP-SMX	40/200	Daily
TMP-SMX	40/200	Thrice weekly
Trimethoprim	100	Daily
Nitrofurantoin	50 or 100	Daily
Cefaclor	250	Daily
Cefalexin (cephalexin)	125 or 250	Daily
Norfloxacin*	200	Other fluoroquinolones are likely to be as effective.*
Postcoital Prophylaxis		
TMP-SMX	40/200	Single dose
TMP-SMX	80/400	Single dose
Nitrofurantoin	50 or 100	Single dose
Cefalexin	250	Single dose
Ciprofloxacin*	125	Single dose
Norfloxacin*	200	Single dose
Ofloxacin*	100	Single dose

Table 53-4 Antimicrobial prophylaxis regimens for women with recurrent acute uncomplicated cystitis. See text and Figure 53-2 for management strategy. *Women should be cautioned about pregnancy when fluoroquinolones are being used. Fluoroquinolones are highly effective but not recommended. *TMP-SMX,* Trimethoprim-sulfamethoxazole.

infecting strain in the fecal flora.[30] Experimental studies in mice also suggest that some same-strain recurrent UTIs may be caused by a latent reservoir of uropathogens in the bladder epithelium that persist after the initial UTI,[31] and indirect evidence indicates that this pathogenesis pathway may occur in humans.[32] If the recurrence is within 1 or 2 weeks of treatment, an antimicrobial-resistant uropathogen should be considered, and a urine culture should be performed followed by treatment with an alternative regimen. It is reasonable to treat later recurrences the same as the original infection, although if TMP-SMX has been used in the previous 6 months, an alternative drug should be considered.[15]

The goal of long-term management of recurrent cystitis should be to improve the quality of life while minimizing antimicrobial exposure.[15] Women with recurrent cystitis may benefit from behavioral modification (Fig. 53-2), such as avoiding spermicides, increasing fluid intake, and ensuring postcoital micturition, although the benefit of these practices has not been proved. Although ingestion of cranberry products has been thought to have preventive properties based on small clinical studies and *in vitro* inhibition of uropathogen adherence to uroepithelial cells, a recent randomized, placebo-controlled trial (RCT) showed no benefit from cranberry juice.[33] Women who do not want to try or who obtain no benefit from the preceding approaches should be offered antimicrobial prophylaxis.

Antimicrobial prophylaxis has been shown to reduce the risk of recurrent cystitis by approximately 95% (Table 53-4; see also Fig. 53-2).[34] Prophylaxis should be considered for women who experience three or more infections during a 12-month period, or whenever the woman thinks that her life is being adversely affected by frequent recurrences. Several approaches have been used, including continuous prophylaxis, postcoital prophylaxis, and intermittent self-treatment (which is really an early treatment method).[15] In postmenopausal women with recurrent UTI, intravaginal estriol is effective, presumably by normalizing the vaginal flora, which reduces the risk for coliform colonization of the vagina.[30] This approach offers an alternative to antimicrobial strategies (see Fig. 53-2).

Acute Uncomplicated Pyelonephritis in Women

Acute pyelonephritis is suggested by fever (temperature ≥38°C), chills, flank pain, nausea and vomiting, and costovertebral angle tenderness. Cystitis symptoms are variably present. Symptoms may vary from a mild illness to a sepsis syndrome with or without shock and renal failure. Pyuria is almost always present, but leukocyte casts, specific for UTI, are infrequently seen. Gram stain of the urine sediment may aid in differentiating gram-positive and gram-negative infections, which can influence empiric therapy. A urine culture,

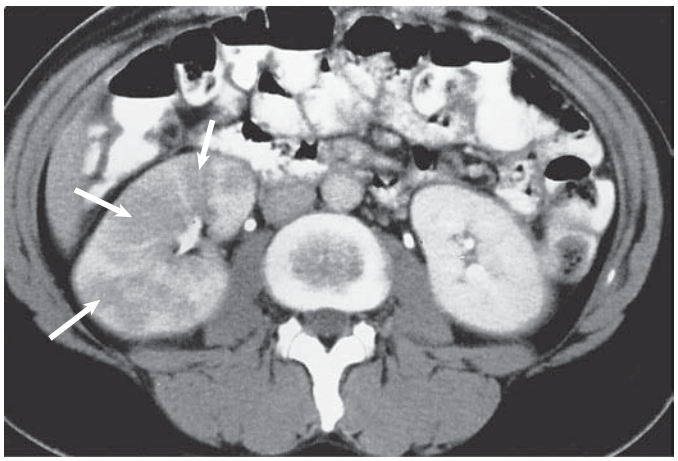

Figure 53-4 Acute pyelonephritis. Contrast-enhanced CT scan shows areas of lower density caused by infection and edema *(arrows)*. *(Courtesy W. Bush, University of Washington, Seattle.)*

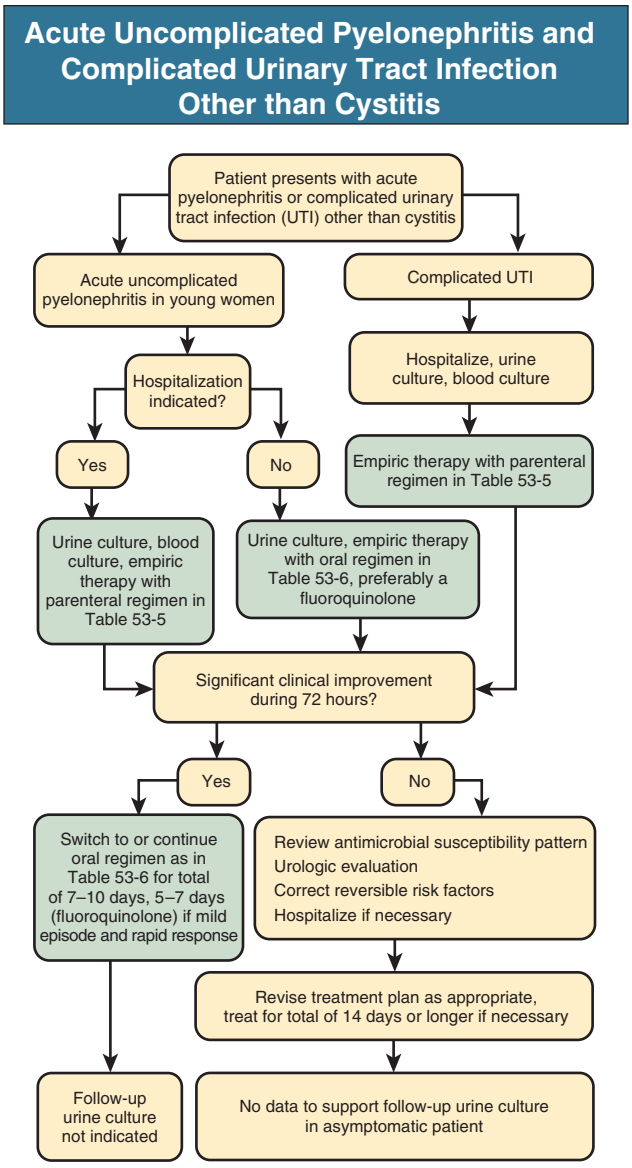

Figure 53-5 Management algorithm for acute uncomplicated pyelonephritis and complicated urinary tract infection other than cystitis.

which should be performed in all women with acute pyelonephritis, will have 10^4 cfu/ml or more of uropathogens in up to 95% of patients.[16]

On pathologic examination, the kidney shows a focal inflammatory reaction with neutrophil and monocyte infiltrates, tubular damage, and interstitial edema (Fig. 53-3). Although imaging studies are generally not performed, the infected kidney is often enlarged, and contrast-enhanced computed tomography (CT) shows decreased opacification of the affected parenchyma, typically in patchy, wedge-shaped, or linear patterns (Fig. 53-4).

The availability of effective oral antimicrobials, especially the fluoroquinolones, allows initial oral therapy in appropriate patients or, in those requiring parenteral therapy, the timely conversion from intravenous to oral therapy and reduced need for hospitalization. Indications for admission to the hospital include inability to maintain oral hydration or to take medications; uncertain social situation or concern about compliance; uncertainty about the diagnosis; and severe illness with high fevers, severe pain, and marked debility. Outpatient therapy is safe and effective for select patients who can be stabilized with parenteral fluids and antibiotics in an urgent care facility and sent home with oral antibiotics under close supervision. In one population-based study of acute pyelonephritis in adult women, only 7% were hospitalized.[4]

The management strategy for acute uncomplicated pyelonephritis is shown in Figure 53-5. Many effective parenteral (Table 53-5) and oral (Table 53-6) regimens are available for patients with acute uncomplicated pyelonephritis. In the outpatient setting, an oral fluoroquinolone should be used for initial empiric treatment of infection caused by gram-negative bacilli.[26] TMP-SMX or other agents can be used if the infecting strain is known to be susceptible. If enterococci are suspected from the Gram stain, amoxicillin should be added to the treatment regimen until the causative organism is identified. Second- and third-generation cephalosporins also appear effective, although published data are sparse. Neither nitrofurantoin nor fosfomycin is approved or recommended for the treatment of pyelonephritis. When antimicrobial resistance or tolerance of oral medications is a concern, one or more doses of a broad-spectrum parenteral antimicrobial is recommended until *in vitro* activity can be ensured.[22]

For hospitalized patients, ceftriaxone is an effective and inexpensive agent if the Gram stain is not suggestive of gram-positive bacterial infection. If enterococci are suspected on the basis of a stain showing gram-positive bacteria, ampicillin plus gentamicin, ampicillin-sulbactam, and piperacillin-tazobactam are reasonable broad-spectrum empiric choices. TMP-SMX should not be used alone for empiric therapy for pyelonephritis in areas with a high prevalence of resistance to this combination. Patients with acute uncomplicated pyelonephritis can often be switched to oral therapy after 24 to 48 hours, although longer intervals of parenteral therapy are occasionally indicated in patients whose symptoms and signs do not improve rapidly, such as those with continued high fever, severe flank pain, or persistent nausea and vomiting.

Treatment of acute uncomplicated pyelonephritis can be limited to 7 days for mildly to moderately ill patients who have a rapid response with resolution of fever and symptoms soon after initiation of treatment. However, β-lactam regimens shorter than 14 days have been associated with unacceptably high failure rates in some studies.[26] One study demonstrated superiority of a 7-day ciprofloxacin regimen over a 14-day TMP-SMX regimen, with the difference accounted for entirely by the higher rate of resistance of the uropathogens to TMP-SMX.[14]

Routine post-treatment urine cultures in asymptomatic patients are not cost-effective, but cultures should be performed if symptoms persist or recur. Recurrent infections are treated with a 7- to 14-day course of an antibiotic to which the organism is susceptible. Symptomatic patients who have persistent infection with the same strain as the initial infecting strain warrant 10 to 14 days of therapy, or even longer in some cases, and complicating factors should be looked for and corrected if found.

Parenteral Regimens for Acute Uncomplicated Pyelonephritis and Complicated Urinary Tract Infection*

Drug	Dose (mg)	Interval
Ceftriaxone	1000-2000	q24h
Cefepime	1000-2000	q12h
Fluoroquinolones†		
Ciprofloxacin	200-400	q12h

Table 53-5 Parenteral regimens for acute uncomplicated pyelonephritis and complicated urinary tract infection. *Duration depends on clinical setting (see text and Fig. 53-5). †Avoid, if possible, in pregnancy. §Recommended if methicillin-resistant *Staphylococcus aureus* (MRSA) is suspected or known.

Acute Cystitis in Healthy Adults with Possible Occult Renal or Prostatic Involvement

Acute cystitis in healthy individuals other than young women is more likely to involve occult renal or prostatic infection (see Box 53-1) and may respond poorly to short-course therapy. Clinicians lack noninvasive tools to localize infections to the kidney or prostate, so clinical estimation of risk in a given patient is imprecise. Some patients, such as those who are diabetic or pregnant, warrant special attention because of the serious complications that can occur if treatment is inadequate. Symptoms, signs, and laboratory findings in this group are the same as those in uncomplicated cystitis in women. Urethritis must be excluded in dysuric sexually active men by a urethral Gram stain or a first-voided urine specimen wet-mount evaluation for urethral leukocytosis.

A urine culture specimen should be obtained routinely in patients before treatment (see Fig. 53-1). Empiric treatment is similar to that used for uncomplicated cystitis in women, although it is reasonable to treat men, who may have prostatic involvement, for longer. Nitrofurantoin and fosfomycin should be avoided except for cystitis in pregnancy, in which duration of treatment is 5 days or single-dose, respectively. A recent large retrospective study of male veterans with UTI found no difference in recurrence rates with 7 days of treatment versus longer, with a trend toward more *Clostridium difficile* infections in those treated longer.[35]

Routine post-treatment cultures are not indicated unless the patient is symptomatic, except in pregnant women (see Fig. 53-1). In men, early recurrence of UTI with the same species suggests a

Oral Regimens for Acute Uncomplicated Pyelonephritis and Complicated Urinary Tract Infection

Drug	Dose (mg)	Interval	Comment
Fluoroquinolones			Preferred for empiric treatment; avoid if possible in pregnancy, nursing mothers, or persons <18 years old
Ciprofloxacin	500	q12h	
Ciprofloxacin extended release	1000	q24h	
Levofloxacin	250 to 750	q24h	
Trimethoprim-sulfamethoxazole	160/800	q12h	Use only when the causative pathogen is known to be susceptible. If used in pregnancy (not approved use), avoid in first trimester.
Cefpodoxime proxetil	200	q12h	Data are sparse; use only when the causative pathogen is known to be susceptible.
Amoxicillin-clavulanate	500/125 to 875/125	q8h	Use only when the causative pathogen is known to be susceptible, or in addition to a broad-spectrum agent when empiric coverage against enterococci is desirable.

Table 53-6 Oral regimens for acute uncomplicated pyelonephritis and complicated urinary tract infection. Duration depends on clinical setting (see text and Fig. 53-5).

prostatic source of infection and warrants a 4- to 6-week regimen of either a fluoroquinolone (preferable) or TMP-SMX, depending on the antimicrobial susceptibility of the infecting strain.

Complicated Infections

Patients with complicated UTI may present with classic signs of cystitis and pyelonephritis but may also have vague or nonspecific symptoms, such as fatigue, irritability, nausea, headache, and abdominal or back pain. Signs and symptoms may exist for weeks to months before diagnosis. Complicated UTI, as with uncomplicated infection, is generally associated with pyuria and bacteriuria, although these may be absent if the infection does not communicate with the collecting system.

Urine culture should always be performed in patients with suspected complicated UTI. The IDSA consensus definition of complicated UTI is 10^5 cfu/ml or more in women and 10^4 cfu/ml or more in men,[16] but lower counts in symptomatic persons, as demonstrated in patients with uncomplicated UTI, may well represent significant bacteriuria. This is especially true when the specimen is collected from a urinary catheter. Thus, it is reasonable to use a colony count threshold of 10^3 cfu/ml or more to diagnose complicated UTI.

The wide variety of underlying conditions (see Box 53-1), diverse bacterial agents (see Table 53-2), and paucity of RCTs make generalizations about antimicrobial therapy difficult. Figure 53-1 outlines the management strategy for complicated cystitis, and Figure 53-5 provides a management algorithm for complicated infections other than cystitis.

Correction of any underlying anatomic, functional, or metabolic defect must be attempted, because antibiotics alone may not be successful.[1] For empiric therapy in patients with mild to moderate illness who can be treated with oral medication, the fluoroquinolones provide the broadest spectrum of antimicrobial activity, cover most expected pathogens, and achieve high levels in the urine and urinary tract tissue. An exception is moxifloxacin, which in contrast to other fluoroquinolones such as ciprofloxacin and levofloxacin, may not achieve sufficient concentrations in urine to be effective for complicated UTI. If the infecting pathogen is known to be susceptible, TMP-SMX or other agents are reasonable therapeutic choices.

For initial treatment in more seriously ill, hospitalized patients, several parenteral antimicrobial agents are available (see Table 53-5). The broader-spectrum agents shown in Table 53-5 are preferable for health care–associated infections. In contrast to uncomplicated UTI, *S. aureus* is more common in complicated UTIs, and if suspected, the therapeutic regimen should have activity against *S. aureus*. Studies show that a high proportion of *S. aureus* isolates, even in the community, are methicillin resistant (MRSA), so vancomycin should be included in the empiric treatment regimen if *S. aureus* is suspected. Potential concerns that must be considered in the management of complicated UTI include the increasing prevalence of resistance to fluoroquinolones in institutional settings and the frequency of enterococcal infections.

The antimicrobial regimen can be modified when the infecting strain has been identified and antimicrobial susceptibilities are known. Patients receiving parenteral therapy can be switched to oral treatment after clinical improvement. Few studies have been performed that evaluate duration of treatment in populations with complicated UTIs. However, it is desirable to limit the duration of treatment, especially for milder infections, to reduce the selection pressure for drug-resistant flora. In one study, clinical and microbiologic success rates after treatment were almost identical in patients with acute pyelonephritis or complicated UTI treated with a 5-day course of levofloxacin or a 10-day course of ciprofloxacin.[36] These data suggest that a 7- to 10-day regimen is reasonable for most patients with complicated UTI, depending on their severity of illness and clinical response; shorter regimens, such as a 5-day regimen of a urinary fluoroquinolone, are likely to be sufficient in those patients who are less severely ill, are infected with uropathogens susceptible to the antibiotic used, and have a rapid response to treatment. At least 10 to 14 days of therapy is recommended in patients who have a delayed response.

Chronic Kidney Disease

Because of the wide variety of underlying diseases and comorbidities, prior instrumentation of the urinary tract, and differences in age and gender, the incidence of UTI in patients with chronic kidney disease (CKD) is not known.[37] Moreover, there are few data on urine concentrations of antimicrobials used for the treatment of UTI in patients with CKD.[38] Studies in animals suggest that (1) urine drug concentrations are necessary to sterilize urine, (2) effective tissue concentrations are necessary to treat pyelonephritis, and (3) serum concentrations of antimicrobials are correlated with the drug concentrations in renal tissue. Thus, for patients with CKD who have a therapeutic serum drug level and adequate perfusion of the renal parenchyma, the delivery of therapeutic concentrations of both the parenchyma and the urine should be adequate, but some oral agents for cystitis may not deliver adequate concentrations to the urine.[38] For patients with low glomerular filtration rate (GFR) and pyelonephritis or cystitis, the agents listed in Tables 53-5 and 53-6 for pyelonephritis and complicated cystitis should be adequate to treat these infections in patients with chronic renal impairment if the organism is susceptible.[38]

As noted previously, however, β-lactams are not as effective as fluoroquinolones, even in patients with normal renal function.[26] For oral treatment, renally adjusted doses of ciprofloxacin or levofloxacin, but not moxifloxacin, are recommended. Nitrofurantoin and sulfamethoxazole are not recommended in patients with reduced creatinine clearance, although trimethoprim concentrations appear to be adequate.[37] Likewise, according to the package insert, renal impairment significantly decreases the excretion of fosfomycin, which thus also should not be used in such patients.

Catheter-Associated Infections

Approximately 15% to 25% of patients in general hospitals have a urethral catheter inserted at some time during their stay, and approximately 5% to 10% of long-term care facility residents are managed with urethral catheterization, in some cases for years. The incidence of bacteriuria associated with indwelling catheters is 3% to 10% per day of catheterization, and the duration of catheterization is the most important risk factor for the development of catheter-associated bacteriuria.

Catheter-associated bacteriuria is the most common source of gram-negative bacteremia in hospitalized patients. Complications of long-term catheterization (≥30 days) include almost universal bacteriuria, often with multiple antibiotic-resistant flora, and (in addition to cystitis, pyelonephritis, and bacteremia, as seen with short-term catheterization) frequent febrile episodes, catheter obstruction, stone formation associated with urease-producing uropathogens, and local genitourinary infections. Other rare complications include fistula formation and bladder cancer. An increase in mortality risk has been reported with catheter-associated bacteriuria, but it is difficult to distinguish the role of the catheter because most deaths occur in patients who have severe underlying disease.

Most episodes of catheter-associated bacteriuria are asymptomatic and do not require routine screening or treatment because

treatment does not reduce the complications of bacteriuria and can lead to antimicrobial resistance.[7] Moreover, the presence or absence of pyuria does not differentiate symptomatic from asymptomatic urinary infection.[7] Symptomatic UTIs, often caused by many multidrug-resistant uropathogens, warrant broad-spectrum therapy, as described previously. In a symptomatic catheterized patient, a urine culture specimen should be obtained from a freshly placed catheter if the catheter has been in place for a few days, because the catheter biofilm may result in spurious culture results. Moreover, clinical outcomes are improved if the catheter is replaced at the time of antimicrobial therapy.[39] Seven days is the recommended duration of antimicrobial treatment for patients who have prompt resolution of symptoms, and 10 to 14 days if response is delayed.[40]

Preventive measures are indicated to reduce the morbidity, mortality, and costs of catheter-associated infection. Effective strategies include avoidance of a catheter when possible and, when the catheter is necessary, sterile insertion, prompt removal, and strict adherence to a closed collecting system.[6,40] Bundling of preventive steps may be useful.[41] Meta-analyses have shown that rates of catheter-associated bacteriuria, at least in patients catheterized for less than 2 weeks, are higher in patients with an indwelling urethral catheter than in those with intermittent or suprapubic catheterization.[42] Likewise, condom catheterization is preferable to indwelling urethral catheterization in appropriately selected men.[43] Although highly effective in reducing catheter-associated UTI rates, prophylactic systemic antimicrobial agents are generally not recommended for routine use because of concerns about selection for antimicrobial resistance. Antimicrobial-coated catheters appear to be effective in reducing catheter-associated bacteriuria in patients catheterized for less than 2 weeks, but these have not been shown to be effective in reducing symptomatic infection.

Spinal Cord Injury

Spinal cord injury alters the dynamics of voiding and often requires the use of bladder drainage with catheters. The diagnosis of UTI in patients with spinal cord injuries is often problematic and is based on the combination of symptoms and signs (which are often nonspecific), pyuria, and significant bacteriuria. Uropathogens are usually present in quantities of 10^5 cfu/ml or more. Fluoroquinolones are the empiric oral agents of choice in patients with mild to moderate infection, although many uropathogens, even in the outpatient setting, are resistant to this class of antibiotic, and parenteral antibiotics may be needed.

Treatment of asymptomatic bacteriuria in patients with spinal cord injuries is not of proven benefit and increases the risk for infection with antimicrobial-resistant uropathogens.[7,44] Likewise, antibiotic prophylaxis is generally not recommended, although it may be considered for select outpatients with frequent symptomatic UTIs for whom there are no correctible risk factors. Recent studies have shown that use of a hydrophilic-coated catheter for intermittent catheterization is associated with a reduction in the incidence of symptomatic UTI in patients with spinal cord injury.[45]

Prostatitis

Prostatitis occurs in up to 25% of men during their lifetime, but it is caused by acute or chronic bacterial infection in a minority.[46] The most common organisms causing bacterial prostatitis are gram-negative bacilli, including *E. coli*, *Proteus* spp., *Klebsiella* spp., *P. aeruginosa,* and less frequently, enterococci and *S. aureus*. The pathogenesis of prostatitis is believed to be related to reflux of infected urine from the urethra into the prostatic ducts. Prostatic calculi, commonly found in adult men, may provide a nidus for bacteria and protection from antibacterial agents.

Acute bacterial prostatitis is rare. Patients present with dysuria, frequency, urgency, obstructive voiding symptoms, fever, chills, and myalgias. The prostate is tender and swollen. Prostatic massage, as a diagnostic test, is contraindicated in men in whom the diagnosis of acute prostatitis is being considered because of the risk for precipitating bacteremia. The patient will usually have pyuria and a positive urine culture. Patients who are severely ill require hospitalization and parenteral antibiotics, but many patients can be treated in the outpatient setting with oral fluoroquinolones. The recommended duration of treatment is 14 to 30 days.[46] Rarely, abscess formation may occur.

Chronic bacterial prostatitis is characterized by recurrent UTIs with the same uropathogen with intervening asymptomatic periods. The prostate typically is normal to palpation during asymptomatic periods. Chronic bacterial prostatitis is characterized microscopically by the presence of 10 or more leukocytes per high-power field in expressed prostatic secretions or postmassage voided urine in the absence of significant pyuria in first-voided and midstream urine specimens, as well as a uropathogen colony count at least 10-fold higher in the expressed prostatic secretions or postmassage voided urine compared with the first-voided midstream urine. In addition, macrophage-laden fat droplets (oval fat bodies) are usually prominent in the prostatic secretions. These tests, however, are infrequently performed by urologists. Cure rates, which historically have been low, are 60% to 80% with the fluoroquinolones, which are the antibiotics of choice. The optimal duration of treatment is unknown, but 4 to 6 weeks is recommended by some authorities,[46] whereas others recommend up to 3 months. Some patients require long-term, low-dose suppressive therapy to prevent symptomatic UTIs. Surgical intervention is only rarely considered and is associated with high morbidity.

Renal Abscess

Renal cortical and corticomedullary abscesses and perirenal abscesses occur in 1 to 10 per 10,000 hospital admissions.[47] Patients usually present with fever, chills, back or abdominal pain, and costovertebral angle tenderness, but they may have no urinary symptoms or findings if the abscess does not communicate with the collecting system, as often occurs with a cortical abscess. Bacteremia may be primary (cortical abscess) or secondary (corticomedullary or perirenal). The clinical presentation may be insidious and nonspecific, especially with perirenal abscess, and the diagnosis may not be made until admission to a hospital or at autopsy. CT is recommended to establish the diagnosis and location of a renal or perirenal abscess (Fig. 53-6). Empiric antibiotic therapy should be broad and cover *S. aureus* and other uropathogens causing complicated UTI (see Fig. 53-5 and Table 53-5) and modified once urine culture results are known.

A *renal cortical abscess* (renal carbuncle) is usually caused by *S. aureus*, which reaches the kidney by hematogenous spread. Treatment with antibiotics is usually effective, and drainage is not required unless the patient is slow to respond. A *renal corticomedullary abscess,* in contrast, usually results from ascending UTI in association with an underlying urinary tract abnormality, such as obstructive uropathy or VUR, and is usually caused by common uropathogenic species such as *E. coli* and other gram-negative bacilli. Such abscesses may extend deep into the renal parenchyma, perforate the renal capsule, and form a perirenal abscess. Treatment with antimicrobial agents without drainage may be effective if the abscess is small and if the underlying urinary tract abnormality can be corrected. Aspiration of the abscess may be necessary in some patients, and nephrectomy may occasionally be required in patients with diffuse renal involvement or with severe sepsis. Perirenal abscesses

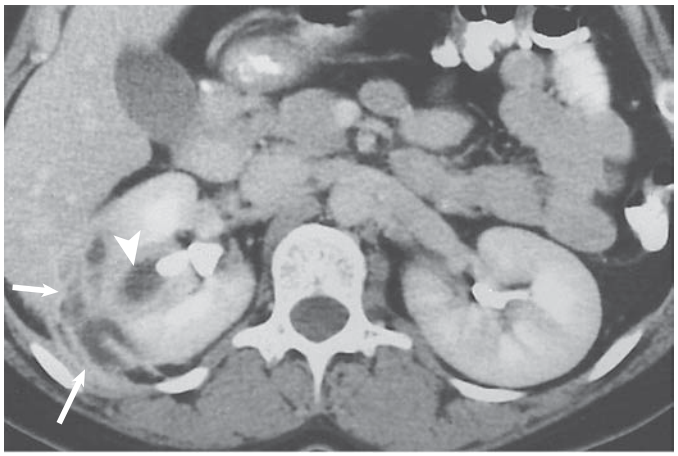

Figure 53-6 Renal abscess. Contrast-enhanced CT scan shows an abscess in the medulla of the kidney *(arrowhead)* with penetration and extension into the perinephric space *(arrows)*. *(Courtesy L. Towner.)*

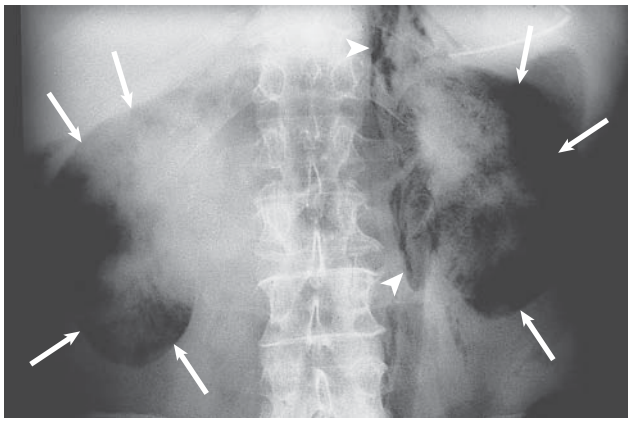

Figure 53-7 Emphysematous pyelonephritis. A plain radiograph in this febrile diabetic patient revealed diffuse gas formation throughout both kidneys *(outlined by arrows)* and gas dissecting in the left retroperitoneal space *(arrowheads)*. *(Courtesy W. Bush, University of Washington, Seattle.)*

usually occur in the setting of obstruction or other complicating factors (see Box 53-1) and result from ruptured intrarenal abscesses, hematogenous spread, or spread from a contiguous infection. Causative uropathogens are those usually found in complicated UTIs (see Table 53-2), including *S. aureus* and enterococci; polymicrobial infections are common. Anaerobes or *Mycobacterium tuberculosis* may be causative (see Chapter 54). A previously high mortality rate has been lowered with earlier diagnosis and therapy. In contrast to the other types of renal abscesses, drainage of pus is the cornerstone of therapy, and nephrectomy may be indicated.

Papillary Necrosis

More than half of patients who develop papillary necrosis have diabetes, almost always in conjunction with a UTI, but the condition also complicates sickle cell disease, analgesic abuse, and obstruction. Renal papillae are vulnerable to ischemia because of the sluggish blood flow in the vasa recta, and relatively modest ischemic insults may cause papillary necrosis. The clinical features are those typical of pyelonephritis. In addition, passage of sloughed papillae into the ureter may cause renal colic, renal impairment or failure, or obstruction with severe urosepsis. Papillary necrosis in the setting of pyelonephritis is associated with pyuria and a positive urine culture. Causative uropathogens are those typical of complicated UTI. CT is the preferred diagnostic procedure. Radiologic findings include an irregular papillary tip; dilated calyceal fornix; extension of contrast material into the parenchyma; and a separated crescent-shaped papilla surrounded by contrast, called the *ring sign*. Broad-spectrum antibiotics are indicated. Papillae obstructing the ureter may require removal with a cystoscopic ureteral basket or relief of obstruction by insertion of a ureteral stent.

Emphysematous Pyelonephritis

Emphysematous pyelonephritis is a fulminant, necrotizing, life-threatening variant of acute pyelonephritis caused by gas-forming organisms, including *E. coli*, *Klebsiella pneumoniae*, *P. aeruginosa*, and *P. mirabilis*.[48] Up to 90% of cases occur in diabetic patients, and obstruction may be present. Symptoms are suggestive of pyelonephritis, and there may be a flank mass. Dehydration and ketoacidosis are common. Pyuria and a positive urine culture are usually present. Gas is usually detected by a plain abdominal radiograph or ultrasound (Fig. 53-7). CT is the diagnostic modality of choice, however, because it can localize the gas better than ultrasound. Accurate localization of gas is important because gas may also form in an infected obstructed collecting system or renal abscess; although serious, these conditions do not carry the same poor prognosis and are managed differently. Parenteral broad-spectrum antibiotics and percutaneous catheter drainage with relief of obstruction may be adequate for less severely ill patients, but nephrectomy is warranted for those who are more severely ill and those less severely ill who do not respond to the preceding steps. Medical treatment is associated with mortality of 60% to 80%, which is lowered to 20% or less with surgical intervention (e.g., nephrectomy, percutaneous drainage).

Renal Malacoplakia

Malacoplakia is a chronic granulomatous disorder of unknown etiology involving the genitourinary, gastrointestinal, skin, and pulmonary systems.[49] It is characterized by an unusual inflammatory reaction to a variety of infections and is manifested by the accumulation of macrophages containing calcified bacterial debris called Michaelis-Gutmann bodies (Fig. 53-8). The underlying disorder appears to be a monocyte-macrophage bactericidal defect. The diagnosis is made by histologic examination of involved tissue. Genitourinary malacoplakia, most often involving the bladder, is usually associated with gram-negative UTI. Patients with renal malacoplakia generally have fever, flank pain, pyuria and hematuria, bacteriuria, and if both kidneys are involved, impaired renal function. CT usually shows enlarged kidneys with areas of poor enhancement, and the condition may be indistinguishable from other infectious or neoplastic lesions. On occasion, the malacoplakia may extend through the renal capsule into the perinephric space, simulating a renal carcinoma (Fig. 53-8). Treatment consists of therapy with a broad-spectrum antimicrobial, attempted correction of any underlying complicating conditions, and improvement of renal function. Nephrectomy is recommended for advanced unilateral disease. When the disease is bilateral or occurs in a transplanted kidney, the prognosis is very poor.

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis is a poorly understood, uncommon but severe chronic destructive granulomatous inflammation of renal parenchyma associated with obstruction and infection of the urinary tract.[50] The renal parenchyma is replaced with a diffuse or segmental cellular infiltrate of foam cells, which are lipid-laden macrophages. The process may also extend beyond the renal capsule to the retroperitoneum. Its pathogenesis appears to be multifactorial,

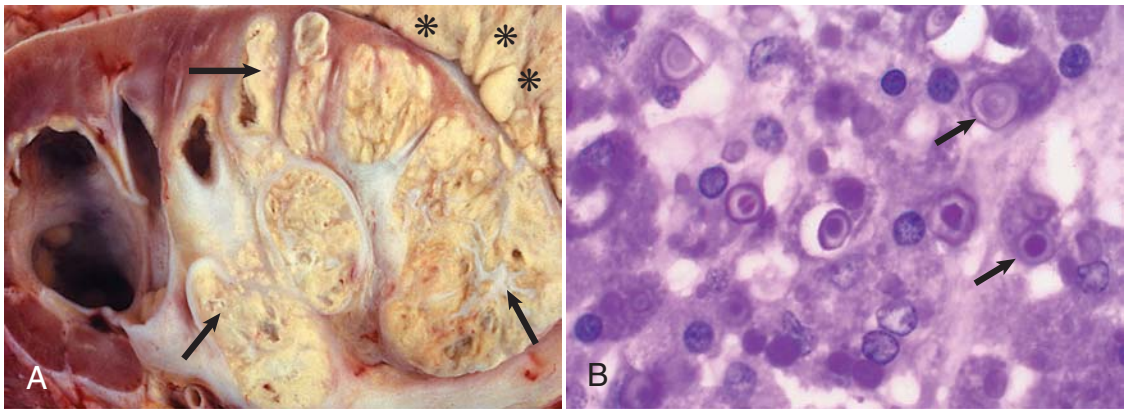

Figure 53-8 Renal malacoplakia. A, Malacoplakia involving most of the kidney *(arrows)* with extension through the capsule *(asterisks)*. A small portion of normal kidney is present that is associated with hydronephrosis secondary to obstruction by the malacoplakia. **B,** The kidney tissue shows many macrophages containing intracytoplasmic inclusions (*arrows* identify two particularly well-demarcated macrophages with Michaelis-Gutmann bodies). *(Courtesy L. Truong, Baylor College of Medicine, Houston, and N. Sheerin, Guy's Hospital, London.)*

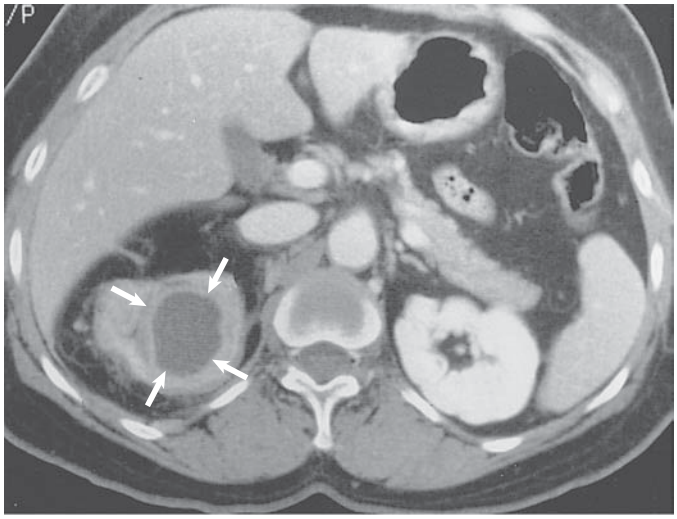

Figure 53-9 Xanthogranulomatous pyelonephritis. Contrast-enhanced CT scan with the inflammatory mass outlined by *arrows*. Pathologic diagnosis confirmed xanthogranulomatous pyelonephritis. *(Courtesy W. Bush, University of Washington, Seattle.)*

with infection complicating obstruction and leading to ischemia, tissue destruction, and accumulation of lipid deposits. Patients with xanthogranulomatous pyelonephritis are characteristically middle-aged women and have chronic symptoms such as flank pain, fever, chills, and malaise. Flank tenderness, a palpable mass, and irritative voiding symptoms are common. The urine culture is usually positive with *E. coli,* other gram-negative bacilli, or *S. aureus*. CT generally shows an enlarged nonfunctioning kidney, often the presence of calculi and low-density masses (xanthomatous tissue), and in some cases, involvement of adjacent structures (Fig. 53-9). It may be difficult to distinguish from neoplastic disease. Broad-spectrum antimicrobials are indicated, but total or partial nephrectomy is usually necessary for cure.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria, as noted previously, is a common and generally benign infection.[7,29] Pyuria is often present, especially in elderly people, and is a predictor for subsequent symptomatic UTI in some groups. Causative uropathogens are the same as those causing UTIs in the same population. Screening for and treatment of asymptomatic bacteriuria is generally not warranted.[7] However, patients at high risk for serious complications warrant a more aggressive approach to diagnosis and treatment, including pregnant women and patients undergoing urologic surgery. Current management strategies in patients with a renal transplant, including long-term antimicrobial prophylaxis, help prevent both asymptomatic bacteriuria and symptomatic UTI. It is not clear, however, whether screening for or treatment of asymptomatic bacteriuria in such patients is worthwhile.[7] Some authorities advise treatment of asymptomatic bacteriuria found in patients with anatomic or functional abnormalities of the urinary tract, diabetic patients, and patients with urea-splitting bacteria (e.g., *P. mirabilis, Klebsiella* spp.).[29] Evidence-based guidelines for screening and treatment of asymptomatic bacteriuria in these populations are needed.

Asymptomatic bacteriuria in catheterized patients in hospitals and long-term care facilities, although thought to be generally benign, represents a large reservoir of antimicrobial-resistant urinary pathogens that increases the risk of cross-infection among catheterized patients and results in frequent inappropriate antimicrobial use.[40]

IMAGING OF THE URINARY TRACT

Urologic consultation and evaluation of the urinary tract should be considered in patients who present with symptoms or signs of obstruction, urolithiasis, flank mass, or urosepsis. Similarly, such an evaluation should be considered for those patients with presumptive uncomplicated or complicated UTI who have *not* had a satisfactory clinical response after 72 hours of treatment, to exclude complicating factors. A renal ultrasound can detect the size and contour of the kidneys and bladder, the presence of a renal mass or abscess, certain renal and ureteral calculi, hydronephrosis suggestive of obstructive uropathy, and elevated postvoid residual urine.[51] A plain abdominal radiograph (kidneys-ureters-bladder, KUB) can identify radiopaque calculi along the genitourinary tract, especially proximal and distal ureteral stones that can be missed on ultrasound. However, renal ultrasound and KUB are less sensitive than CT for detection of many conditions in patients with complicated UTI. Thus, any finding suggesting mass or complex fluid collection should prompt follow-up imaging with CT. CT offers fine anatomic detail and is thus the superior study for evaluation of focal inflammation, renal or perirenal abscess and masses, and both radiopaque and radiolucent stones. However, CT also carries the greatest risk profile, exposing the

patient to both intravenous contrast and ionizing radiation.[51] Non–contrast-enhanced spiral CT is a rapid, safe, and sensitive method for evaluating patients with suspected renal stones. Radionuclide imaging procedures have no role in the evaluation of adults with UTI, although they are very useful in children with pyelonephritis (see Chapter 63).

Excretory urography and cystoscopy in women with recurrent cystitis rarely demonstrate abnormalities or alter management,[3] and therefore are not recommended. Likewise, imaging studies in young women with acute pyelonephritis are also generally not cost-effective and have a low diagnostic yield, although it is reasonable to obtain such studies after two episodes of pyelonephritis, or if any complicating factor is present (see Box 53-1). Imaging studies and cystoscopy are probably unnecessary in a man who has had a single UTI with no obvious complicating factors and whose infection responds promptly to treatment.

CHAPTER 54

Tuberculosis of the Urinary Tract

R. Kasi Visweswaran and Suresh Bhat

DEFINITION

Tuberculosis (TB), caused mostly by *Mycobacterium tuberculosis,* is a major global health problem. According to a recent report by the World Health Organization (WHO), there were almost 9 million new cases in 2011 and 1.4 million deaths attributed to TB.[1] From 1999 to 2020, there will be an estimated 1 billion new cases of TB if control measures are not improved. In developed countries, TB usually affects older individuals and immigrants from countries with high prevalence. The incidence of TB is 100 times greater in patients with human immunodeficiency virus (HIV), and TB is the most common opportunistic infection in HIV-infected patients.[2] TB also is more common in patients with chronic kidney disease (CKD), especially when associated with anatomic abnormalities or immunosuppression. In some endemic areas, TB has been reported to occur in up to 9% of patients receiving hemodialysis, 9% of renal allograft recipients, and 12% of children with nephrotic syndrome.[3]

Genitourinary TB occurs in about 5% of active TB cases in the non–HIV-infected population.[4] It is almost always secondary to a symptomatic or asymptomatic primary lesion in the lung. Renal involvement may also occur as a complication of miliary (septicemic) TB.

In recent years, the incidence of multidrug-resistant (MDR) TB and extensively drug-resistant (XDR) TB has increased. According to WHO estimates, there were 630,000 cases of MDR TB in 2001.[1] This scenario has compromised programs to eradicate TB.

ETIOLOGY

The tubercle bacillus is a nonmotile, nonsporing, strictly aerobic straight or slightly curved rod-like bacillus that is weakly gram positive and acid and alcohol fast. Mycobacteria have a lipid shell ("lipid barrier") containing mycolic acid that resists proteolysis and uptake into phagolysosomes; muramyl dipeptide, which stimulates a T cell response that elicits the characteristic granuloma; and cell wall glycolipids that inhibit macrophage function. This surrounding coat of inert lipids and surface proteins allows mycobacteria to survive inside phagocytes, where they may remain dormant for years.[5]

Whereas most TB including genitourinary TB is caused by *M. tuberculosis,*[5] other mycobacteria may rarely cause clinical disease, especially in immunocompromised hosts. These include *M. avium-intracellulare*, *M. kansasii, M. bovis, M. fortuitum,* and *M. szulgai*.

PATHOGENESIS

The clinical and pathologic manifestations of TB depend on the virulence of the organism and the effectiveness of the host response. The host response may lead to complete containment of infection or result in an illness of varying severity. Strain differences may also determine whether an infected person develops primary TB, reactivation TB, or a chronic asymptomatic infection. A low serum level of 25-hydroxyvitamin D may also compromise cell-mediated immunity and increase the risk for activation of latent TB.

When an infected droplet with the size of 1 to 5 μm is deposited in the respiratory tract, tonsillar fossa, or gastrointestinal tract, a primary focus develops with the formation of a nonspecific, asymptomatic granuloma. The organisms from the primary focus drain to the regional lymph gland, causing its enlargement, resulting in the *primary complex*. This is often asymptomatic and self-limited.

Bacilli from the regional lymph node may also enter through the thoracic duct into the blood, resulting in silent dissemination to various sites, including the cortex of the kidneys (Fig. 54-1). Here the bacilli elicit an inflammatory response, resulting in granuloma formation that may heal and form a scar, remain dormant for many years, or rupture into the proximal tubule of the nephron. The bacilli in the nephron are trapped at the level of the loop of Henle, where they multiply. The relatively poor blood flow, hypertonicity, and high ammonia concentration in the renal medulla impair the immune responses and favor the formation of medullary granulomas. These granulomas (tuberculomas), which contain macrophages, may undergo coagulative necrosis, forming cheese-like caseous material (Fig. 54-2), and occasionally rupture into the calyx.[6]

The renal medulla is the most common site of involvement of clinical renal TB and is usually unilateral.[7] When this caseous focus ruptures into the collecting system, cavities and ulcers are formed, and involvement of renal papillae may lead to sloughing and papillary necrosis. Healing in the kidney occurs by fibrosis and scarring, resulting in strictures and obstruction. Calcification commences intracellularly by the accumulation of phosphate ions from the disintegration of nucleoproteins and calcium ions from cell membrane damage. These lesions may harbor live mycobacteria, and such dystrophic lesions should be considered active disease and not a sign of healing. Dystrophic calcification of damaged structures may result in a nonfunctioning kidney called "putty" or "cement" kidney. Spread of TB to contiguous structures may occur; ureteritis is common and may result in strictures and obstructive uropathy (Fig. 54-3).

The bladder may develop hyperemia near the ureteral orifice, followed by superficial ulcers and granulomatous changes involving all layers (pancystitis). Healing by fibrosis at the ureteral orifice results in a refluxing "golf-hole" ureter. Extensive fibrosis of the bladder wall results in a thick, small-capacity bladder called "thimble" bladder (Fig. 54-4). Bladder infection may also rarely result from instillation of bacille Calmette-Guérin (BCG) in the bladder as part of treatment of superficial bladder carcinomas.

Involvement of the genital tract is also common. As many as 70% to 80% of men with TB of the urinary tract have epididymitis, prostatitis, seminal vesiculitis, orchitis, or cold abscesses. In women, genital tract involvement is less common; but if present, it usually presents as salpingitis, often diagnosed during investigation for infertility.

Transplanted kidneys may transmit TB to their recipients.[8]

Clinical Features of Urinary Tuberculosis

Features	Frequency (%)	Symptoms
Asymptomatic	25	Detected during autopsy, surgery, or investigations for other diseases
Asymptomatic urinary abnormalities	25	Persistent pyuria, microscopic abnormalities, hematuria
Lower urinary tract symptoms (most common)	40	Frequency, urgency, dysuria, incontinence, nocturia, suprapubic pain, perineal pain
Male genital tract involvement	75	Epididymitis, hemospermia, infertility, reduced semen volume
Female genital tract involvement	<5	Amenorrhea, infertility, vaginal bleeding, pelvic pain
Constitutional symptoms	<20	Fever, reduced appetite, anorexia, weight loss, night sweats
Miscellaneous	—	Urolithiasis, hypertension, acute kidney injury, chronic kidney disease, abdominal colic, abdominal mass

Table 54-1 Clinical features of urinary tuberculosis.

Figure 54-4 Thimble bladder. Cystogram shows small-capacity bladder.

CLINICAL MANIFESTATIONS

Urinary tract TB may be asymptomatic or may mimic other disorders. Patients may present with constitutional symptoms or symptoms related to the lower urinary tract, abdomen, or genitalia (Table 54-1). A high index of suspicion enables early diagnosis. Most patients are 20 to 40 years of age, with a male-female ratio of 2:1. Because active genitourinary TB presents 5 to 15 years after primary infection, it is relatively rare in children. Risk factors for TB include close contact with sputum smear–positive individuals, vagrancy, social deprivation, neglect, immunosuppression, HIV infection or acquired immunodeficiency syndrome (AIDS), diabetes mellitus, CKD, vitamin D deficiency, and other debilitating illness.

Almost 25% of patients have no clinical or laboratory evidence of abnormality, and the diagnosis of urinary TB is made on investigation for other diseases, during surgery, or at autopsy. Another 25% have asymptomatic urinary abnormalities, usually persistent asymptomatic pyuria or hematuria. In patients with persistent pyuria, conventional urine cultures do not yield growth, and the urine is usually acidic; thus the term *acid-sterile pyuria*. Of the patients who are symptomatic, lower urinary tract symptoms, such as frequency, urgency, dysuria, nocturia, frank pyuria, or hematuria, occur in more than 75% of TB patients. Increased urinary frequency is an early symptom and results from inflammation of the bladder. The defect in the urinary concentrating mechanism explains the nocturia.

Recurrent bouts of painless macroscopic (gross) hematuria should alert the clinician to the possible diagnosis of urinary TB, although glomerular diseases such as IgA nephropathy should also be considered. Macroscopic hematuria in urinary TB is a result of bleeding from the ulcerating lesions, inflammation of the urothelium, or rupture of a blood vessel in the vicinity of a cavity. Colicky pain may occur as a presenting manifestation of urinary TB when it is associated with stone, clot, sloughed papilla, or other causes of acute obstruction.

In advanced disease, frequency and urgency related to reduced bladder capacity (thimble bladder) occur. Incomplete emptying, increased susceptibility to infection, and secondary vesicoureteral reflux (VUR) may also occur. In chronic ureteral obstruction, an enlarged kidney, infection, or perinephric collection leads to a dull-aching loin pain. Severe suprapubic pain with backache and dysuria suggests acute tuberculous cystitis. Patients with TB cystitis may show worsening of frequency and urgency after antituberculous treatment because of fibrosis and bladder wall contraction and is a

part of healing process. This should not be mistaken for a nonresponse to therapy. Episodes of pyuria, which may suggest secondary bacterial infection or drainage of a caseous focus into the collecting system, may also be a manifestation of renal TB. Persistence of pyuria after appropriate therapy should lead to an evaluation for urinary TB.

Longstanding renal TB may result in mild tubular proteinuria (<1 g/24 h) in up to 50% of patients. About 15% have proteinuria of more than 1 g/24 h, and nephrotic syndrome caused by amyloidosis may develop in some patients. Rare cases of mesangial proliferative glomerulonephritis have also been reported.

Anemia is seen in less than 20% of patients with nonmiliary disease, but the frequency is higher in those with CKD.[9] A few patients have nephrogenic diabetes insipidus. Renal tubular acidosis may occur. Hyporeninemic hypoaldosteronism may result from the tubulointerstitial injury secondary to obstructive uropathy.[10] Renal function is usually normal, but CKD may develop if both kidneys are extensively damaged.

Some patients with urinary TB present with reduced glomerular filtration rate (GFR), pyuria, microscopic hematuria, and proteinuria, but the urine cultures for mycobacteria are repeatedly negative. These patients respond favorably to antituberculous chemotherapy combined with corticosteroids. The kidneys are of normal size and show diffuse interstitial nephritis, with caseating granulomas containing the bacilli in 75% of the biopsy samples.[11] Hypertension is unusual in renal TB, but intimal proliferation of vessels near inflamed areas may lead to segmental ischemia and renin release.[12] In patients with a nonfunctioning kidney, nephrectomy may help improve the hypertension. Relief of any obstruction may also help lower the blood pressure. Nephrolithiasis may occur in 7% to 18% of patients. Secondary infection with *Escherichia coli* may be seen in 20% to 50% of patients.

Genital involvement is common in men with urinary TB. Epididymitis may present with scrotal discomfort, mass, or a cold abscess that may rupture, leading to a nonhealing posterior scrotal sinus. Thickening of the vas deferens may result in the "beaded" vas. TB of the prostate may present with lower urinary symptoms and perineal pain. The prostate may be hard or boggy. Penile and urethral TB may present with strictures, fistulas, ulcers, or papulonecrotic skin lesions. Hemospermia, reduction of semen volume, and infertility are other manifestations of genital involvement. Direct spread of *M. tuberculosis* to the sexual partner is possible.

Only 5% of women with renal TB also have genital TB. The major manifestation of genital involvement in women is infertility resulting from adherent salpingitis. Secondary amenorrhea, vaginal bleeding, and pelvic pain caused by inflammation may occur.

Constitutional symptoms, such as fever, weight loss, night sweats, fatigue, and anorexia, occur in less than 20% of patients and indicate active infection in other organs or secondary bacterial infection of the urinary tract. A careful examination to identify pulmonary, lymph node, or skeletal TB must be undertaken in all patients who present with constitutional symptoms. The chest radiograph may show evidence of active or healed tuberculous lesions in more than half of cases. Rarely, hypercalcemia may be present as a result of increased synthesis of calcitriol by the granulomas.

PATHOLOGY

Urinary TB may present as a miliary or ulcerocavernous pathologic process. The *miliary* form of TB is rare and is seen particularly in immunosuppressed individuals. The gross appearance of the kidney is characteristic; the cortex is studded with yellowish white, hard, pinhead-sized nodules that on microscopy show several coalescent granulomas with central caseation.

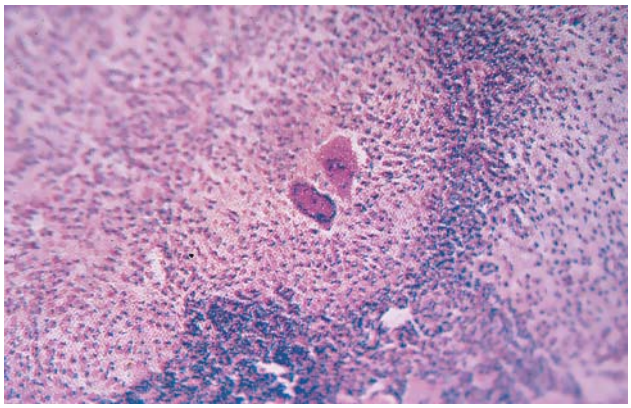

Figure 54-5 Tuberculous granuloma. The granuloma is undergoing caseating necrosis in the center surrounded by granuloma epithelioid cells and lymphocytes, and Langhans giant cell. *(Courtesy Department of Pathology, Amrita Institute of Medical Sciences, Kochi, Kerala, India.)*

In the more common *ulcerocavernous* form, the kidneys will initially appear normal or show yellow nodules on the outer surface. On cut section, granulomas and ulcers in the renal pyramid or medullary cavities may be seen. Larger cavities filled with caseous material communicating with the collecting system may also occur (see Fig. 54-2). Other gross findings include multiple ulcers in the infundibular region of the calyces, calyceal stenosis with caliectasis, ulcers or strictures of the ureter with hydronephrosis, pyonephrosis, subcapsular collections, and perinephric abscesses. The bladder may show ulcers or be grossly fibrotic and contracted.

On microscopy, in early disease, neutrophilic infiltration with phagocytosis of the bacilli may be present. Subsequent histologic features depend on the virulence of the organism and the cell-mediated immunity. In TB patients with an effective cell-mediated response, granulomas are seen, characterized by the presence of macrophages with engulfed bacilli surrounded by epithelioid cells and Langhans giant cells (Fig. 54-5). There is often a cuff of lymphocytes and plasma cells surrounding the lesion. Healing occurs by fibrosis and scarring. In those with a less effective immune response, caseating necrosis is characterized by amorphous, cheese-like eosinophilic material replacing the normal tissue architecture. The presence of caseous necrosis generally implies that the lesion is active. Later, this may calcify. Dystrophic calcification suggests activity rather than healing.

Kidneys may also be enlarged from amyloidosis or diffuse proliferative glomerulonephritis. In tuberculous interstitial nephritis, interstitial granuloma formation associated with normal-sized kidneys and negative urine cultures is seen.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

A high index of suspicion is necessary to diagnose genitourinary TB. Elderly patients, those recently exposed to infection, immunocompromised individuals, and patients with TB elsewhere are at high risk. Suspicion may also occur if there is sterile pyuria, which is present in 50% of patients. The tuberculin test (Mantoux test) is useful for proving infection (or prior immunization with BCG), but not necessarily disease. A positive test response only suggests prior exposure to the antigen and does not indicate active infection. A negative test response in the absence of an immunosuppressed

state helps to rule out tuberculous infection in countries with high tuberculosis burden. Patients with stage 4 or 5 CKD, particularly in the setting of malnutrition, may display anergy and have a false-negative result.[13] *M. tuberculosis*–specific enzyme-linked immunospot (ELISPOT) assay is useful for rapid confirmation of diagnosis and is gradually replacing the Mantoux test in most countries.

Isolation of *M. tuberculosis* by urine culture is the definitive diagnostic test. Fully voided early-morning urine samples for 3 to 5 consecutive days are cultured on two standard solid mycobacterial culture media: egg-based Lowenstein-Jensen and agar-based Middlebrook 7H10. These transparent media enable earlier visualization of microcolonies, which grow by 6 to 12 weeks. Sensitivity tests are performed to choose the optimum chemotherapeutic agents. However, this may take an additional 6 to 12 weeks. Any tissue specimen submitted for mycobacterial culture should be macerated with sterile sand by a mortar and pestle before inoculation. Direct demonstration of acid-fast bacilli in urine by Ziehl-Neelsen stain is not reliable for diagnosis because *M. smegmatis,* a saprophyte, may be easily mistaken for *M. tuberculosis*.

Rapid methods for diagnosis of TB are increasingly available. With use of the radiometric broth method for acid-fast bacilli isolation, a positive growth can be obtained in about 9 days. Serologic tests with the soluble antigen fluorescent antibody test and the polymerase chain reaction (PCR) can be used for early diagnosis of TB.[14] ELISPOT assays are used as *in vitro* diagnostic tests and measure T cell–specific *M. tuberculosis* antigens. The test results are unaffected by prior tuberculin testing or low CD4 counts.[15] Another reliable and simple test using whole blood is based on quantifying the interferon-γ released from the white blood cells that have been exposed to some of the mycobacterial antigens. The availability of the result in 24 hours is the main advantage.[16] Detection of lipoarabinomannan (LAM) in urine using lateral flow assay is a simple and rapid test for the detection of TB in patients with advanced HIV infection with a CD count less than 200 cells/μL. The results are available in 30 minutes. A cartridge-based, rapid and reliable automated test endorsed by WHO to identify targeted nucleic acid sequences in the *M. tuberculosis* genome (Xpert MTB/RIF) is now available.[17] This test detects the DNA sequences specific for *M. tuberculosis* (MTB) and rifampin (RIF) resistance by PCR, and results can be generated in 2 hours.[17] Ultrasound-guided fine-needle aspiration cytology is useful as a diagnostic tool in defining the granulomatous nature of the lesion in patients with positive urine culture. Histologic diagnosis is made by identifying the pathologic triad of caseating necrosis, loose aggregates of epithelioid histiocytes, and Langhans giant cells.

Imaging studies are essential to assess the extent and severity of involvement once a diagnosis of genitourinary TB is made. Extensive dystrophic calcification in advanced renal TB is described as "cumulus cloud" calcification (Fig. 54-6). Plain radiographs of chest and spine show active or healed tuberculous lesions in 60% to 70% of patients. Abnormalities in the excretory urogram may be seen in 70% to 90%. Minimal erosion of the tip of the calyx with spasticity, incomplete filling, distortion, infundibular stenosis, hydrocalicosis, multiple ureteral strictures, hydronephrosis, hydroureter, or nonvisualization of the kidney may be present. The renal pelvis, which may be dilated initially, may eventually be obliterated, leading to a distorted appearance called "hiked-up pelvis" (Kerr kink sign). Irregularities or multiple strictures lead to a beaded or corkscrew appearance of the ureter or hydronephrosis. Later, thickening and straightening of the whole ureter may occur ("pipe-stem" ureter). The bladder may appear irregular and fibrosed, and VUR may occur. Antegrade or retrograde pyelography can identify the number, length, or site of ureteral strictures and assist in placement of a ureteric stent across the stenotic segment.

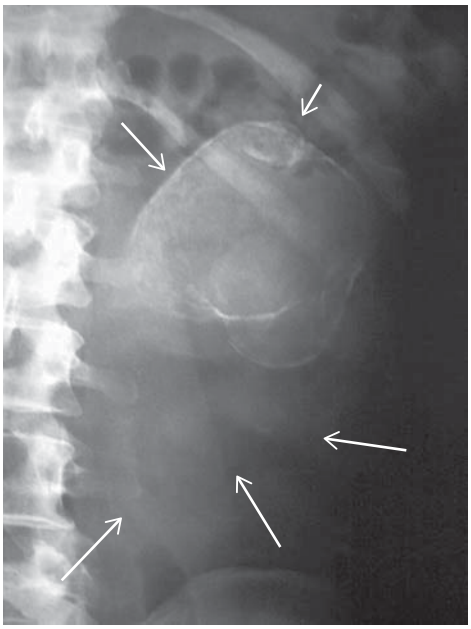

Figure 54-6 Renal calcification. Plain radiograph shows calcification in the upper half of the left kidney. Arrows outline the kidney.

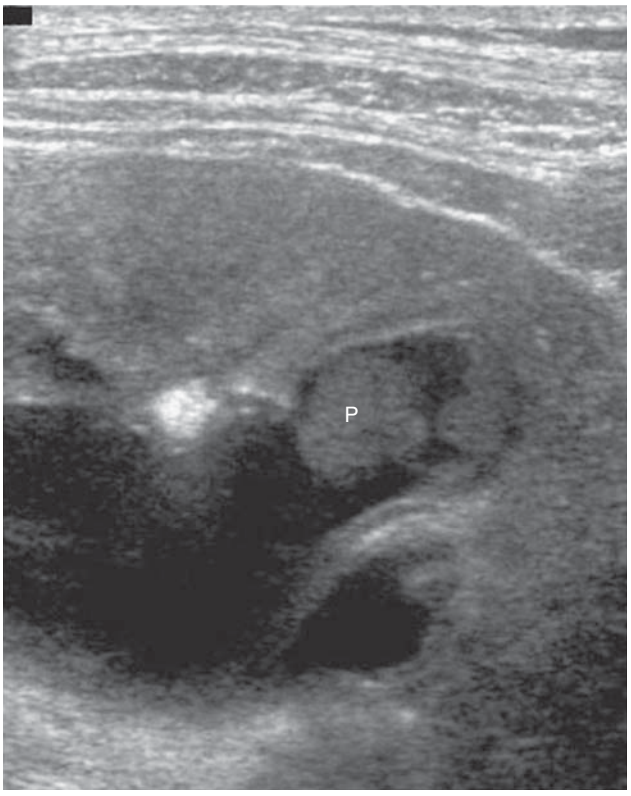

Figure 54-7 Necrosed papilla. High-resolution ultrasound scan of the kidney shows a sloughed, necrosed papilla *(P)* in the calyx. *(From reference 19, with permission of the American Institute of Ultrasound in Medicine.)*

High-resolution ultrasound is useful to rule out obstruction and to study the parenchyma closely to identify granulomas, small abscesses, bladder mucosal thickening, or calcification[18] (Figs. 54-7 and 54-8). The earliest finding is mucosal thickening and calyceal irregularity.

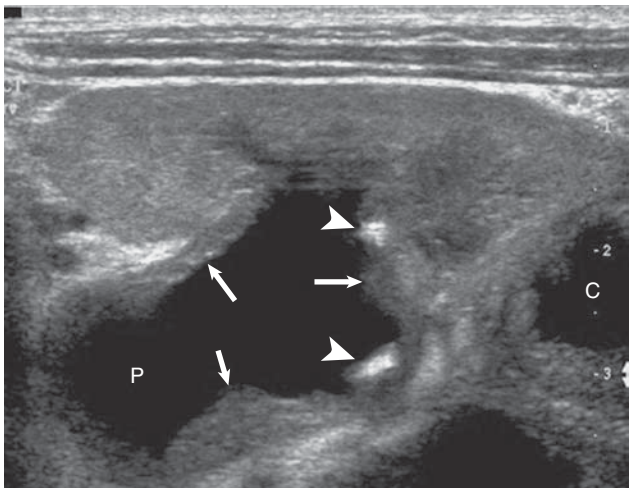

Figure 54-8 Thickened mucosa and calcifications. High-resolution transverse ultrasound scan of kidney shows mucosal thickening *(arrows)* of calyces and the pelvis *(P)*. There are calcifications of the wall of the calyx and pelvis *(arrowheads)*. A parenchymal cavity *(C)* is also shown. *(From reference 19, with permission of the American Institute of Ultrasound in Medicine.)*

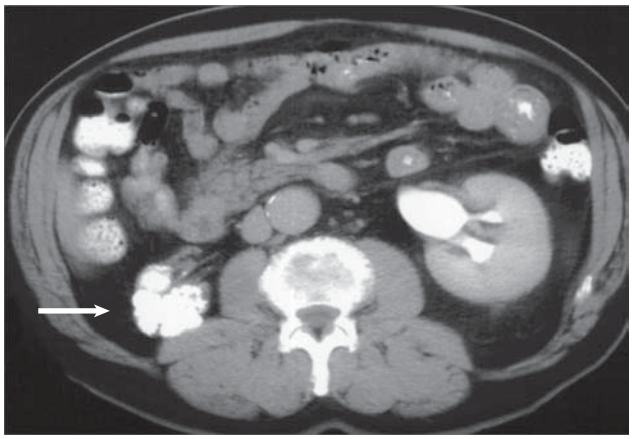

Figure 54-9 Calcified kidney. Contrast-enhanced CT image shows contracted calcified right kidney *(arrow)* and normal opposite side.

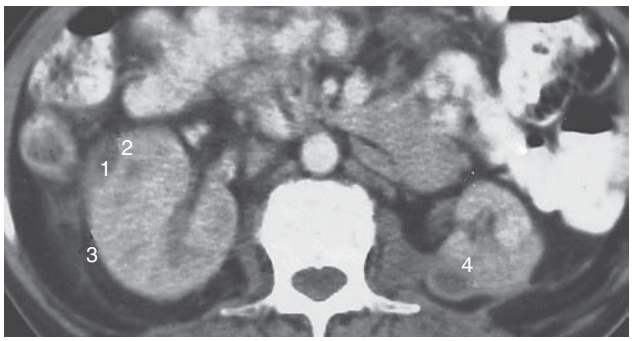

Figure 54-10 Renal tuberculosis. CT scan shows an enlarged left kidney with multiple cavities present bilaterally (marked *1, 2, 3,* and *4*). *(Courtesy Professor K. Sasidharan, Kasturba Medical College, Manipal, India.)*

Computed tomography (CT) is the most sensitive method for identifying renal parenchymal scarring, calcification, and cavitary lesions (Figs. 54-9 and 54-10). Cortical thinning is a common CT finding and may be either focal or global. These imaging modalities are helpful in the follow-up of patients with cavities or mass lesions in the kidney. Cystoscopy under general anesthesia helps visualize the mucosal lesions, the golf-hole ureteral orifice, or the efflux of toothpaste-like caseous material. Biopsy during the acute stage is avoided because of the risk of dissemination of TB.

Tuberculosis mimics numerous diseases. Chronic nonspecific urinary infections may be confused with renal TB, which is further confounded because secondary bacterial infection may complicate 20% of cases of renal TB. Absence of response to usual antibiotics should raise suspicion of urinary TB. Conditions causing recurrent painless hematuria, such as IgA nephropathy and schistosomiasis (see Chapter 56), are often misdiagnosed as TB in endemic areas. In interstitial cystitis, lower urinary symptoms similar to tuberculous cystitis may occur, but the urinalysis does not show gross pyuria, and cultures for acid-fast bacilli are negative. On radiologic examination, chronic pyelonephritis, renal papillary necrosis, medullary sponge kidney, calyceal diverticulum, renal carcinoma, xanthogranulomatous pyelonephritis, and multiple small renal calculi need to be differentiated from TB. In a few reported cases of pseudotuberculous pyelonephritis, caseating granulomas resembling TB were observed in the renal parenchyma, but no mycobacteria or other microorganisms were detected in the renal tissue or urine culture.[19]

NATURAL HISTORY

The prognosis of genitourinary TB depends on the host resistance and the load and virulence of the organism. In many cases, foci in the urinary tract remain dormant indefinitely. Progression occurs through formation of tuberculous granuloma, caseation, ulceration, and dystrophic calcification. Most manifestations result from the complications, which can be prevented by timely chemotherapy and appropriate surgical intervention when indicated. With the advent of effective chemotherapeutic measures, the long-term complications and sequelae of TB have decreased significantly.

TREATMENT

Genitourinary TB is usually amenable to medical treatment. Many antituberculous drugs reach the kidneys, urinary tract, urine, and cavitating lesions in high concentration, and there are fewer organisms in the lesions compared with cavitating lung lesions. A wide variety of antituberculous agents are available (Table 54-2).

A short-course regimen is recommended.[20] Treatment is started with daily rifampin (rifampicin) (600 mg), isoniazid (300 mg), and pyrazinamide (1500 mg) in the morning. Unless the culture sensitivity indicates otherwise, pyrazinamide is discontinued after 2 months, and isoniazid and rifampin are continued for another 4 months. If the patient is very sick with irritative bladder symptoms, streptomycin in daily doses of 1 g may be added during the first 2 months. However, if the patient is older than 40 years, the daily dose of streptomycin is reduced to 0.75 g with periodic monitoring for ototoxicity and vestibular toxicity.

If the probability of drug resistance is high, ethambutol in daily doses of 800 to 1200 mg may also be used in the first 2 months. Longer courses of antituberculous treatment ranging from 9 months to 2 years are useful in patients who do not tolerate pyrazinamide, those responding slowly to a standard regimen, those with miliary or central nervous system disease, and in children with multisite involvement.

Fixed-dose combinations of anti-TB drugs incorporating two or more drugs in the same tablet have the advantages of increased compliance, administration of adequate dose, minimization of inadvertent medication errors, and avoidance of drug resistance.

Antituberculous Drugs					
Drug	**Dose Form**	**Dosage**	**Side Effects**	**Mode of Action**	**Remarks**
Isoniazid	Tablet: 100 mg, 300 mg	5 mg/kg daily (oral) (maximum 300 mg/day)	Peripheral neuropathy, hepatitis, hypersensitivity reactions	Bactericidal for groups I and II	Pyridoxine (50 mg) prophylaxis necessary
Rifampin (Rifampicin)	Capsule or tablet: 150, 300, 450 mg	10 mg/kg daily (oral) (maximum 600 mg/day)	Hepatitis, febrile reactions, acute interstitial nephritis	Bactericidal for groups I, II, and III	—
Pyrazinamide	Tablet: 400, 500 mg	25 mg/kg daily (oral) (maximum 2 g/day)	Hepatotoxicity, hyperuricemia	Bactericidal for group II	Combination with aminoglycoside useful
Streptomycin	Powder for injection: 1 g	15 mg/kg daily IM (maximum dose 1 g; dose reduced in those age >40)	Ototoxicity, nephrotoxicity	Bactericidal for group I	—
Ethambutol	Tablet: 100, 400 mg	15-25 mg/kg daily (oral) (maximum, 2.5 g/day)	Optic neuritis (reversible), rash	Bacteriostatic for groups I and II	Used to inhibit development of resistant mutants; use with caution in renal failure.
Thiacetazone	Tablet: 150 mg	150 mg (oral) (not for intermittent therapy)	Rashes, exfoliative dermatitis, hepatic failure	Bacteriostatic and inhibits emergence of isoniazid resistance	Not used in renal failure
Ciprofloxacin	Tablet: 250, 500 mg	500-1000 mg (oral)	Hypersensitivity, drug interaction	—	Not used in children
Ciprofloxacin	Tablet: 200, 400 mg	400-500 mg (oral)	—	—	Not approved by FDA for tuberculosis
Capreomycin Kanamycin	—	15-30 mg/kg daily IM	Ototoxicity, nephrotoxicity	Bactericidal for group I	Avoided in older patients and those with renal failure

Table 54-2 Antituberculous drugs. The main drugs are listed with dosage form, dosage, side effects, and mode of action. *Mycobacterium tuberculosis* exists as three subpopulations. Group I is extracellular, occurs mainly in cavitating lesions, and responds to streptomycin, isoniazid, and rifampin. Group II resides intracellularly in macrophages, replicates slowly, and responds to pyrazinamide, isoniazid, or rifampin. Group III organisms exist within closed caseous lesions, survive better in neutral pH, replicate slowly, and respond best to rifampin. *FDA,* U.S. Food and Drug Administration; *IM,* intramuscularly.

During treatment, healing by fibrosis may lead to obstruction of one or both ureters, with hydronephrosis, parenchymal damage, and renal failure. Dehydration or salt depletion may occur from tubulointerstitial damage resulting in altered tubular function. Adrenal involvement may contribute to salt wasting. Oliguric acute kidney injury caused by allergic interstitial nephritis may occur in patients receiving intermittent rifampin therapy.

Surgical Treatment

The role of surgical treatment in patients with urinary TB is limited. For ureteral strictures, timely introduction of stents across the narrow segment may avoid the need for major surgical procedures. Two broad types of surgical treatments are considered.

Reconstructive surgery involves the correction of obstruction to the ureter by pyeloplasty, ureteroureterostomy, correction of reflux by ureteral reimplantation, and increasing the bladder capacity by augmentation cystoplasty, which involves anastomosis of an isolated segment of bowel to the contracted bladder.

Ablative surgery involves removal of the diseased parts together with the infected material containing the dormant organisms. The need for removal of a unilateral nonfunctioning kidney is controversial. Because prolonged antituberculous treatment for 18 to 24 months effectively sterilizes caseous and calcified masses of the tuberculous cement kidney, nephrectomy is advocated only in patients with secondary sepsis, pain, bleeding, uncontrollable hypertension, or continued positive urinary cultures. Tuberculous abscesses can be aspirated under ultrasound or CT guidance and antituberculous drugs directly instilled into the cavity.

Treatment Regimens in Special Situations

Women During Pregnancy and Lactation

Most antituberculous drugs are safe for use during pregnancy. However, streptomycin is ototoxic to the fetus and must be avoided. If a four-drug schedule is indicated, streptomycin is replaced by ethambutol. There is no contraindication to the use of these drugs during breastfeeding, and it is not necessary to isolate the baby from the mother. The baby should receive BCG immunization and isoniazid prophylaxis. Because rifampin interacts with the efficacy of oral contraceptives, women taking these agents together should be advised to take a higher dose of estrogen or to use alternative methods of contraception.

Patients with Liver Disease

The usual short-term (6-month) chemotherapy regimen can be used in patients with liver disorders if there is no evidence of chronic liver disease, hepatitis virus carrier state, past history of acute hepatitis, or excessive alcohol consumption. In chronic liver disease, isoniazid and two of the nonhepatotoxic drugs (streptomycin and ethambutol) can be used for 8 to 12 months. If rifampin is used, liver function should be closely monitored. Pyrazinamide is contraindicated. In those with acute hepatitis unrelated to TB or its therapy, it would be safer to defer the chemotherapy until the acute hepatitis has resolved.

If immediate treatment of TB during acute hepatitis is mandatory, streptomycin plus ethambutol for 3 months followed by isoniazid and rifampin for 6 months is advised.

Patients with Chronic Kidney Disease

In patients with CKD, isoniazid, rifampin, and pyrazinamide, which are eliminated by the biliary route, can be given in normal dosages. Those receiving isoniazid should also be given pyridoxine (50 mg/day) to prevent peripheral neuropathy. Because streptomycin and ethambutol are excreted by the kidney, dosage modification of these drugs is necessary in renal failure. Streptomycin (15 mg/kg) is administered every 24 to 72 hours for a GFR of 10 to 50 ml/min and every 72 to 96 hours for a GFR of less than 10 ml/min to maintain a therapeutic peak level of 20 to 30 µg/ml. Patients taking streptomycin who have a sense of fullness of the ear or have tinnitus or who are older than 45 should have an audiogram to detect ototoxicity early. For ethambutol, the dose is administered every 24 to 36 hours if GFR is 10 to 50 ml/min and every 48 hours if GFR is less than 10 ml/min. Monthly questioning for symptoms of visual dysfunction (alterations in visual fields, acuity, blue-green vision) with early referral for ophthalmic examination may identify ethambutol toxicity early, with potential reversibility.

Renal Allograft Recipients

A modified treatment regimen is recommended for renal allograft patients, with adjusted doses of isoniazid and ethambutol for 18 months, combined with ofloxacin (200 mg twice daily) for the first 9 months and pyrazinamide (750 mg twice daily) for the first 3 months.[21] Rifampin should be avoided in patients receiving a calcineurin inhibitor (CNI) because enzyme induction will make it more difficult to maintain adequate CNI blood levels. If rifampin is used in those receiving a non–cyclosporine-based immunosuppressive regimen, the maintenance dose of prednisolone should be doubled.

Acquired Immunodeficiency Syndrome

Short-term chemotherapy is sufficient for AIDS patients. If the follow-up cultures are positive, prolonged therapy for up to 2 years may be needed based on antibiotic sensitivity.

Patients Who Fail Treatment

Failure to show clinical or radiologic improvement with treatment may signify poor compliance, inadequate regimen and dosage, incorrect diagnosis, MDR TB, delayed response, or the paradoxical reaction known as "immune reconstitution inflammatory syndrome." This syndrome is characterized by unexpected worsening of symptoms or appearance of new lesions, including lymphadenopathy, serosal effusions, and pleural infiltrates. This syndrome is more common in those prescribed antiretroviral treatment for coexisting HIV and TB infections.[22]

Monitoring of Patients

After 2 months of intensive chemotherapy, urine is cultured for *M. tuberculosis* for 3 consecutive days. If cultures remain positive, sensitivity is done and treatment modified accordingly. After completion of treatment, all patients should have three consecutive early-morning samples of urine for *M. tuberculosis* culture, and this is repeated after 3 months and 1 year. Intravenous urography or ultrasound is repeated at the end of 2 months and at the completion of treatment to detect any evidence of obstruction. In cases of renal calcification, the patient should be evaluated yearly by three early morning samples of urine for culture of mycobacteria and by plain radiography of the abdomen for up to 10 years, because calcification may harbor *M. tuberculosis* and may progress to destruction of the kidney.

Considerable progress has been made in the areas of TB diagnostics, antituberculous drugs, and vaccines during the last decade. New antituberculous agents and several vaccines are in various phases of clinical trial. The global plan to eradicate tuberculosis is showing increasing promise.

CHAPTER 55

Fungal Infections of the Urinary Tract

Carol A. Kauffman

Funguria is a frequent finding in hospitalized patients. Almost always, the organisms found in urine are *Candida* species, although several other yeasts, and less often, molds and endemic fungi, can also be found (Table 55-1). Candiduria is not a symptom, a sign, or a disease, but frequently it is a perplexing phenomenon for the physician to address. In reality, most patients with candiduria are asymptomatic and have colonization of the bladder or of an indwelling urinary catheter. The most difficult diagnostic problem is determining when *infection,* rather than colonization, is present. Diagnostic tests to define whether candiduria is related to colonization or infection have not been standardized; similarly, diagnostic studies to localize the site of infection to either the bladder or the kidneys are not well established. In contrast to the situation with candiduria, growth in urine of organisms such as *Blastomyces dermatitidis, Aspergillus* spp., and *Cryptococcus neoformans* almost always reflects disseminated infection. This chapter outlines an approach to the diagnosis and treatment of candiduria and other, less common fungal urinary tract infections (UTIs).

CANDIDA

Epidemiology

Candida species are common inhabitants of the perineum but are not found in urine in appreciable numbers in healthy hosts. However, a variety of predisposing factors allow these commensals to grow in the urine and in some cases, to invade the bladder or the upper urinary tract and cause infection. These factors are more frequently encountered in hospitalized patients, especially those in the intensive care unit (ICU).[1] In a recent point prevalence survey of positive urine cultures obtained from hospitalized patients, *Candida* species were found in almost 10% of specimens and were the third most common microorganism isolated from urine.[2]

Risk factors for candiduria, but not specifically for *Candida* UTI, include increased age, female gender, antibiotic use, urinary drainage devices, prior surgical procedures, and diabetes mellitus[3-5] (Table 55-2). In the largest surveillance study, urinary drainage devices, mostly indwelling urethral catheters, were present in 83% of patients who had candiduria.[3] In a multicenter study of patients in an ICU setting, independent risk factors associated with candiduria were age over 65, female gender, diabetes mellitus, prior antibiotic use, mechanical ventilation, parenteral nutrition, and length of hospital stay before ICU admission.[4] A case-controlled study that compared candiduria caused by *Candida glabrata* with that from *Candida albicans* found that *C. glabrata* was more common in patients with diabetes and in those who had received prior treatment with fluconazole.[5] Most patients in these studies had colonization and not infection with *Candida*.

Prospective controlled studies assessing risk factors for well-documented *Candida* UTI have not been performed because firm diagnostic criteria have not been established. However, clinical experience suggests that UTI is more common in diabetic patients and those with urinary tract obstruction.

Pathogenesis

Candida tends to cause disease by either the hematogenous or the ascending route. This contrasts with most UTIs caused by bacteria, in which infection ascends from bladder to the collecting system of the kidney. The pathogenesis of hematogenous seeding of *Candida* to the kidney has been studied with animal models.[6] Multiple microabscesses develop throughout the cortex, with the yeasts penetrating through the glomeruli into the proximal tubules, where they are shed into the urine (Fig. 55-1). Healthy animals eventually clear the infection, but immunocompromised animals do not. Consistent with the experimental studies, renal microabscesses have been identified at autopsy in most patients with invasive candidiasis. For ascending infection with *Candida,* obstruction is an important factor in some patients. Virulence factors of *Candida,* such as those that control adherence and biofilm formation, are also likely relevant, but have not been studied in the context of *Candida* UTI.[6,7]

A unique syndrome seen early after kidney transplantation is graft site candidiasis, which appears to result from contamination of the donor kidney during the harvest procedure.[8] Arteritis with aneurysm formation and rupture can result from direct fungal invasion into the arterial wall. Most patients lose the graft, and mortality is high.

Microbiology

Candida albicans accounts for 50% to 70% of all *Candida* urinary isolates, and *C. glabrata* for about 20% of isolates.[3] *Candida tropicalis* and *Candida parapsilosis* are less common, and other species are rarely isolated. Certain populations of patients have a predominance of *C. glabrata*. Older adults frequently have *C. glabrata* isolated from urine, but urine cultures from neonates rarely yield *C. glabrata*. In a prospective survey of candiduria in renal transplant recipients, *C. glabrata* represented 53% and *C. albicans* only 35% of isolates.[9]

It is important to know the species causing candiduria for therapeutic reasons. Resistance to fluconazole, the primary agent used for the treatment of *Candida* UTIs, is common among isolates of *C. glabrata* and in all isolates of *Candida krusei.* In contrast, almost all isolates of *C. albicans, C. tropicalis*, and *C. parapsilosis* are susceptible to fluconazole.

Clinical Manifestations

Most patients with candiduria are asymptomatic, and indeed, most do not have infection. A large prospective surveillance study of patients with candiduria noted that less than 5% of patients with

Fungal Genitourinary Tract Infections			
Fungal Infection	**Prostate**	**Bladder**	**Kidney**
Blastomycosis	+++	+	++
Histoplasmosis	+	+/–	++
Coccidioidomycosis	+	+/–	++
Aspergillosis	+/–	+/–	++
Mucormycosis	+/–	+/–	++
Cryptococcosis	++	+/–	+++
Candidiasis	++	++++	++++

Table 55-1 Fungal genitourinary tract infections. Shown is the relative frequency of the site of infection for various fungal organisms.

Risk Factors for Different Types of Candida Urinary Tract Infections	
Type	**Risk Factors**
Renal (hematogenous)	Neutropenia, recent surgery, central venous catheter, parenteral nutrition, antibiotics, dialysis
Lower urinary tract	Indwelling bladder catheter, older age, female, diabetes, obstruction, antibiotics, urinary tract instrumentation
Upper urinary tract	Older age, diabetes, antibiotics, obstruction, urinary tract instrumentation (e.g., nephrostomy tube, ureteral stent)

Table 55-2 Risk factors for candiduria.

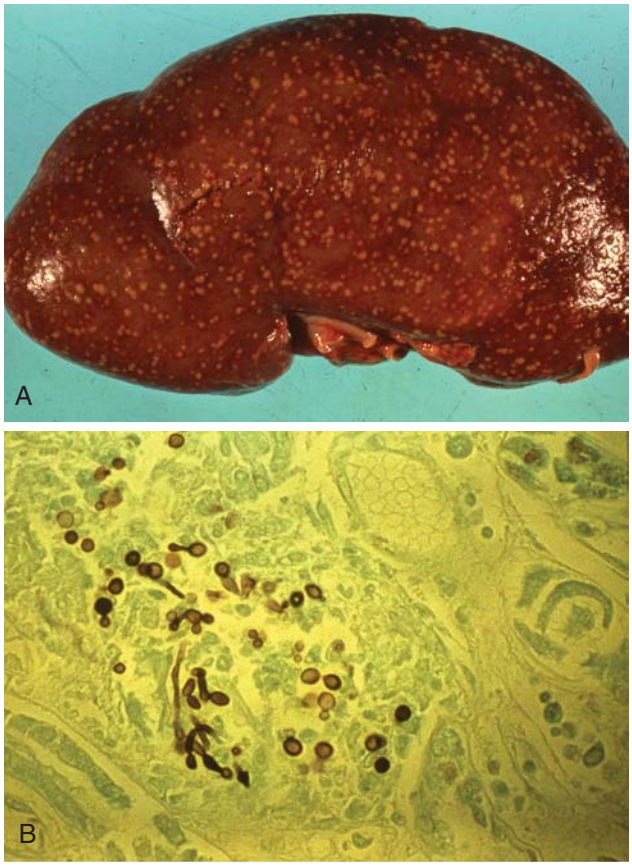

Figure 55-1 Hematogenous renal candidiasis. A, Multiple small abscesses are grossly obvious throughout the kidney. **B,** Histopathologic demonstration of a microabscess caused by *Candida albicans* in the cortex of the kidney (methenamine silver stain; yeast shown in *gray-brown color*).

candiduria had any symptoms suggesting UTI.[3] When patients have symptomatic cystitis or pyelonephritis, symptoms are indistinguishable from those noted with bacterial infections. Cystitis is manifested by dysuria, frequency, urgency, and suprapubic discomfort; patients with upper tract infection can present with fever, chills, and flank pain. Urinary tract obstruction occurs from formation of a bezoar or fungal ball in the bladder or the collecting system.

Patients who have had seeding of the renal parenchyma during an episode of candidemia manifest the symptoms and signs associated with invasive candidiasis and not UTI. Chills, fever, hypotension, and other manifestations of sepsis are often noted in patients who are candidemic.

Diagnosis

Major diagnostic difficulties are encountered in trying to differentiate contamination of a urine specimen from colonization of the bladder or an indwelling urethral catheter from invasive infection of the bladder or the kidney.[10] Contamination is most easily differentiated by simply repeating the urine culture to determine if candiduria persists. It may be necessary to obtain the second urine specimen by sterile bladder catheterization if the patient is unable to accomplish a clean-catch collection. In those patients who have an indwelling urethral catheter, the catheter should be replaced and a second urine specimen collected. For either of these circumstances, if the repeated culture yields no yeasts, no further diagnostic studies or therapeutic interventions are needed.

Distinguishing colonization from infection is not straightforward. Compared with bacterial UTIs, in which the diagnosis is based on appropriate symptoms combined with the findings of pyuria and quantitative bacterial counts, no studies have established the importance of quantitative urine cultures or pyuria for the diagnosis of *Candida* UTI.[11]

The role of quantitative urine cultures to differentiate upper tract infection from bladder colonization was assessed by investigators in the 1970s and unfortunately showed broad ranges of colony counts for both colonization and infection.[11] In patients who did not have indwelling catheters, documented renal infection was found with colony counts as low as 10^4 yeast colony-forming units per milliliter (cfu/ml). For patients who had indwelling catheters, colony counts between 2×10^4 and 10^5 cfu/ml or more were noted, and there was no correlation with biopsy-proven renal infection. A murine model of hematogenous renal candidiasis noted that renal involvement could be seen with any concentration of *Candida* in the urine.[12]

The techniques routinely used in most clinical laboratories for the detection of bacteria will also detect *Candida* in urine. However, *C. glabrata* grows more slowly than other species and more slowly than bacteria, and colonies may not appear for 48 hours, which is often after routine cultures of urine have been discarded. Laboratories should be notified if *C. glabrata* is a likely pathogen.

Pyuria is often not a helpful diagnostic criterion for infection in patients with candiduria. Concomitant bacteriuria is frequently noted in patients with candiduria and may be responsible for pyuria. In patients who have an indwelling bladder catheter, pyuria is routinely noted, whether or not infection is present. In patients who do not have an indwelling bladder catheter or bacteriuria, the presence of pyuria is helpful.

Imaging procedures, including abdominal ultrasound and computed tomography (CT), are essential to document obstruction at

any level in the urinary tract and to determine the presence of fungus balls in bladder or kidney (Fig. 55-2). In some patients, it is helpful to perform cystoscopy and biopsy of the bladder wall to determine whether inflammation is present and to evaluate the extent of invasion (Fig. 55-3).

Treatment with Systemic Antifungal Agents

Most patients who have candiduria do not need treatment with an antifungal agent. For patients who are asymptomatic, treatment should be given only to those who are at high risk for development of candidemia or in whom the presence of candiduria, regardless of symptoms, is likely to represent disseminated infection. The guidelines for the management of candidiasis published by the Infectious Diseases Society of America (IDSA) recommend treatment for patients about to undergo urologic procedures, very-low-birth-weight infants, and neutropenic patients[13] (Table 55-3). Patients who have candiduria and who are to undergo a urologic procedure are at increased risk for development of candidemia and should be treated with an antifungal agent a few days before and after the procedure. Candiduria in neutropenic patients and in very-low-birth-weight infants has a high probability of representing

Figure 55-2 Fungal hydronephrosis. Several fungus balls (dark round "holes" in the contrast dye) in the ureter and pelvis of the right kidney causing hydronephrosis.

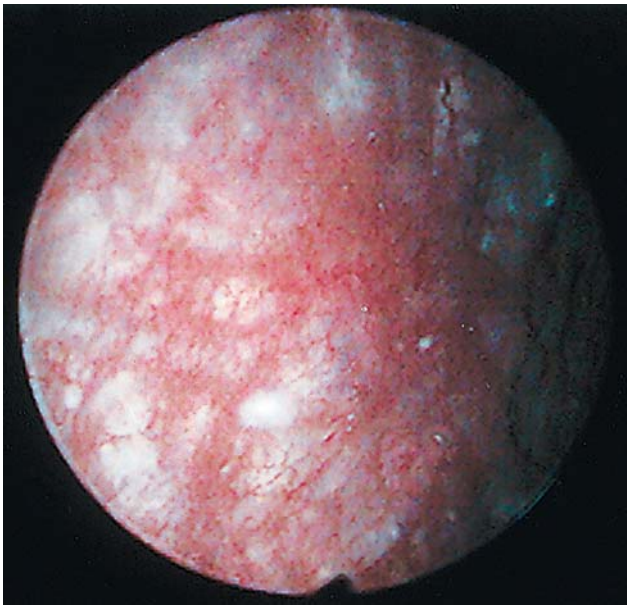

Figure 55-3 *Candida* cystitis. Cystoscopic appearance of extensive cystitis caused by *Candida krusei*.

Treatment Recommendations for *Candida* Urinary Tract Infections

Infection	Treatment	Other/Alternative Therapy
Asymptomatic candiduria	No treatment indicated except: Urologic surgery Low-birth-weight infant or neutropenic patient	 Treat a few days before and after the procedure with: Fluconazole, 200-400 mg daily, *or* Amphotericin B, 0.3-0.6 mg/kg/d Treat as for disseminated candidiasis/candidemia
Cystitis	Preferred: oral fluconazole, 200 mg daily × 14 days*	Alternatives include: Amphotericin B, 0.3-0.6 mg/kg/d × 1-7 days Flucytosine, 25 mg/kg q6h × 7-10 days†
Pyelonephritis	Preferred: oral fluconazole, 200-400 mg daily × 14 days	Alternatives include: Amphotericin B, 0.5-0.7 mg/kg/d × 14 days Flucytosine, 25 mg/kg q6h × 14 days
Renal (hematogenous)	Treat as for disseminated candidiasis/candidemia	—
Fungus balls	Surgical removal Fluconazole, 200-400 mg daily until resolved	Alternatives include: Amphotericin B, 0.5-0.7 mg/kg/d Flucytosine, 25 mg/kg q6h
Prostatitis Epididymo-orchitis	Surgical drainage Fluconazole, 400 mg daily until resolution noted on imaging studies	Alternatives include: Amphotericin B, 0.5-0.7 mg/kg/d

Table 55-3 Treatment recommendations for candiduria and *Candida* urinary tract infections (UTIs). *Fluconazole dosage in renal failure: creatinine clearance (Cr Cl) 20-50 ml/min, reduce dose by 50%; CrCl <20 ml/min, reduce dose by 75%; *q6h,* every 6 hours. †Flucytosine dosage in renal failure: CrCl 20-40 ml/min, reduce dose to 25 mg/kg every 12 hours; CrCl <20 ml/min, reduce dose to 25 mg/kg every 24 hours.

disseminated candidiasis; thus, these groups also should be treated with an antifungal drug. Asymptomatic candiduria in the renal transplant patient does not warrant systemic antifungal treatment unless obstruction is present or symptoms suggestive of local or systemic infection develop.

In non–high-risk patients who have asymptomatic candiduria, removal of an indwelling urinary catheter will eradicate candiduria in many patients.[3] If catheterization cannot be discontinued, the existing catheter should be removed and a new one inserted. This will often eradicate candiduria transiently, but it is highly likely that the organisms will return within a short time. Relief of obstruction, whether it is present in the upper or lower urinary tract, is essential for the long-term eradication of *Candida* from the urinary tract.

Patients who have symptoms suggestive of cystitis or pyelonephritis, and in whom bacteria as well as *Candida* are found in the urine culture specimen, should be treated initially with an antibacterial agent. If no bacteria are present, treatment with an antifungal drug is appropriate. Eradication of the organism with antifungal therapy is more likely if the indwelling catheter is also removed.[14] Oral fluconazole, which is an azole antifungal agent and is excreted as active drug in the urine, is the agent of choice (see Table 55-3). A loading dose of 400 mg should be given, followed by 200 mg daily for 14 days.[13,15] Fluconazole does not effectively treat *C. krusei* infections, and many *C. glabrata* infections also do not respond to fluconazole.

The possibility of drug-drug interactions should be evaluated before fluconazole is prescribed. Phenytoin, warfarin, cyclosporine, tacrolimus, and sulfonylurea agents are a few of the drugs for which serum concentrations will increase and may reach toxic levels after the addition of fluconazole. Azoles should be used with caution in patients on drugs that prolong the QTc interval.

The other available azole agents, itraconazole, voriconazole, and posaconazole, are not excreted into the urine as active drug. Whether tissue concentrations might be high enough to treat invasive kidney or bladder infections is not known, but there is little clinical experience to suggest that they will be effective.[15]

Intravenous (IV) amphotericin B deoxycholate is effective in treating *Candida* UTIs but should be reserved for patients who have upper tract infection or for whom fluconazole therapy has failed, which will be predominantly those who have *C. glabrata* infection. Because of its inherent nephrotoxicity, IV amphotericin B must be used judiciously in patients who have renal dysfunction. The recommended dosage is 0.3 to 0.7 mg/kg/day for 1 to 7 days, although this may be extended to 2 weeks for those with complicated upper tract infection.[13] The dose used depends on renal function and number of days infusions will be given; for example, some clinicians have had success with 0.3 mg/kg daily for 3 days, whereas others use a single dose of 0.7 mg/kg. Infusion-related side effects are seen in some patients, even when low dosages are used, and can include rigors, fever, nausea, vomiting, and headache.

Lipid formulations of amphotericin B are not recommended for treatment of fungal UTIs. The decreased nephrotoxicity that results from the addition of the lipid component likely also precludes the drug's effectiveness by failing to achieve adequate levels in the urinary tract.[15]

One of the few uses of flucytosine is for the treatment of *Candida* UTIs. Flucytosine, which is excreted into the urine in high concentrations as active drug, should be used only when fluconazole is not tolerated or the organism is fluconazole resistant. The usual dosage of flucytosine is 25 mg/kg orally every 6 hours for 7 to 10 days.[15] Most species of *Candida,* with the exception of *C. krusei,* are susceptible to flucytosine, but resistance emerges quickly when this agent is used alone. Serious adverse effects of flucytosine include bone marrow suppression and hepatotoxicity. These effects are dose related, and the risk increases greatly with renal failure (see Table 55-3).

The echinocandins (caspofungin, micafungin, and anidulafungin) have minimal or no excretion into the urine as active drug. The tissue concentrations achieved with these agents may be adequate to treat invasive *Candida* infections of the bladder or kidney, but clinical data are limited.[16] Therefore, echinocandins currently cannot be recommended for the treatment of *Candida* UTIs.

Local Antifungal Administration

Continuous bladder infusion of amphotericin B, 50 mg in 1 liter of sterile water through a triple-lumen catheter, is sometimes used to treat *Candida* bladder infection. Bladder irrigation clears candiduria more quickly than systemic antifungal agents.[17] However, the effect is brief, and recolonization occurs within 1 to 2 weeks. Amphotericin B bladder irrigation is rarely required as a strategy given the need for catheter placement and the availability of more convenient treatment options.[18] The one exception might be lower tract infection with azole-resistant *C. krusei* or *C. glabrata*.

In the patient with kidney obstruction caused by a fungus ball, irrigation through a percutaneous nephrostomy tube with amphotericin B is recommended, in addition to systemic antifungal therapy with fluconazole.[13] Absorption of amphotericin B does not occur, and direct infusion is not nephrotoxic. Surgical or endoscopic removal of the fungus ball is essential to eradicate the infection.

Localized *Candida* Infections

Prostatitis and prostatic abscess caused by *Candida* species present with symptoms that are similar to those of bacterial prostatic infection. The initial presentation may be urinary retention; physical examination reveals a tender prostate, and imaging can show either discrete abscesses or diffuse inflammation. Treatment is drainage if an abscess is present, and fluconazole, which achieves excellent concentrations in the prostate, for several months until the infection has resolved.[19] Epididymo-orchitis is less common and usually presents as a tender scrotal mass. Surgical drainage or orchiectomy is required, along with fluconazole therapy until resolution has occurred.

OTHER YEASTS

Cryptococcus neoformans infection in immunosuppressed hosts, especially patients with acquired immunodeficiency syndrome (AIDS), is a systemic illness with involvement of many organs, including the genitourinary (GU) tract. In autopsy series, kidney involvement has been noted in 25% to 50% of patients who died of cryptococcosis, but symptoms rarely are referable to the GU tract. The prostate is frequently infected and can be a reservoir for persistent *C. neoformans* infection. Isolated prostatitis and epididymo-orchitis have been reported in the absence of systemic cryptococcosis.[20] The diagnosis is usually made at the time of biopsy of a mass or nodule; granulomatous inflammation is typically seen. Treatment of localized GU tract cryptococcal infection is fluconazole, 400 mg daily, for 6 to 12 months.

Saccharomyces cerevisiae has been described rarely as a cause of UTI. The presentation is the same as for *Candida* species. In clinical microbiology laboratories that do not identify yeasts in urine to the species level, this organism will not be differentiated from *Candida*. *S. cerevisiae* is often resistant to fluconazole, and successful treatment may require amphotericin B.

ASPERGILLUS AND OTHER MOLDS

The urinary tract is an uncommon site of infection with molds. However, individual case reports have noted genitourinary infections caused by a variety of molds, including the Mucorales (e.g., *Rhizopus, Mucor*), *Aspergillus, Penicillium*, and *Paecilomyces*.[21] The most common mold infection is aspergillosis. Hematogenous spread to the kidney with invasive disease in immunosuppressed patients results in numerous renal microabscesses and infarcts. This may be an incidental finding in light of massive dissemination at autopsy. Patients who have symptomatic UTI usually present with urinary tract obstruction from masses of fungal elements causing fungal balls, which can be visualized on CT scan or ultrasound. Treatment is surgical removal of the obstructing mass, often nephrectomy, and systemic antifungal therapy for the specific mold. Mortality is extremely high.

ENDEMIC FUNGI

All of the major endemic mycoses have been reported to infect the GU tract. For all of these organisms, infection is by hematogenous spread to the GU tract. For upper tract infection, treatment is the same as that for disseminated infection. The treatment of focal infection, which is more likely to involve the lower GU tract, is usually surgical removal of the infected tissue combined with antifungal therapy.

Blastomyces dermatitidis has the greatest propensity to cause symptomatic infection. In patients with disseminated blastomycosis, involvement of the GU tract occurs in as many as a third of cases and usually manifests as prostate or epididymal infection.[22] In most patients, this involvement is discovered incidentally when urine cultures yield the organism or when a biopsy is performed for a prostatic or epididymal mass.

Symptomatic GU tract involvement with histoplasmosis is uncommon. However, at autopsy, kidney lesions are often found in patients who have disseminated histoplasmosis.[23] Patients are usually asymptomatic in regard to urinary symptoms. Individual cases of testicular abscesses, epididymitis, and prostate nodules have been reported.

Coccidioidomycosis rarely causes symptomatic UTI. However, autopsy series of cases of disseminated coccidioidomycosis have noted kidney involvement in more than 50% of cases.[24] The finding of *Coccidioides* species in the urine in such patients is not uncommon. Localized infection, presenting as abscesses or mass lesions of the epididymis or prostate, also occurs in patients with disseminated coccidioidomycosis.

CHAPTER 56

The Kidney in Schistosomiasis

Rashad S. Barsoum

Schistosomiasis is a parasitic disease usually acquired by teenagers, often leading to complications that may extend into the fourth and fifth decades of life. It was known to the ancient Egyptians as "the bloody urine disease"[1] and is also known as *bilharziasis* in honor of its discoverer, Theodor Bilharz, the German physician who practiced in Egypt in the 1850s.

The life cycle of the parasite is shown in Figure 56-1. Infection is acquired through contact with contaminated waters in the ponds and slow-flowing canals originating from certain rivers. Cercariae enter through the skin or mucous membranes and migrate through the lymphatics and blood circulation into the portal or perivesical venous system, where they mature into sexually differentiated adult worms and live in almost continuous copulation. Females leave the males only to lay eggs, traveling against the blood flow, aiming at the rectal or bladder mucosa. The ova are driven out by visceral contraction during defecation or urination in the respective excreta. Contact with fresh water within a couple of days allows the eggs to hatch, releasing miracidia, which infect specific snails. In this "intermediate" host, the organisms mature asexually into cercariae, which are eventually released, searching for their "definitive" host, usually humans and occasionally apes and cattle. The snail demography defines the endemicity and frequency of schistosomiasis in different geographic regions. Because this is largely influenced by climatic factors such as temperature and humidity, it is possible to accurately monitor the global epidemiology of schistosomiasis by satellite remote sensing.[2]

According to World Health Organization estimates, about 200 million inhabitants of 76 countries on five continents are infected, and an additional 600 million are at risk. Of the infected subjects, 60% are symptomatic, 10% have serious sequelae, and 1% die of the disease each year, mainly in China, the Philippines, Egypt, Brazil, northern Senegal, and Uganda.

Three species are mainly responsible for almost all the morbidity from the disease, namely, *Schistosoma haematobium* throughout Africa and adjacent regions; *Schistosoma mansoni* in Africa, South America, and the Caribbean islands; and *Schistosoma japonicum* in the Far East (Fig. 56-2). The other four significant human-pathogenic schistosomal species (*Schistosoma intercalatum, Schistosoma mekongi, Schistosoma guineensis, and Schistosoma mattheei*) have a patchy distribution in certain geographic locations, hence their limited impact on the global epidemiology of schistosomiasis.

S. haematobium affects the urinary tract, whereas *S. mansoni* and *S. japonicum* affect the colon and rectum, ultimately reaching the liver and inducing periportal fibrosis. Sporadically, all three species cause "metastatic lesions" when ova are driven by the bloodstream to the lungs, brain, spinal cord, heart muscle, eyes, and other sites.[3] Overall morbidity is variable and depends on the virulence of the infective strains, host resistance, environmental factors, and standards of primary medical care. For example, chronic lower urinary tract disease among infected subjects is reported to vary from 2% in Nigeria in the west of Africa to 52% in Tanzania in the east.[4]

PATHOGENESIS

Schistosomes cause morbidity through two major mechanisms: (1) local reactions around the ova deposited in different tissues and (2) systemic effects attributed to the host's response to circulating antigens released from the worms or the ova (Fig. 56-3).[4,5]

The local reaction is a cell-mediated immune response to soluble egg antigens diffusing out of trapped ova through micropores in the eggshell. The initial response is innate, being driven by tissue macrophages, and involves natural killer cells, neutrophils, and complement. This response is followed by a specific immune response orchestrated by T helper (Th) lymphocytes.

The schistosomal granuloma is composed of mononuclear cells, eosinophils, neutrophils, basophils, and fibroblasts, which are recruited and activated by a variety of Th lymphokines as well as specific chemoattractants of parasitic origin (Fig. 56-4). These cells are involved in the elimination of the parasite by direct phagocytosis (monocytes), lymphocytotoxicity (T lymphocytes), antibody-dependent cytotoxicity (eosinophils), and antibody- and complement-dependent cytotoxicity (neutrophils). Later, the granuloma is modulated by gradual switching from Th1 to Th2 activation, largely mediated by a change in the monokine profile that favors release of interleukin (IL)–4, which is associated with a phenotypic change of the committed tissue macrophages. At this stage, the intensity of the inflammatory reaction is reduced, and progressive fibrosis is induced largely through the release of IL-4, IL-5, IL-10, somatostatin, and transforming growth factor β. Further on, tolerance to the parasite is achieved by an established population of regulatory T cells, which develop under the combined influence of host- and parasite-derived mediators. With the final extinction of the inflammatory reaction, granulomas in the bladder, lower ureters, and seminal vessels heal with dystrophic calcification.[6,7]

The systemic immune response is primarily a humoral reaction to circulating schistosomal antigens, which originate mainly from the worm's digestive enzymes (gut antigens), with a minor contribution from the tegument and ova. The gut antigens consist of a positively charged glycoprotein and a negatively charged proteoglycan (circulating cationic antigens and circulating anionic antigens, respectively). These antigens are present in most of the schistosomal immune complex–mediated lesions, particularly in glomeruli.[8] The antibody response is biphasic, reflecting the successive Th1 and Th2 stages of lymphocyte activation. In the Th1 stage, B cells tend to synthesize IgM, IgG1, and IgG3 under the influence of IL-2. During the Th2 phase, IgG2, IgG4, and IgA predominate; these have a limited ability to fix complement and may even block its deposition, hence their importance in modulating the granulomas.[4,6]

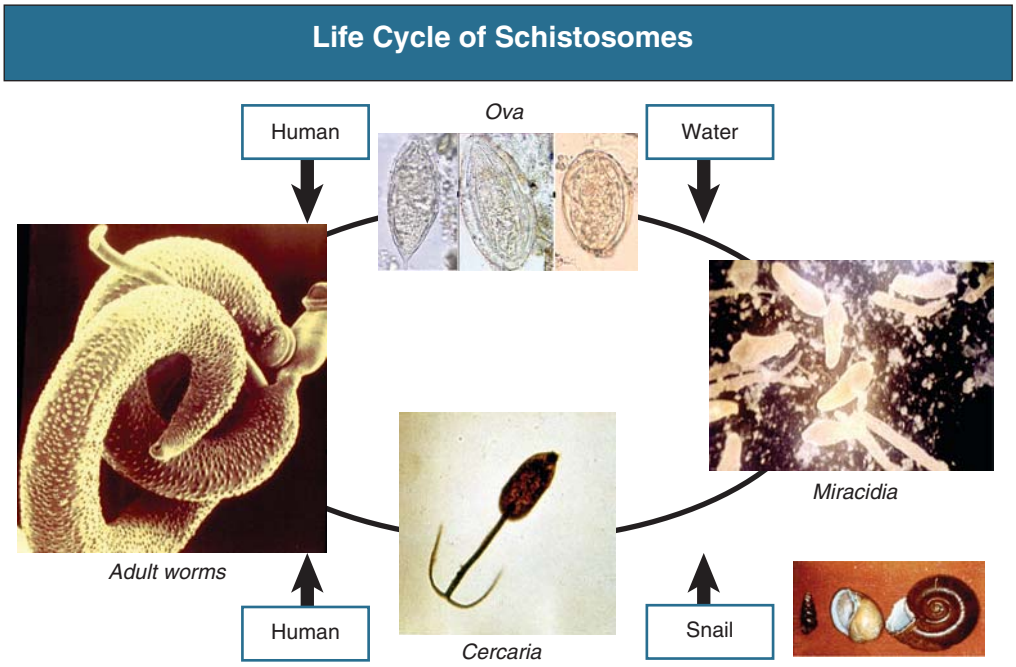

Figure 56-1 Life cycle of schistosomes.

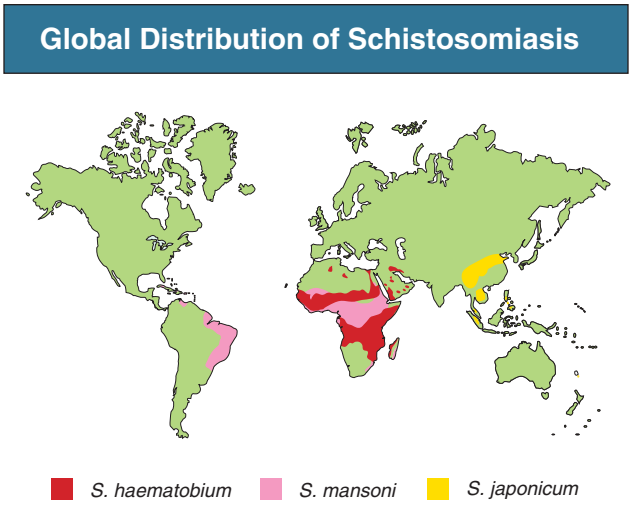

Figure 56-2 World map showing the geographic distribution of the main pathogenic schistosomes.

CLINICAL MANIFESTATIONS

Schistosomal lesions in the urinary system mirror the two major pathogenetic mechanisms. On one hand, there are local lesions, mostly affecting the lower urinary tract, caused by the local granulomatous response to *S. haematobium* ova.[9] On the other hand are those lesions caused by immune complex deposition in the glomeruli, usually associated with hepato-intestinal *S. mansoni* and, less commonly, urogenital *S. haematobium* infections.[10] Although glomerular lesions can be readily induced by *S. japonicum* in experimental animals,[11] this species does not seem to cause significant kidney disease in humans.

Lower Urinary Tract Schistosomiasis

The lower urinary tract and adjacent genital structures are the primary sites of *S. haematobium* infection. Clinical disease starts by the coalescence of multiple granulomas that form small "pseudotubercles" in the bladder mucosa (Fig. 56-5). These may consolidate to form sessile, occasionally pedunculated masses or ulcerate, leading to painful terminal hematuria, the most typical presenting symptom. Hematuria may vary from microscopic (40% to 100% in different reports) to gross (0% to 97%).[12] Ulcers eventually heal by fibrosis, with calcified granulomas under the atrophic and dirty mucosa, leading to the characteristic cystoscopic appearance of sandy patches and also the radiologic appearance of linear bladder calcifications in 2% to 62% of cases.[12] Similar lesions may occur in the lower ureters, bladder neck, seminal vesicles, and other organs in the vicinity (Fig. 56-6).

The bladder lesions predispose to secondary bacterial infection, particularly with *Pseudomonas* or *Proteus* species, usually following instrumentation. *Proteus* infection is notorious for favoring stone formation, which further complicates the scenario. The subsequent fibrotic process may involve the bladder neck, leading to outflow obstruction, or the vesicoureteral junction, leading to ureteral obstruction or vesicoureteral reflux. Involvement of the detrusor is a late event that may interfere with the motor function of the bladder, leading to an atonic or a hyperirritable viscus. Eventually, the bladder becomes a deformed, contracted, and calcified organ that accommodates a very small amount of urine that it can hardly void.

Bladder Cancer

Chronic bilharzial cystitis is precancerous. In a study of almost 10,000 Egyptian patients with bladder cancer, schistosomal association was confirmed in 55.3%. The predominant lesions were transitional cell carcinoma (65.8%) and squamous cell carcinoma (28.4%).[13] The tumor, particularly when of the squamous cell type, remains localized for a long time before spreading to the surrounding pelvic tissues or a distant site, thanks to the occlusion of lymphatics by the preceding fibrotic process.

Associated infection with human papillomavirus is encountered in about one fourth of cases, which suggests an etiologic role in malignant transformation.[14] Specific p53 gene mutations were detected in one third of cases.[15] This may be attributed to neutrophil-generated reactive oxygen molecules, cleavage of conjugated urinary carcinogens, or production of nitrosamines by bacterial enzymes.[16]

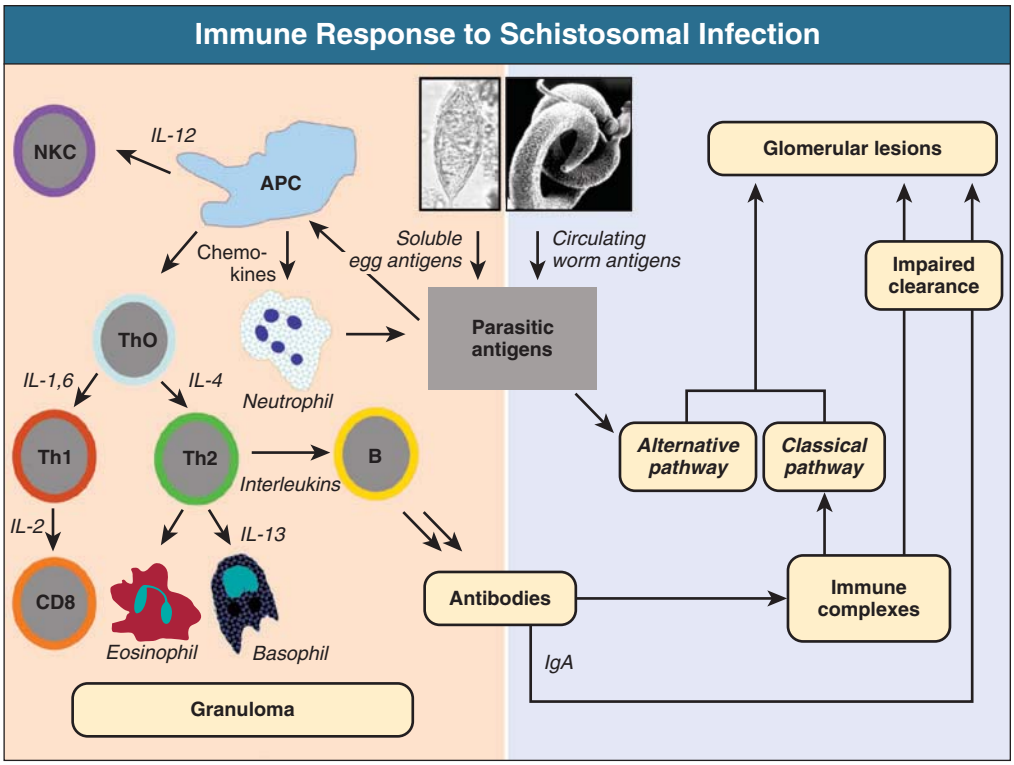

Figure 56-3 Immune response to schistosomal infection. The local immune response to deposited ova leading to granuloma formation is shown on the left; all cells shown in the diagram, in conjunction with antibodies or complement, participate in eventual parasite elimination (see text). The systemic immune response is shown on the right; note the important role of impaired clearance of schistosomal antigens and IgA in the development of glomerular lesions. *APC,* Antigen-presenting cell; *IL,* interleukin; *NKC,* natural killer cell.

Figure 56-4 *Schistosoma haematobium* granuloma. Note the egg's terminal spike, which identifies *S. haematobium,* and the distortion of shell from proteases and oxidants released by the local neutrophil infiltration. (Hematoxylin-eosin; ×500.)

Development of malignancy is suspected when the symptoms of chronic cystitis exacerbate, along with recurrence of hematuria many years after the initial presentation and the passage of small pieces of necrotic tissue with urine (necroturia). A characteristic radiologic sign is the irregular 'eating up' of the bladder calcification on a plain radiograph. Cystography shows the tumor mass as an irregular filling defect or bladder ulcer. Cystoscopy shows the tumor and provides the means for a histologic diagnosis (Fig. 56-7).

Human Immunodeficiency Virus Infection

Several recent studies have established an epidemiologic link between schistosomiasis and human immunodeficiency virus (HIV). It has been shown that women and men with lower urinary schistosomiasis were at a significantly increased risk of acquiring, and subsequently transmitting HIV to their sexual partners. The immunologic perturbation induced by schistosomiasis seems to accelerate the progression and spread of HIV infection in endemic areas.[17]

Upstream Consequences

Although ureteral strictures and calcifications are common, the hypertrophied upper ureteral musculature usually overcomes the lower obstruction, thereby limiting the upstream consequences. Nevertheless, hydronephrosis and progressive renal failure may develop when there is extensive ureteral scarring, in the presence of stones or secondary bacterial infection, or when the vesicoureteral junction is incompetent (Fig. 56-8). The frequency of upper urinary tract disease from *S. haematobium* is variably reported from different geographic regions—for example, from less than 10% in Niger to 48% in Cameroon.[10]

Interstitial Nephritis

Chronic pyelonephritis is the eventual outcome of complicated *S. haematobium* infection, resulting from obstruction, reflux, and bacterial infection. Granulomas have occasionally been seen in the renal interstitium but tend to be discrete and of no functional significance (Fig. 56-9). Immune-mediated tubulointerstitial nephritis has been described with *S. mansoni* in humans,[18] but the role of immune mechanisms remains questionable in *S. haematobium* pyelonephritis.

Figure 56-7 Bilharzial bladder cancer.

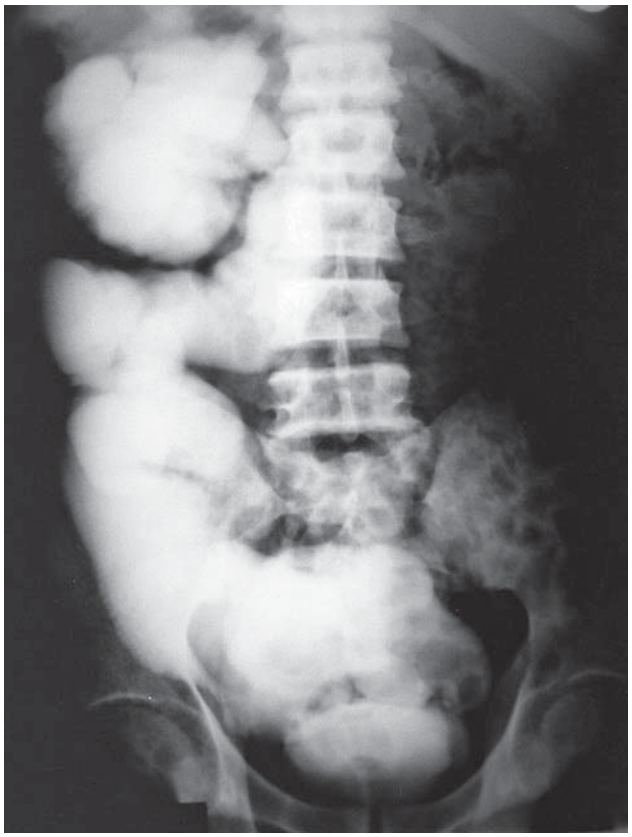

Figure 56-8 Ascending cystogram showing right megaureter caused by vesicoureteral reflux.

The typical pathologic picture is that of a deformed kidney with calyceal dilation, distortion, and atrophic parenchyma. Dense interstitial infiltration, fibrosis, and periglomerular scarring are present. The glomeruli may show ischemic collapse or other schistosomal lesions, such as proliferative glomerulonephritis (GN) or amyloidosis.

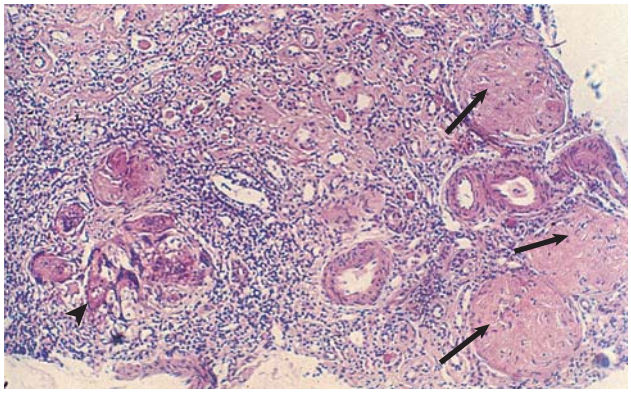

Figure 56-9 Schistosomal chronic interstitial nephritis. Note the dense cellular infiltration and fibrosis, atrophic dilated tubules, and thickened vessels. Three glomeruli heavily infiltrated with amyloid are seen on the right side *(arrows);* a schistosomal granuloma is seen in the lower left corner *(arrowhead).* (Hematoxylin-eosin stain; original magnification ×75).

The clinical picture is that of chronic tubulointerstitial nephritis (see Chapter 64), often associated with residual manifestations of lower urinary tract involvement. Hypertension is a late feature, being checked by concomitant tubular salt wastage. Anemia and osteodystrophy may be disproportionately severe because of the associated secondary distal tubular acidosis and nutritional deficiency in endemic areas.

Glomerulonephritis

Immune complex–mediated GN has been described in experimental[11] and human[10] infection, mainly with *S. japonicum* and *S. mansoni*. The latter species accounts for most clinically significant disease in humans. *S. haematobium* GN is rare and usually subclinical, though a small epidemic of acute nephritis was reported in an Egyptian village where the infection had been recently introduced as a result of change in the agricultural irrigation system.[19]

Schistosomal gut antigens are present in circulating immune complexes as well as in the immune deposits in mesangial, subendothelial, and intramembranous locations. The presence of liver fibrosis is critical because it results in impaired hepatic clearance of schistosomal antigens and immune complexes. These are mostly generated within the portal venous system, which accommodates the adult worms. Evidence of autoimmune reactivity has also been reported, but its potential pathogenetic role is ill-defined.

Most patients are 20- to 40-year-old men with evidence of hepatosplenic schistosomiasis. Renal involvement is asymptomatic in up to 40% of those, being identified by accidental or surveillance urinalysis, which may display various grades of proteinuria, or abnormal sediment. Some 15% of those with hepatosplenic schistosomiasis have overt GN, with proteinuria and microhematuria on presentation, with or without the nephrotic syndrome, hypertension, and impaired kidney function. Liver function test results are often normal. A polyclonal gammopathy is seen in most cases, whereas a monoclonal IgM response is seen in those with associated hepatitis C virus (HCV) infection and cryoglobulinemia. Rheumatoid factor activity and anti-DNA antibodies are detected in 5% to 10% of cases, particularly in association with *Salmonella* infection (see later discussion), but they do not correlate with clinical severity. Rheumatoid seropositivity is detected in much higher titers when HCV infection is associated.[20]

Six histologic classes of schistosomal GN have been proposed (Table 56-1 and Fig. 56-10).[10,20] Class I (mesangial proliferative), class

Classification of Schistosomal Glomerulonephritis

Class	Histology	Immunofluorescence	Etiologic Agent	Prevalence	Clinical Findings	Treatment of Renal Disease
I	Mesangial proliferative GN	IgM, C3 Schistosomal gut antigens	*S. haematobium* *S. mansoni* *S. japonicum*	27%-60% of asymptomatic patients, 10%-40% of patients with renal disease	Microhematuria Proteinuria	May respond to antiparasitic treatment
II	Diffuse proliferative exudative GN	C3, *Salmonella* antigens	*S. haematobium* *S. mansoni* + *Salmonella* species	*Salmonella* infections Reduced serum C3	Acute nephritic syndrome, toxemia	May respond to treatment of *Salmonella* and schistosomal infections
III	Membranoproliferative GN	IgG, IgA, C3, schistosomal antigens	*S. mansoni (S. haematobium*?)	7%-20% of asymptomatic patients and in 80% of patients with overt renal disease	Hepatosplenomegaly, nephrotic syndrome, hypertension, renal failure	No
IV	Focal segmental glomerulosclerosis	IgM, IgG (occasionally IgA)	*S. mansoni*	11%-38%	Hepatosplenomegaly, nephrotic syndrome, hypertension, renal failure	No
V	Amyloid	AA protein	*S. mansoni* *S. haematobium*	16%-39%	Hepatosplenomegaly, nephrotic syndrome, hypertension, renal failure	No
VI	Cryoglobulinemic GN	IgM, C3	*S. mansoni* + hepatitis C virus	Unknown	Hepatosplenomegaly, nephrotic syndrome, purpura, vasculitis, arthritis, hypertension, renal failure	Interferon + ribavirin, corticosteroids, immunosuppression, plasma exchange

Table 56-1 Classification of schistosomal glomerulonephritis. *GN,* Glomerulonephritis.

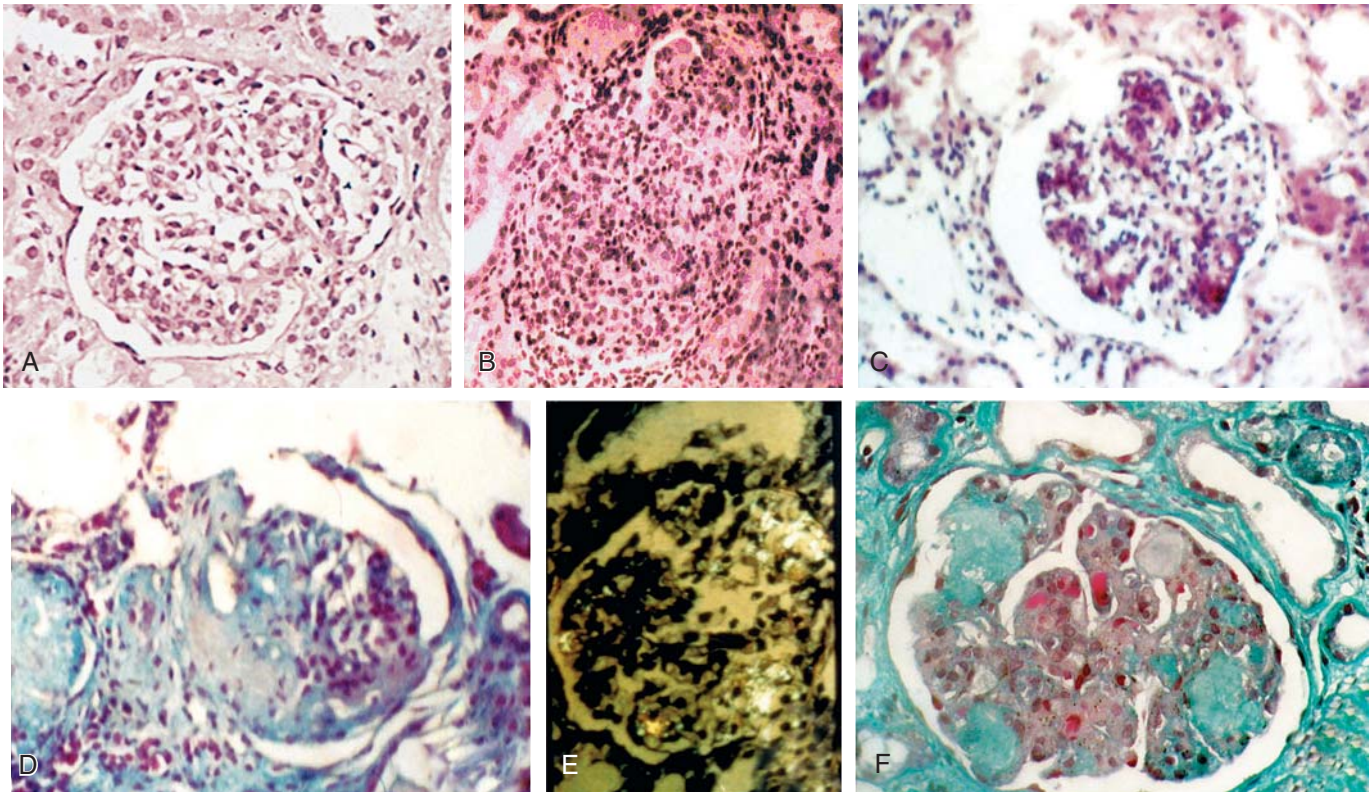

Figure 56-10 Schistosomal glomerulopathy. A, Mesangial proliferative glomerulonephritis (GN), hematoxylin-eosin stain (class I). **B,** Schistosoma- and *Salmonella*-associated exudative GN, hematoxylin and eosin stain (class II). **C,** Membranoproliferative (mesangiocapillary) GN type I, hematoxylin and eosin stain (class III). **D,** Focal segmental glomerulosclerosis, Masson trichrome stain (class IV). **E,** Green birefringence under polarized light in a glomerulus with mesangial proliferation in a patient with mixed *Schistosoma haematobium and Schistosoma mansoni* infection, Congo red stain (class V). **F,** Amyloid deposits and cryoglobulin capillary thrombi (red stain) in a glomerulus displaying focal mesangial proliferation in a patient with schistosomal hepatic fibrosis and associated hepatitis C virus infection (class VI).

III (membranoproliferative), and class IV (focal segmental proliferative and sclerosing) result from the deposition of immune complexes representing different stages in the evolution of "pure schistosomal" hepatosplenic disease. The main deposits in class I are schistosomal antigens, IgM, and C3; and in class III and class IV, IgG and IgA, usually without schistosomal antigens. The IgA deposits parallel the severity of proteinuria and mesangial proliferation. Impaired hepatic clearance and increased mucosal synthesis of IgA have been documented in those patients.[21] Whereas class I lesions are seen in most asymptomatic cases, class III and class IV are usually symptomatic and progressive, even with eradication of the parasitic infection.

Class II (diffuse proliferative and exudative) is associated with urinary or biliary coinfection with *Salmonella* strains, usually *Salmonella paratyphi* A in Africa and *Salmonella typhimurium* in Brazil, which are attached to specific receptors in the tissues of adult schistosomes. C3 and *Salmonella* antigens have been detected in the glomerular capillary walls and the mesangium. In these patients the clinical presentation is typical of acute postinfectious GN, associated with manifestations of *Salmonella*-related toxemia (fever, exanthema, and severe anemia).

Serum amyloid A protein deposits are detected by special stains or electron microscopy in up to 15% of biopsy samples from patients with class III and class IV, whereas AA-amyloidosis may be the predominant lesion (class V) in less than 5% of patients with clinically overt schistosomal GN. It occurs with heavy, often mixed infection regardless of the anatomic site. Minimal amyloid deposits do not seem to alter the clinical presentation or prognosis, but typical class V lesions are grossly nephrotic and relentlessly progressive.

A class VI lesion was more recently described in patients with hepatosplenic schistosomiasis and HCV infection.[20] This association is common, particularly in Egypt, where it is believed that the virus was acquired many decades earlier, when intravenous injections were used for mass treatment of schistosomiasis. Some soft evidence suggests that the virus may be transmitted with the infected cercariae. The lesion consists of a mixture of mesangial proliferation, amyloid deposition, fibrinoid necrosis, and cryoglobulinemic thrombi in the glomerular capillaries with tubular casts. Patients have chronic hepatitis, cirrhosis, nephrotic syndrome, cryoglobulinemic skin vasculitis, polyarthritis, and rapidly progressive renal failure associated with severe protein-calorie malnutrition.

DIAGNOSIS

Schistosoma haematobium Urinary Tract Disease

The bedside diagnosis of lower urinary schistosomiasis is easily made, particularly in patients with the typical pattern of painful terminal hematuria after exposure to fresh river waters in an endemic area. Diagnosis is more difficult when the history of exposure is less convincing (e.g., swimming pools) or when the clinical presentation is atypical (such as bacterial pyelonephritis, typhoid, or amyloidosis).

The diagnosis is made by finding ova in a fresh urine sample, which is easy because of their abundance, large size, and typical appearance with terminal spike (see Fig. 56-4). Live ova, containing mobile miracidia, indicate active infection, whereas dead, calcified ova may continue to be shed from fibrotic lesions for many months or even years.

Serologic diagnosis is based on finding circulating schistosomal antigens or antibodies by gel diffusion, precipitation, complement fixation, chromatography, immunoelectrophoresis, indirect hemagglutination, microfluorometry, radioimmunoassay, or various forms of enzyme-linked immunosorbent assay (ELISA) techniques. The circumoval precipitin test is most frequently used in clinical laboratories. These techniques are useful in confirming the diagnosis in the absence of ova, which occurs with old infections when the worms are sterile but continue to release their antigens. Serologic tests are also useful in assessing the response to treatment because titers usually become negative within 3 to 6 months of complete eradication of infection.

The radiologic appearances of bladder and seminal vesicle calcification are so typical that no further confirmatory tests are needed in an endemic area. Cystoscopic findings are equally pathognomonic although seldom required. Early pseudotubercles are easily distinguished from mycobacterial infection by their size and the surrounding mucosal pathologic changes. The presence of sandy patches with associated masses, polyps, and even neoplasms makes the diagnosis. Tissue biopsy confirms the parasitic nature of the lesions. Different imaging techniques (e.g., ultrasound, intravenous urography, voiding cystography) are useful in the diagnosis of upstream complications, including obstruction and reflux (see Chapter 60).

The main differential diagnosis for urinary schistosomiasis is tuberculosis, which also causes hematuria, strictures, back pressure, and chronic kidney disease. This differential can be resolved with appropriate parasitologic and bacteriologic techniques (see Chapter 54).

Schistosoma mansoni Glomerulonephritis

Overt glomerular disease in patients with hepatosplenic schistosomiasis is suspected in those who develop hypertension, nephrotic or nephritic syndrome, or chronic kidney disease. Occult glomerular disease is indicated by the presence of abnormal urinary sediment or kidney function. Although renal biopsy is essential for the diagnosis and classification, none of the lesions is pathognomonic unless schistosomal antigens are detected, which is unusual in clinically overt cases when sought with conventional immunofluorescence. Identification of *S. mansoni* eggs in the stools (Fig. 56-11) or submucosal rectal biopsy samples supports the diagnosis. Concomitant *Salmonella* or HCV infection can be detected by appropriate microbiologic tests. The various serologic abnormalities described are of limited diagnostic value, except the high rheumatoid factor, monoclonal IgM expansion, and low C4 that are typical of class VI.

Other glomerular disorders associated with hepatic fibrosis, such as secondary IgA nephropathy and hepatic glomerulosclerosis,

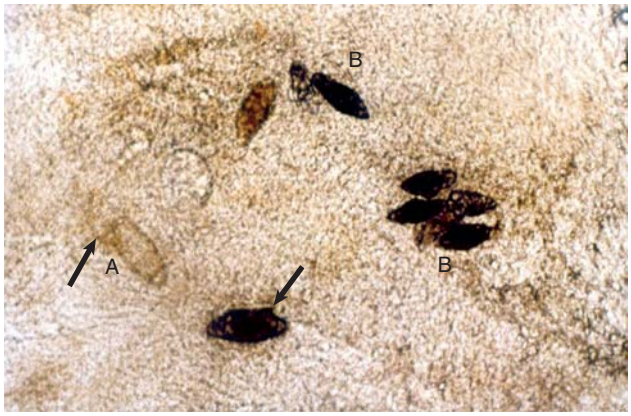

Figure 56-11 Stool smears showing living *(A)* and dead *(B) Schistosoma mansoni* ova. Species are identified by the lateral spike *(arrows).*

should be considered in the differential diagnosis. However, in both these conditions the renal lesions are relatively mild, mainly with microhematuria at presentation but rarely with nephrotic-range proteinuria or impaired renal function. The glomerular deposits are mostly mesangial, in contrast to those seen in schistosomiasis, in which subendothelial and intramembranous deposits may also be present.

TREATMENT

Schistosoma haematobium Urinary Tract Disease

S. haematobium is susceptible to antimony compounds, organophosphates (metrifonate), and niridazole, but the current drug of choice is praziquantel, the most effective and least toxic. It is administered as a single oral dose of 40 mg/kg body weight. Antiparasitic treatment cures the early bladder disease, yet it has no effect on sandy patches or other fibrotic lesions. Ureteral distention with radiologic evidence of hydronephrosis may be reversed in a few weeks after successful treatment.

Antibacterial therapy usually controls acute episodes of cystitis and pyelonephritis. However, it must be combined with simultaneous eradication of parasitic infection if still active, especially when the urinary bacterial infection is a result of typhoid *(Salmonella typhi)*.

Chronic fibrotic lesions are difficult to treat. Surgery or the placement of stents may be necessary for the relief of an obstructive lesion. However, particular caution is required in dealing with the vesicoureteral junction to avoid induction of reflux. Several plastic procedures are available to restore the distorted ureteral, bladder, or urethral anatomy. Associated bacterial infections may require long-term low-dose antibiotics.

Regular dialysis in such patients can be difficult owing to the negative effects of chronic infection; the associated schistosomal lesions in the liver, lungs, and other organs; and the comorbid impact of undernutrition, viral infection, or malignant disease. The same factors reflect on the outcome of renal transplantation, with the additional risk for urinary leakage, which is many-fold higher than usual owing to the presence of fibrotic granulomas and anatomic distortion in the bladder wall. Reinfection with *S. haematobium* has also been described in patients living in an endemic area.[22]

Schistosoma mansoni Glomerulonephritis

S. mansoni is more resistant to treatment and may require higher doses of praziquantel (40 to 60 mg/kg body weight) or the use of oxamniquine (single dose of 15 mg/kg body weight in South America or two doses of 15 mg/kg body weight given 12 hours apart in Africa). Nevertheless, eradication of the parasite can be curative only in classes I and II. In class II, it must be combined with antibiotics for the control of *Salmonella* infection (usually ampicillin and cotrimoxazole). Antischistosomal therapy (praziquantel or oxamniquine) and immunosuppressive therapy are ineffective in all other classes of schistosomal GN.[10]

Dialysis may be difficult in those who reach end-stage renal disease because of the frequent presence of esophageal or gastric varices that carry the risk for bleeding with anticoagulation for hemodialysis. Endoscopy is essential before the start of regular hemodialysis, with prophylactic sclerotherapy if necessary. Although peritoneal dialysis is a viable option in some cases, it is relatively contraindicated in those with significant ascites because of the risk for excessive protein loss in the effluent.

Renal transplantation is a viable option in those who develop end-stage renal disease, in the absence of major risk factors such as viral infection, undernutrition, or hepatic insufficiency. Uncomplicated residual hepatic fibrosis in the recipient does not seem to significantly modify the pharmacokinetics of the immunosuppressive agents used in transplant recipients. However, variations in cyclosporine blood levels have been noted[15] and attributed to altered absorption of the drug. Associated viral hepatitis may have a considerable impact on the protocols of donor selection and prophylactic immunosuppression and on the eventual outcome (see Chapters 102 and 105).

Recurrence of schistosomal GN has been described in a few patients,[23] suggesting the persistent release of antigens from living worms. Though not an evidence-based practice, many authorities recommend the administration of a single dose of praziquantel to recipients known to have been previously infected with the parasite.

CHAPTER 57

Glomerular Diseases Associated with Infection

Bernardo Rodriguez-Iturbe, Emmanuel A. Burdmann, and Rashad S. Barsoum

GENERAL CHARACTERISTICS OF GLOMERULAR DISEASES ASSOCIATED WITH INFECTION

The observation of dark scanty urine in the convalescent period of scarlet fever is more than two centuries old. At the beginning of the last century, Clemens von Pirquet, on the basis of clinical observations, postulated that the disease resulted from antibodies that instead of having beneficial effects were pathogenic—an insight that opened the field of immune-mediated renal disease.

Today, the incidence of infection-related glomerulonephritis (GN) is declining in developed countries, and usually the disease is associated with older individuals and debilitating conditions such as diabetes, malignant neoplasia, acquired immunodeficiency syndrome (AIDS), and alcoholism. The prognosis in elderly individuals is poor, with less than 25% recovering full renal function. In recent years there has been a tendency for an increase in GN associated with *Staphylococcus* (IgA dominant) and fewer cases associated with *Streptococcus,* but a wide variety of pathogens have been reported (Box 57-1). In general, the infection-related GNs have a better prognosis than other forms of GN, but in adult patients with other comorbid factors they carry a significantly higher risk of chronic kidney disease (CKD).[1]

Histologic Patterns and Pathogenesis

The histologic patterns and the most typical infectious diseases associated with them are shown in Table 57-1. Mesangial proliferative GN is usually acute and self-limited. Microscopic hematuria and non-nephrotic proteinuria are present in association with deposits of IgG, IgM, and C3. Serum complement may be transiently decreased. Diffuse proliferative GN is also acute and self-limited if the infection is eradicated. IgG, IgM, and C3 deposits are prominent in the mesangium and glomerular capillaries, and electron-dense deposits are present in mesangial, subendothelial, and subepithelial locations. Staphylococcal infections, particularly methicillin resistant, may induce diffuse proliferative GN with crescent formation and exclusive or predominant IgA deposition. Membranoproliferative GN (MPGN) is commonly observed with chronic infections. The clinical presentation is usually with severe proteinuria, microscopic hematuria, and variable degrees of hypertension. Immunoglobulins and C3 deposits are present. In the setting of liver disease (as in *Schistosoma mansoni* infection), IgA may be a predominant component of the immune deposits. Membranous nephropathy (MN) is associated with chronic infections and may manifest as the nephrotic syndrome. Finally, vasculitis may develop in association with viral (especially hepatitis B virus [HBV] and human immunodeficiency virus [HIV]) or bacterial (rarely *Streptococcus*) infections.

Infection-related GN, especially when it is immune complex associated, occurs more frequently and has a worse prognosis in conditions in which there is difficulty clearing the infection or immune complexes. These conditions include HIV infection, infections acquired in the neonatal period (when tolerance is often induced, such as is observed with HBV infection), chronic liver disease, diabetes, and chronic alcoholism.

Glomerulonephritis associated with infections usually results from glomerular deposition of immune complexes containing bacterial antigens, but other mechanisms may also occur. Staphylococcal infections may cause GN induced by bacterial wall superantigens that induce a nonspecific polyclonal immunoglobulin response. Focal segmental glomerulosclerosis (FSGS) with glomerular collapse (collapsing glomerulopathy) may occur with HIV or parvovirus B19 infection. The hemolytic uremic syndrome (HUS) may result from verotoxin-producing *Escherichia coli* or *Shigella* species (see Chapter 29). Amyloidosis may result from chronic infections such as tuberculosis, leprosy, and schistosomiasis. Interstitial nephritis manifested as acute renal failure may result from several viral (especially Epstein-Barr virus [EBV]) or bacterial (especially *Legionella*) infections. Hantavirus can also induce a hemorrhagic fever–renal failure syndrome in which infection of the interstitial capillaries and tubules leads to acute renal failure (see Chapters 69 and 70).

BACTERIAL INFECTIONS

Poststreptococcal Glomerulonephritis

Epidemiology

Poststreptococcal glomerulonephritis (PSGN) is more common in males (2:1) and usually affects children 2 to 14 years old. Certain strains of group A *Streptococcus pyogenes* are nephritogenic: impetigo caused by streptococci of M types 47, 49, 55, and 57 and upper respiratory infections with types 1, 2, 4, and 12.[2] More recently, ingestion of unpasteurized milk contaminated with group C *Streptococcus (Streptococcus zooepidemicus)* has caused clusters of cases and at least one large epidemic.[3] The risk of nephritis in epidemics may range from 5% in throat infections to as high as 25% in M type 49 pyoderma. The risk of PSGN is reduced by early antibiotic treatment. A genetic predisposition is suggested because there is an association of PSGN with HLA-DR4 and HLA-DR1 and higher attack rates in siblings than expected for the general population.

Poststreptococcal glomerulonephritis is becoming less common in industrialized countries and, instead of affecting predominantly children, now occurs more commonly in debilitated elderly individuals, alcoholics, diabetics, and intravenous drug users. The reduction in incidence of PSGN likely relates to improvement in public health, more rapid and frequent use of antibiotics, and perhaps the common practice of fluorination of water, which reduces the expression of virulence factors in cultures of *S. pyogenes.* Nevertheless, PSGN remains common in developing countries, where it may have an incidence of 9.3 to 9.8 cases per 100,000 population,[4] and it represents a major problem in indigenous populations. For example, in

Australia more than 95% of the cases occur in aboriginal tribes in remote locations.[5]

Pathogenesis

Two nephritogenic streptococcal antigens have been identified: nephritis-associated plasmin receptor (NAPLr), which was characterized as glyceraldehyde-3-phosphate dehydrogenase (GAPDH); and streptococcal pyrogenic exotoxin B (SPEB) and its more immunogenic precursor, zymogen. GAPDH and SPEB have been demonstrated in renal biopsy specimens of acute PSGN, and antibody titers to both these antigens are elevated in most convalescent sera.[2] GAPDH has been localized in areas of the glomeruli with plasmin-like activity, suggesting a local direct mechanism of glomerular inflammatory damage, but it is not co-localized with complement or immunoglobulin.[6,7] In contrast, SPEB is co-localized with both complement and IgG, suggesting a participation in the immune-mediated glomerular damage.[8] SPEB is the only putative streptococcal nephritogenic antigen that so far has been demonstrated in the subepithelial electron-dense deposits known as humps, the most typical histologic lesion of acute PSGN (Fig. 57-1). In studies from Latin America and central Europe, SPEB but not GAPDH is usually detectable in renal biopsy specimens of PSGN patients.[9] In contrast, GAPDH was present in PSGN in a study of Japanese patients.[6,7] These contrasting results raise the possibility that different streptococcal antigens are capable of inducing acute nephritis in different ethnic groups. Indeed, a study of the group C *S. zooepidemicus* strain that caused the epidemic outbreak in Brazil revealed an absence of the gene related to SPEB, which documents that this antigen was not involved in that epidemic.[9]

Poststreptococcal glomerulonephritis is thought to occur when persistent streptococcal infection results in antigenemia and the development of circulating immune complexes that primarily deposit in the subendothelial and mesangial locations to initiate an inflammatory cascade with local complement activation and the recruitment of neutrophils and monocytes-macrophages. Subepithelial immune deposits (humps) develop when cationic antigens (e.g., SPEB) are involved and result from dissociation of immune complexes in the subendothelial space with transit and re-formation on the outer aspect of the glomerular basement membrane.

Several issues remain unresolved. For example, immune complex disease generally results in activation of the classical complement pathway, yet in most cases, C4 levels are normal and only C3 is found in the deposits. This could be explained by the presence of antigens (such as GAPDH) that activate the alternative pathway. In some patients, C3Nef IgG antibodies that are capable of activating the alternative complement pathway have been demonstrated in sera. Activation of the mannose-binding lectin complement pathway by bacterial antigens has been postulated (see Chapter 16), but individuals genetically unable to activate this pathway may still develop PSGN.

Finally, the role of autoimmune mechanisms remains to be clarified. Rheumatoid factors (especially IgG rheumatoid factor) and

cryoglobulins are found in the serum of one third of patients in the first week of the disease. Rheumatoid factors (antibody to IgG) have been shown in one third of the renal biopsy specimens and in the eluate from the kidney in a fatal case. Anti-IgG reactivity may result from the loss of sialic acid from autologous IgG due to streptococcal neuraminidase (sialidase) or from binding of the Fc fragment of IgG to type II Fc receptors in the streptococcal wall.[2] Anti-IgG antibody, induced by streptococcal IgG Fc-binding protein, may play a role in the renal accumulation of IgG-containing complexes.[10] Additional manifestations of autoimmune reactivity include the anti-C1q antibodies, particularly in severe cases, and rarely anti-DNA reactivity, antineutrophil cytoplasmic antibody (ANCA), and autoimmune hemolytic anemia.[2]

Pathology

Renal biopsy shows a diffuse endocapillary GN with proliferation of mesangial and endothelial cells (see Fig. 57-1). There is glomerular and interstitial infiltration of monocytes and lymphocytes. Glomerular accumulation of neutrophils is common and is termed exudative GN. Glomerular immune deposits of C3 (100% of the cases), IgG (62%), IgM (76%), and properdin and the terminal membrane attack complex C5b-C9 (85% of the cases, usually co-deposited with C3) are seen in glomerular capillary loops and in the mesangium. A seminal work by Sorger and colleagues[11] described three patterns of immunofluorescence in the glomeruli and their clinical correlations: the mesangial pattern of irregular and heavy immune deposits, the starry sky pattern of deposits scattered in mesangium and in capillary walls, and the garland pattern formed by gross deposits in the capillary loops (see Fig. 57-1). The garland pattern is clinically relevant because it is associated with heavy proteinuria and a large number of electron-dense subepithelial immune deposits. Ultrastructural studies demonstrate the subepithelial humps, which are typical, although not pathognomonic of PSGN because they may also be observed in postinfectious GN of other causes (classically endocarditis-associated GN secondary to *Staphylococcus* infection), cryoglobulinemia, and lupus nephritis. Recent reports have called attention to the identification of NAPLr antigen in biopsies with features of MPGN, raising the possibility of a more varied histologic presentation on PSGN than previously recognized.

Glomerulonephritis resolves by apoptosis of the excess cells. Residual renal injury is common, and biopsy specimens obtained years later show variable degrees of focal glomerulosclerosis and mesangial expansion even in the absence of clinical disease. The prognostic significance of these changes is undetermined.

Clinical Manifestations

Most patients give a history of a previous streptococcal infection, although it has often resolved at presentation. The incubation period is longer after skin infections (several weeks) than after throat infections (2 weeks).

The classic presentation is acute nephritic syndrome. Hypertension is found in 80% of patients. Edema occurs in 80% to 90% of cases and is the chief complaint in 60%; yet ascites is distinctly unusual. Primary sodium retention is the cause of expanded intravascular volume, hypertension, and edema. Plasma renin activity and aldosterone are reduced and natriuretic peptide levels are increased. Hematuria is universal and in 30% of cases is macroscopic. The nephrotic syndrome may occur at the onset in 2% of the children and 20% of adults. Rapidly progressive renal failure, resulting from extracapillary crescent formation, occurs in less than 1% of patients. Increments in serum creatinine occur in 25% to 40% of the children and in up to 83% of adults.

Positive cultures for *Streptococcus* are obtained in 10% to 70% of the cases during epidemics and in about 20% to 25% of sporadic cases. Antistreptolysin O (ASO) titers are increased in more than two thirds of patients with PSGN after throat infections, and anti-DNAse B titers are elevated in 73% of the post-impetigo cases. The streptozyme panel (which measures antibodies to four antigens, anti-DNAse B, antihyaluronidase, ASO, and antistreptokinase) is more sensitive, and the result is positive in more than 80% of patients. Antibody titers to GAPDH and SPEB/zymogen, although more sensitive and specific,[2,4] are not clinically available.

Serum C3 levels are depressed in more than 90% of patients in the first week of disease and return to normal in less than 2 months. Levels of C4, a measure of classical complement pathway activation, may be normal. Serum IgG and IgM are elevated in 80% of the cases, and in contrast with another poststreptococcal disease, rheumatic fever, IgA is normal. Cryoglobulins, elevated rheumatoid factor, and anti-C1q antibodies are present in up to one third of patients in the acute phase. Subclinical disease, manifested by microscopic hematuria and fall in serum complement, occurs four to five times more frequently than clinically overt disease and often involves siblings of index cases. On occasion, whole families have various manifestations of PSGN; it is therefore important to inquire about a history of streptococcal infections and signs of nephritic syndrome among family members.

Management

Renal biopsy is not routinely indicated in PSGN but may be required to confirm the diagnosis in the presence of unusual clinical features, such as nephrotic proteinuria, decreased C3 levels lasting for more than a month (suggests lupus or hypocomplementemic MPGN), or increasing renal dysfunction (suggests crescentic GN).

Management includes culture and treatment of any remaining streptococcal infection. Early antibiotic treatment is likely to prevent PSGN.

Treatment is with penicillin IM (a single intramuscular [IM] injection of 1.2 million units of benzathine penicillin in adults or half this dose in small children) or oral penicillin, or erythromycin (in patients allergic to penicillin) or cephalosporins. Oral treatments should be given in doses every 6 hours for 7 to 10 days.[12]

Treatment of the acute nephritic syndrome includes restriction of fluid and sodium intake and the use of loop diuretics to treat circulatory congestion. An oral long-acting calcium antagonist is usually sufficient to control hypertension. Nitroprusside is used in exceptional cases with hypertensive encephalopathy. Dialysis (either hemodialysis or peritoneal dialysis) is required in 25% to 30% of adults but seldom in children.

Rare complications of acute PSGN include cerebral vasculitis, cerebral vasogenic edema, and posterior reversible leukoencephalopathy. The last is manifested by mental disturbances, visual hallucinations, headache, and convulsions and may be confused with hypertensive encephalopathy. The diagnosis requires the use of magnetic resonance imaging studies.

Anecdotal reports suggest that the rare patients with crescentic GN associated with PSGN may benefit from pulse methylprednisolone therapy, and if spontaneous improvement is not observed in 2 weeks, this therapy may be tried. The prognosis of crescentic PSGN is significantly better than that of crescentic GN from other causes, but complete recovery may be expected in less than half the cases.

Prognosis

Most children with PSGN recover. In older patients, there are higher acute complication rates including a higher prevalence of renal impairment (60% to 70%), congestive heart failure (40%), nephrotic proteinuria (20%), and mortality (25%).[4] Deficiency of complement regulatory proteins (such as factor H–related protein 5) may represent a risk factor for the development of CKD in these patients.[13]

After recovery, mild proteinuria (<500 mg/day) and microscopic hematuria may persist for up to 1 year without worsening the long-term prognosis. Nevertheless, some individuals, especially adults, may have persistent impaired renal function, proteinuria, or hypertension. However, end-stage renal disease (ESRD) occurs in less than 1% of the children observed for one to two decades after the acute attack.[4]

Certain epidemics have reported a high incidence of chronicity, perhaps because of a predominantly adult population.[14] Risk factors for the development of CKD include an onset with nephrotic-range proteinuria, older age, and coexistent diabetic nephropathy and metabolic syndrome.[15]

Endocarditis-associated Glomerulonephritis

The epidemiology of infective endocarditis has changed in the last three to four decades, especially in industrialized countries. Instead of being a disease that affects predominantly young adults with rheumatic heart disease, it now is seen in older patients and in patients at risk, a category that includes drug users, patients with prosthetic valves and implantable devices, patients with HIV infection, and patients who develop health care–associated bacteremia. *Staphylococcus aureus* and *Staphylococcus epidermidis* are the most common pathogens in hospital-acquired infective endocarditis, whereas *Streptococcus* infections are more frequent in community-acquired and native valve endocarditis.[16] Nevertheless, the incidence of methicillin-resistant *S. aureus* (MRSA) causing community-acquired endocarditis is increasing.[17] Gram-negative bacteria (*Enterococcus faecalis, E. coli, Brucella,* and *Proteus*) less frequently cause infective endocarditis. Culture-negative infective endocarditis is usually caused by *Bartonella* species and *Tropheryma whipplei.*[18]

In a survey of 62 patients with infective endocarditis in whom renal tissue was available for study, biopsy and autopsy material demonstrated GN in 26%; localized infarcts, half of which were septic, in 31%; and interstitial nephritis, mostly attributable to antibiotics, in 10%. Cortical necrosis was found in 10% of the patients.[19] The most common GN was diffuse proliferative, followed less frequently by focal GN, MN, and MPGN type I. Crescent formation is found in about half of the proliferative GN forms. Widespread deposition of IgM, IgG, and C3 and electron-dense subendothelial, mesangial, and subepithelial deposits (which resemble poststreptococcal humps) are usually evident. In subacute endocarditis, focal segmental proliferative lesions with fibrinoid necrosis or capillary thrombi and mesangial immune deposits may be present. Variable degrees of cellular infiltration and atrophy and fibrosis may be seen in tubulointerstitial regions. Intense eosinophilic infiltration should suggest another diagnosis, such as acute interstitial nephritis secondary to antibiotics.[19]

The pathogenesis of endocarditis-associated GN involves the deposition of immune complexes containing bacterial antigens in the glomeruli, a mechanism similar to that proposed for PSGN. Cryoglobulins (polyclonal, i.e., type III) are present in 50% of patients and may be found in glomeruli. Some bacteria (classically MRSA) express superantigens that can also activate T cells directly and lead to a polyclonal gammopathy and immune complex GN (see later).

Clinical Manifestations and Diagnosis

Patients often have fever, arthralgias, anemia, and purpura. Rarely, infective endocarditis may manifest as primary renal disease without

characteristic systemic symptoms. Classic findings in endocarditis, such as Osler nodes, Janeway lesions, and splinter hemorrhages, are seldom seen, and the diagnosis may be missed until autopsy in 38% of the patients.[20]

The renal manifestations usually are microscopic hematuria and mild proteinuria (except in patients with membranous GN, which may have proteinuria in the nephrotic range), with or without mild impairment in renal function (except in patients with renal vasculitis, in which renal failure is common). A rapidly progressive clinical course or nephrotic syndrome is unusual. Decreased C3 and C4 levels (consistent with activation of the classical complement pathway), high titers of rheumatoid factor, circulating immune complexes, and type III cryoglobulins are common findings. These serologic findings are observed in 50% of patients with infective endocarditis and in a higher proportion of patients with endocarditis-associated GN, although complement levels may be normal in superantigen-mediated GN.

The differential diagnosis includes antibiotic-associated nephrotoxicity, interstitial nephritis, and embolism. Embolism may originate from the left side of the heart or from the right if the foramen ovale is patent. Microscopic or large emboli may occlude small or large vessels, the latter observed with fungal or *Haemophilus* endocarditis. Large emboli may produce flank pain, hematuria, and pyuria; microemboli produce local infarcts and microabscesses that give the kidney the classic "flea-bitten" appearance. Interstitial nephritis is often associated with fever, eosinophilia, and eosinophiluria (see Chapter 62). Unfortunately, endocarditis-associated GN may also cause fever, and eosinophiluria can complicate crescentic nephritis of any etiology.

Antibiotic treatment usually results in complete eradication of endocarditis with correction of serologic abnormalities, but microscopic hematuria, proteinuria, and elevation of serum creatinine may persist for months after eradication of the infection. Early diagnosis, risk stratification, and prompt start of antibiotic therapy are critical for improving the prognosis.[21] Normalization of C3 levels during therapy correlates with a good outcome. In patients with crescentic GN, pulse corticosteroid therapy and plasma exchange have been used in addition to effective antibiotic therapy, but the value of these treatments remains undefined. The overall mortality of bacterial endocarditis is 20% and increases to 36% in patients who develop renal failure.[22]

Staphylococcal Infections with Glomerular IgA Deposition

In 1995, Koyama and co-workers[23] described a novel form of severe GN that was associated with methicillin-resistant staphylococcal infections and included renal impairment, nephrotic proteinuria, and variable degrees of crescent formation. There was IgA-dominant or co-dominant deposition in association with other immunoglobulin and complement deposits, and the patients had increased serum IgA levels and specific T cell receptor V_{β}^{+} subsets during the course of the disease. They postulated that staphylococcal superantigens were involved in the pathogenesis. The frequency of this condition is undefined, but it represents 1.6% of adult kidney biopsies in one institution.[24]

Clinical and Pathologic Characteristics

In a recent review,[25] IgA-dominant postinfectious GN was four times more frequent in males and the average age was 60 years. Underlying diabetes was present in 55% of the patients, and diabetic glomerulosclerosis frequently coexisted. The most common site of infection was the skin. Acute or rapidly progressive renal failure and proteinuria in the nephrotic range were present in half the patients, and gross hematuria in 20%. However, milder clinical courses occur as well. Complement levels are low in almost 70% of the patients.

Renal biopsy reveals endocapillary proliferative and exudative (63%), mesangial proliferative GN (33%), or crescentic (4%) GN. Typically C3 staining is intense, in contrast with IgA nephropathy.[25] Interstitial fibrosis and tubular atrophy may be mild or severe. Electron microscopy shows electron-dense deposits in the mesangium in the glomerular basement membrane and in subendothelial areas (Fig. 57-2). Large subepithelial electron-dense deposits are reported in some series.[26]

Pathogenesis

Infection-related IgA-dominant GN is associated with methicillin-resistant or methicillin-sensitive *S. aureus* infections in most patients.[25] The pathogenesis may involve staphylococcal superantigens that bind directly to the major histocompatibility complex class II molecules on antigen-presenting cells, which then engage the V_{β} T cell receptor region.[23] The result is an intensive T cell activation with generation of cytokines that activate in B cells a polyclonal IgG and IgA response. Researchers have identified an *S. aureus* cell envelope antigen that is co-localized with the glomerular IgA deposits.[27] Mild elevations in serum IgA levels occur in some patients, suggesting activation of a selective IgA response. Whether staphylococcal antigens are involved in the pathogenesis of IgA nephropathy (see Chapter 23) is a possibility that deserves further study.

Differential Diagnosis and Treatment

Antibiotic treatment of IgA-dominant *Staphylococcus*-related GN may lead to recovery of renal function. Corticosteroid treatment is contraindicated, at least while there is active infection, which makes it important to establish its differential diagnosis with IgA nephropathy, in which corticosteroids may be indicated in severe cases (see Chapter 23). Characteristics that may be helpful in the differential diagnosis with IgA nephropathy are the association with staphylococcal infection (in contrast with upper respiratory infection in IgA nephropathy), the frequent occurrence of hypocomplementemia, massive proteinuria (rare in IgA nephropathy), and intense C3 deposits in the renal biopsy.

Shunt Nephritis

Atrioventricular shunts used to relieve increased intracranial pressure may become infected in about 6% of adult patients.[28] GN may develop in 0.7% to 2% of infected atrioventricular shunts; this may occur 2 months to many years after insertion. The infective organisms are usually *S. epidermidis* and *S. aureus* and less frequently *Propionibacterium acnes,* diphtheroids, *Pseudomonas,* or *Serratia.* In contrast with atrioventricular shunts, ventriculoperitoneal shunts are rarely complicated with GN.

Patients have insidious low-grade fever, arthralgias, weight loss, anemia, rash, hepatosplenomegaly, hypertension, and signs of increased intracranial pressure. Microscopic hematuria is present in 90% of patients, and proteinuria is often in the nephrotic range. Serologic findings include positive rheumatoid factor titers, cryoglobulinemia, and decreased serum C3, C4, and CH50 levels. Raised C-ANCA titers may be found. Eosinophilia in the cerebrospinal fluid, which is a sign of a malfunctioning shunt, may be helpful for the diagnosis.

Renal histology shows MPGN type I in nearly 60% of the cases and non-IgA mesangial proliferative GN in the remainder. IgM, IgG, and C3 deposits are present in the glomerular capillary and mesangium.

(Courtesy Surya Seshan.)*

Treatment requires antibiotic therapy and the prompt removal of the infected atrioventricular shunt, which is usually replaced by a ventriculoperitoneal shunt. Delay in diagnosis and in removal of the shunt worsens the prognosis of the renal lesion. In the event that dialysis is required, hemodialysis is the preferred modality because peritonitis complicating chronic peritoneal dialysis carries the risk of meningitis in patients with a ventriculoperitoneal shunt. Complete recovery occurs in more than half of the patients; persistent urinary abnormalities have been found in 22% and ESRD in 6% of the patients.

Glomerulonephritis Associated with Other Bacterial Infections

Osteomyelitis and intra-abdominal, pelvic, pleural, and dental abscesses can be associated with GN. Infection usually has been present for several months before it is diagnosed. Renal disease may vary from mild urinary abnormalities to rapidly progressive GN, but the most frequent presentation is nephrotic syndrome. Unlike with other infection-associated GN, complement levels are often normal. Renal histology reveals MPGN, diffuse proliferative GN, or mesangial proliferative GN. Crescents may be present. Antibiotic treatment may result in recovery of renal function if it is started early.

Congenital and secondary (or early latent) syphilis may be associated with GN. In congenital syphilis the presenting sign is anasarca 4 to 12 weeks after birth. Nephrotic syndrome may be the primary clinical manifestation (as opposed to the more classic triad of rhinitis, osteochondritis, and rash). In acquired syphilis, renal involvement occurs rarely. In adults the presentation is with nephrotic syndrome or occasionally with an acute nephritic picture. Serologic test results for syphilis are positive (rapid plasmin reagin, Venereal Disease Research Laboratory [VDRL], and fluorescent treponemal antibody absorption test). MN is the most common renal pathologic process, but diffuse proliferative GN with or without crescents, MPGN, and mesangial proliferative GN have also been observed. Treponemal antigens have been identified in the immune deposits. Syphilitic GN responds to antibiotic treatment, although remission may not occur for 4 to 18 months.

Acute typhoid fever from *Salmonella typhi* is characterized by fever, splenomegaly, and gastrointestinal symptoms. In severe cases patients may develop shock and acute renal failure as a part of disseminated intravascular coagulation or HUS, but these complications are rare. Overt mesangial proliferative GN occurs occasionally, but microscopic hematuria and mild proteinuria may be present in 25% of the patients.[29] GN may also occur in patients with schistosomiasis and coexisting *Salmonella* infection of the urinary tract (see Chapter 56).

Leprosy (*Mycobacterium leprae* infection) is associated with proteinuria and renal dysfunction in 3% to 5% of the patients.[30] In autopsy studies, renal findings include GN (5% to 14% of the patients, usually MPGN or diffuse proliferative GN with IgG, C3, IgM, IgA, and fibrin deposits), interstitial nephritis (4% to 54%), or amyloidosis (4% to 31%).[31] It remains controversial whether GN is more common in lepromatous leprosy than in tuberculoid leprosy.

Nephrotic syndrome is the usual clinical presentation. Response of glomerular disease to treatment of leprosy is variable. Multidrug therapy may be associated with liver failure and CKD in more than 20% of the patients.[32]

Pneumococcal pneumonia may rarely be associated with microhematuria and proteinuria, especially if treatment is delayed. Both diffuse proliferative GN and MPGN have been reported, and pneumococcal antigen is present in the immune deposits. Rarely, pneumococcal pneumonia can also be associated with HUS as a result of unmasking of the Thomsen-Friedenreich antigen in glomeruli by pneumococcal neuraminidase, which then allows preformed antibodies to bind and to elicit an immune response.

Gastroenteritis caused by *Campylobacter jejuni* may be associated with mesangioproliferative or diffuse proliferative GN. GN may also occur with other bacterial infections, including those with *E. coli, Yersinia,* meningococcus, and *Mycoplasma pneumoniae.*

VIRAL INFECTIONS

Viral infections may cause acute GN (hepatitis A virus [HAV], parvovirus B19, measles, EBV), chronic GN (HBV, hepatitis C virus [HCV], HIV, parvovirus B19), and interstitial nephritis (Hantavirus, influenza virus, dengue, BK virus, coronavirus, cytomegalovirus [CMV], HAV). The most common infections are those associated with HBV, HCV, and HIV. Pathogenetic mechanisms include deposition or *in situ* formation of exogenous (viral) immune complexes; autoantibody formation directed toward endogenous antigen modified by viral injury; virus-induced release of proinflammatory cytokines, chemokines, adhesion molecules, and growth factors; and direct cytopathic effects of viral proteins.[33]

Hepatitis A Virus–Associated Renal Disease

Acute kidney injury (AKI) may develop in 6% to 8% of the patients with hepatitis A infection, and most of them fully recover.[34] Less frequently, interstitial nephritis or immune complex–related diffuse proliferative GN with immunoglobulin and C3 deposits may occur. Patients with the latter may have nephritic or nephrotic syndrome. Recovery from GN usually coincides with the improvement of hepatitis.

Hepatitis B Virus–Associated Renal Disease

Hepatitis B virus is a DNA virus of the Hepadnaviridae family, which has the human as its only known natural host. It is estimated that there are 350 million people with chronic HBV infection in the world, most of whom do not know they are infected.[35] Hepatitis develops as a result of immune reactivity directed toward infected hepatocytes.

Acute HBV infection may cause nausea, vomiting, fever, hepatomegaly, and a short-lived serum sickness–like syndrome: urticaria or maculopapular rash, neuropathy, arthralgia or arthritis, microscopic hematuria, and non-nephrotic proteinuria.[36] Renal biopsy, if it is performed at this time, shows a mesangial proliferative GN. The clinical picture resolves spontaneously as the hepatitis improves.

Whereas acute HBV infection may resolve uneventfully, more than 90% of infected infants, 25% to 50% of the children infected between the ages of 1 and 5 years, and 6% to 10% of older children and adults develop chronic infection (defined as persistence of HBsAg-positive serology but negative for IgM antibodies to HBV core antigen). Vertical transmission (maternal-infant at birth) is usually present in endemic areas, such as China and Southeast Asia. Horizontal transmission occurs through contamination with blood or by direct contact with mucous membranes. In Europe and the United States, the prevalence is lower, and most carriers acquire the infection as adolescents or adults by horizontal transmission as a consequence of drug abuse, blood transfusions, or sexual relations. HBV carriers may have a variety of renal syndromes.[37]

Hepatitis B Virus–Associated Membranous Nephropathy

Membranous nephropathy may occur in chronic HBV carriers. Children show a male predominance and often have asymptomatic proteinuria or nephrotic syndrome, microscopic hematuria, and normal renal function, often with minimal evidence of liver disease. The prognosis is usually good, and spontaneous remission is common in association with the appearance of anti-HBe antibodies in circulation. Adults might also develop nephrotic syndrome, but often have impaired kidney function and clinically apparent liver disease and are at greater risk for progression to renal failure. Decreased C3 and C4 levels are found in less than half of the patients. Renal histology is consistent with MN, but mesangial immune deposits may also be present, in contrast with idiopathic MN. Virus-like particles have been identified in various areas of the glomeruli. HBeAg can often be demonstrated in the immune deposits by immunohistochemistry.[33]

Hepatitis B Virus–Associated Membranoproliferative Glomerulonephritis

Membranoproliferative glomerulonephritis is the most common glomerular lesion in adult HBV carriers. Cryoglobulinemia may be present, especially if there is concurrent infection with HCV. Chronic liver disease is usually present but may be clinically asymptomatic. Nephrotic or non-nephrotic proteinuria, often associated with microhematuria, is common. Biopsy shows typical type I MPGN, and HBsAg is occasionally shown in the immune deposits.

Mesangial Proliferative Glomerulonephritis with IgA Deposits

There are several reports of IgA nephropathy in HBV infection. It is possible that this is a consequence of chronic liver disease with impaired clearance of IgA circulating immune complexes, leading to hepatic IgA nephropathy (see Chapter 23).

Treatment of Hepatitis B Virus–Associated Glomerulonephritis

Treatment is aimed at eradication of HBV virus. Interferon-alfa (5 million units daily for 6 months) or pegylated interferon-alfa may result in remission, especially in HBV-associated MN. Lamivudine (100 mg orally once daily for 52 weeks) has also been reported to clear HBV virus and to induce remission in HBV-associated MN. A reduction of the dose is necessary when the glomerular filtration rate (GFR) is reduced below 50 ml/min/1.73 m^2. If the GFR is 30 to 49 ml/min/1.73 m^2, the initial dose is 100 mg, and this is followed by 50 mg orally daily; if the GFR is 15 to 29 ml/min/1.73 m^2, the initial dose is the same and subsequent does are reduced to 25 mg daily. In patients with ESRD, the initial dose is 35 mg followed by 10 mg daily.[38] Entecavir and adefovir dipivoxil may provide an alternative, but the nephrotoxicity of adefovir is a deterrent, although the risk is low at standard dosages if kidney function is normal.[38] Recent reports have drawn attention to viral breakthrough after prolonged lamivudine administration, resulting from mutations in the tyrosine-methionine-aspartate-aspartate (YMDD) motif of the nucleotide binding that might lead to the aggravation of renal disease in HBV-associated GN patients. Another potential complication of therapy

is the development of membranous nephropathy after several months of pegylated interferon-α2a treatment.

It has been argued that corticosteroid and immunosuppressive agents should not be used because they are ineffective and may delay or prevent seroconversion and accelerate the progression of liver disease. However, a recent meta-analysis of 12 clinical trials with 317 patients found that combined antiviral and immunosuppressive therapy can improve the proteinuria in HBV-GN patients without altering HBV replication or damaging liver and renal function.[39]

The prevailing view has been that treatment is not required for children with HBV-associated MN because the majority of them undergo spontaneous remission. However, clearance of HBV DNA and HBeAg has been achieved in about half of the children in controlled studies, with a higher incidence of resolution of the proteinuria in the treated group. Because HBV-associated MN may rarely progress to ESRD in children, it is reasonable to treat when proteinuria is severe or there is progression of kidney disease.

Polyarteritis Nodosa

Hepatitis B virus–related vasculitis (HBV-related polyarteritis nodosa [PAN]) has become progressively rarer and is observed primarily in adult men who acquire HBV infection from drug use or blood transfusion, usually less than 12 months after a mild attack of hepatitis. It is almost never observed in children and is rare in areas of the world where HBV infection is acquired at birth or in childhood, such as in Asia.

The typical patient with HBV-related PAN shows signs of serum sickness preceding and during a mild or asymptomatic attack of hepatitis, unlike HBV-associated serum sickness, which resolves spontaneously with clearing of the HBsAg. In these patients the disease progresses to involve numerous organs. It typically involves medium-sized arteries and may have a variety of presentations, including myocardial ischemia, mesenteric angina, cerebral ischemia, and mononeuritis multiplex. Renal vasculitis is manifested by microhematuria, nephrotic or non-nephrotic proteinuria, and renin-dependent hypertension. Manifestations are in general similar to those observed in noninfectious PAN, but patients with HBV-associated PAN more frequently have peripheral neuropathy, abdominal pain, cardiomyopathy, orchitis, hypertension, and renal vessel involvement, whereas pulmonary and cutaneous manifestations are rare, compared with patients with non–HBV-related PAN.[40] Rapidly progressive GN, as seen in microscopic polyangiitis, is infrequent in HBV-related PAN.[40]

The pathogenesis of HBV-associated PAN is thought to be a result of the deposition of HBsAg–anti-HBs immune complexes in the arterial wall, which results in a subsequent inflammatory reaction with the activation of complement. The vessels often show a predominance of IgM and HBsAg, suggesting that the injury is mediated by HBsAg-IgM complexes. Serologic tests reveal HBsAg and anti-HBc antibodies. Serum complement is usually normal, and ANCAs are absent.

Diagnosis requires the detection of circulating HBsAg in association with either histologic or angiographic evidence of vasculitis. Renal biopsy studies demonstrate vascular lesions, which are typically panmural and in different stages of development. Variable degrees of fibrinoid necrosis, fibrin deposition, and leukocyte infiltration are present. HBsAg, IgM, and occasionally IgG are deposited in the vessel wall. Angiographic studies demonstrating narrow segments and saccular or fusiform aneurysms in celiac or renal arteries have higher diagnostic yield than biopsies.

Liver biopsy demonstrates chronic active or persisting hepatitis or, rarely, acute hepatitis. The kidney biopsy, in addition to the arteriolar lesions, may show relatively preserved glomeruli with variable degrees of collapse in the glomerular tuft, likely resulting from ischemic changes. In contrast with idiopathic microscopic polyangiitis, necrotizing lesions with crescent formation are rare. Mesangial proliferative GN, diffuse proliferative GN, MPGN, and MN have all been reported.

Treatment consists of a short course of corticosteroids (prednisone 1 mg/kg/day for 2 weeks) and plasma exchange (9 to 12 exchanges during 3 weeks) followed by interferon-alfa therapy or lamivudine.

Hepatitis C Virus–Associated Renal Disease

Hepatitis C virus, an RNA virus of the Flaviviridae family, is a common cause of chronic hepatitis, cirrhosis, and hepatoma. An estimated 170 million people in the world are chronically infected with HCV; there are nine genetically distinct genotypes, of which the most common is genotype 1. Chronic HCV infection can also be associated with the development of several types of glomerular disease. The most common is MPGN with or without cryoglobulinemia, and this entity is discussed in Chapter 21. HCV may also be associated with MN, especially in kidney transplant patients.

The clinical and histologic findings are similar to those observed in idiopathic MN except that HCV RNA and anti-HCV antibodies are present in the blood. Other reported associations include fibrillary GN, focal glomerulosclerosis (especially in African Americans), and thrombotic microangiopathy with anticardiolipin antibodies (especially after kidney transplantation). The pathogenesis of these lesions involves the deposition of immune complexes in the glomeruli, and recently it has been described that Toll-like receptor 3 could have a pathogenic role, thus suggesting a link between viral infection and GN.[41] Combined antiviral therapy and immunosuppression (cyclophosphamide or rituximab with corticosteroids) may be the treatment of choice for patients with severe renal disease—that is, nephrotic syndrome with or without progressive renal failure—or disease that is refractory to anti-HCV therapy alone.[42] HCV infection may represent a risk factor for graft failure, and pretransplant interferon therapy has been recommended.[43]

Human Immunodeficiency Virus–Associated Renal Disease

Human immunodeficiency virus infection may be associated with myriad renal complications, one of the most common of which is HIV-associated nephropathy. A discussion of HIV-associated nephropathy and other HIV-associated renal disorders is provided in Chapter 58.

Other Virus-Associated Renal Disease

Polyomavirus nephropathy caused by BK virus is an increasingly recognized complication in renal transplantation and can be a cause of decreased renal function. It is described in detail in Chapter 105.

Cytomegalovirus infection may occur in renal transplant recipients, in whom it can infect tubular cells and macrophages in the interstitium, resulting in the characteristic intracytoplasmic "owl-like" inclusions. Whereas there is some evidence that this may be a cause of tubular dysfunction, there is no evidence that this results in glomerular injury. Rarely, however, in nontransplant patients CMV has been reported to cause a diffuse proliferative GN with immune deposits containing CMV antigens. In addition, a rare report has linked CMV infection with collapsing glomerulopathy and ESRD in patients not infected with HIV.

Parvovirus B19 is a single-stranded DNA virus with marked tropism for the erythroid precursor cells. In conditions in which there is increased destruction or decreased production of red cells, as in kidney transplantation and in sickle cell disease, parvovirus infection may cause aplastic anemia. In patients with sickle cell disease, parvovirus-induced aplastic crises are occasionally followed by nephritic or nephrotic syndrome, assumed to be the result of immune complex deposition. Diffuse proliferative GN, MPGN, and collapsing focal glomerulosclerosis (with similarities to heroin- and HIV-associated nephropathy) have been attributed to parvovirus B19 infection, and some studies but not others have detected viral DNA in kidney biopsy specimens. Granular deposition of C3 and IgG in capillary walls and subendothelial deposits have been found. Studies have also suggested a relationship between renal parvovirus infection and chronic allograft nephropathy.[44]

Many viral infections, including varicella, mumps, adenovirus, coxsackievirus, and influenza, can be associated with transient microscopic hematuria, non-nephrotic proteinuria, and a mesangial proliferative GN or diffuse proliferative GN in which viral antigens can be identified in the mesangium. Measles may also cause a diffuse proliferative GN but is better known for its unique ability to induce remission in patients with minimal change disease with nephrotic syndrome.

Dengue hemorrhagic fever, currently the most prevalent mosquito-borne urban viral infection worldwide, may be caused by four serotypes of the Flaviviridae virus family. The clinical manifestations, reflecting increased vascular permeability, include fever, headache, generalized muscle pain, gastrointestinal symptoms, and, in severe cases, bleeding manifestations and shock. The most common renal complication is AKI. Acute endocapillary GN with IgG, IgM, and C3 deposits presenting with hematuria, proteinuria, and renal failure has been reported in dengue patients.

Mild renal abnormalities can also be observed in acute EBV infection, with microhematuria and proteinuria in 10% to 15% of cases. Acute interstitial nephritis is the most common renal complication of this viral infection, but diffuse proliferative GN and MPGN may also occur. Replicating EBV was localized not only to infiltrating macrophages but also to renal proximal tubular cells, which were shown to express the CD21 receptor for EBV.[33]

PARASITIC INFECTIONS

Kidney involvement is fairly common in different parasitic diseases. With the exception of schistosomiasis, malaria, filariasis, and leishmaniasis, such involvement is usually mild, transient, and often masked by the manifestations of the primary disease (Table 57-2).

Malaria

Malaria, caused by a protozoan of the genus *Plasmodium* and acquired through the sting of infected *Anopheles* mosquitoes, is a major world health problem, with 300 to 500 million cases and 1.5 to 2.7 million deaths each year (Fig. 57-3). About 90% of the cases occur in Africa, India, Southeast Asia, and Latin America. Malaria can also be acquired by blood transfusions (prevalence among blood donors in a teaching hospital in Nigeria was 32%), by transplantation of infected donor organs, and by the bite of infected vectors introduced in aircraft ("airport malaria").[45,46] Four major species are responsible for malaria. *Plasmodium falciparum* is usually associated

Table 57-2 Renal lesions in parasitic infection. All conditions documented in humans unless otherwise indicated. *DPGN,* Diffuse proliferative glomerulonephritis; *FSGS,* focal segmental glomerulosclerosis; *MCD,* minimal change disease; *MPGN,* membranoproliferative glomerulonephritis; *MesPGN,* mesangial proliferative glomerulonephritis; *MN,* membranous nephropathy. *Parasitic antigens or specific antibodies detected in the glomeruli.

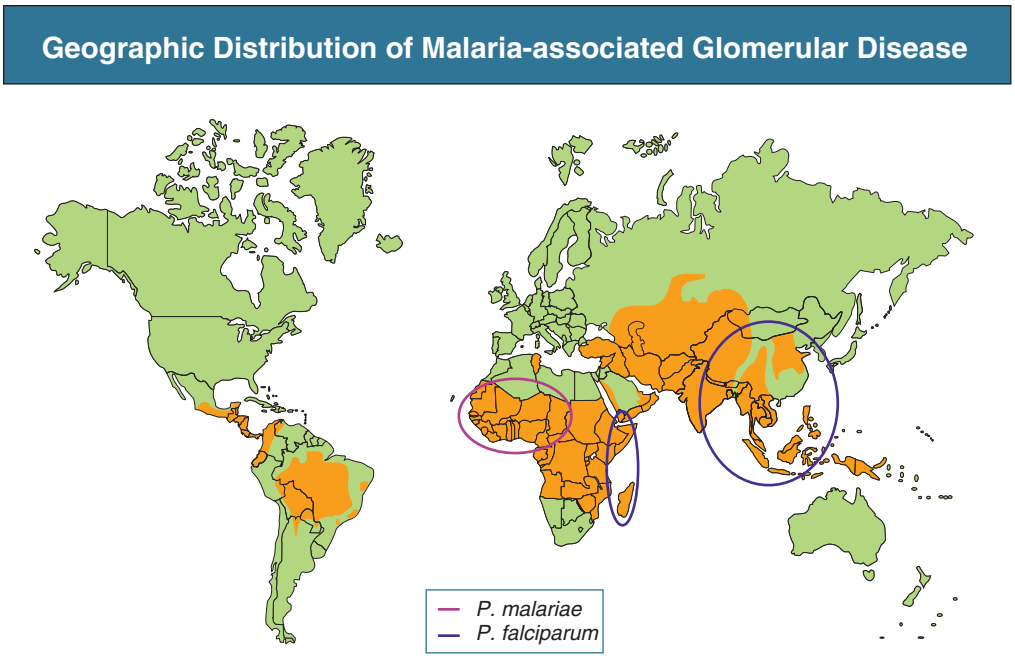

Figure 57-3 Geographic distribution of malaria-associated glomerular disease. Although malaria is endogenous to many areas of the world *(shaded orange)*, the major areas where malaria-associated glomerular disease has been reported *(ringed)* and their respective species are shown.

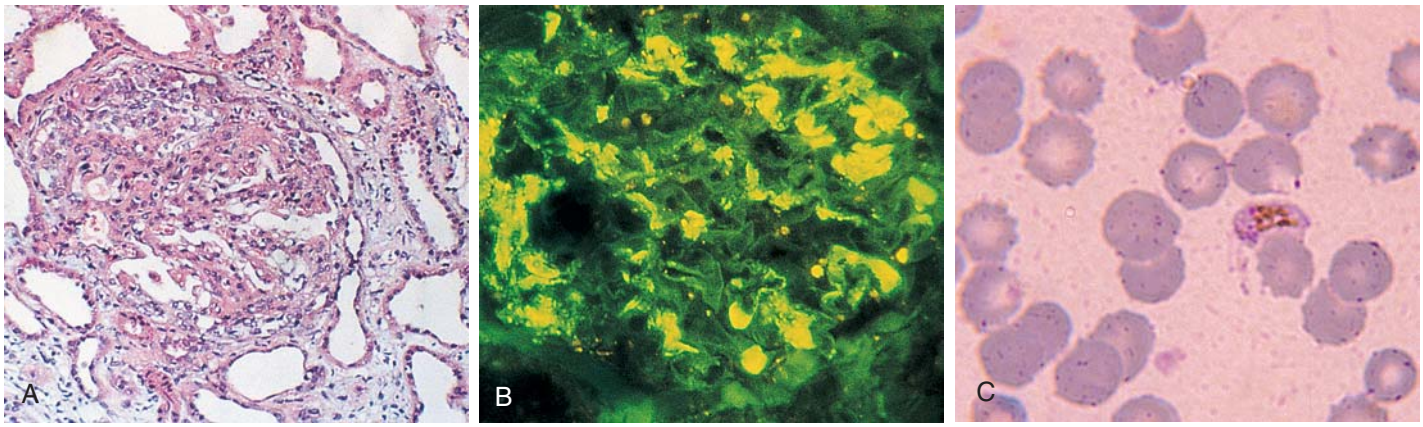

Figure 57-4 Glomerulonephritis (GN) associated with *Plasmodium falciparum* malaria. A, Light microscopy shows a mesangial proliferative GN. **B,** Immunofluorescence may reveal *P. falciparum* antigens in a mesangial pattern. **C,** Peripheral blood smear confirms acute *P. falciparum* infection, with banana-shaped gametocytes and multiple ring forms in erythrocytes. *(**A** reprinted with permission from reference 50; **B** and **C** courtesy V. Boonpucknavig.)*

with heavy parasitemia because it invades red blood cells of any age. Because all red cells can be infected, *P. falciparum* malaria may be associated with AKI and multiple organ failure. This entity is discussed in more detail in Chapter 70.

The immune response to malaria is highly sophisticated, being adapted to the multiplicity of parasitic antigens, which vary with successive generations of the parasite's life cycle, as well as those generated by parasitized red cells. Malarial antigens activate the immune system by initial interaction with the monocytes, as well as direct activation of the alternative complement pathway. Monocyte activation upregulates T helper 1 (Th1) and subsequently Th2 lymphocytes, leading to the secretion of respective chemokines and cytokines. Infected red cells are at least partly responsible for switching the immune response to the Th2 profile, through the preferential expression of certain surface antigens.[46,47]

Acute malaria-associated GN may occur with *P. falciparum* or *Plasmodium vivax* infection.[48] Transient urinary abnormalities such as mild proteinuria and microhematuria are encountered in 25% to 50% of patients; a full-blown nephritic syndrome with hypertension, edema, and impaired kidney function is uncommon. Serum complement C3 and C4 may be reduced in such cases. Renal biopsy typically shows endocapillary proliferation with mesangial expansion and infiltration with pigment-laden macrophages and parasitized red cells. Platelet-fibrin thrombi and patchy necrosis of the tubules may be associated. Immunofluorescence shows granular deposition of IgM, C3, malarial antigens, and occasionally IgG.[46] Dense immune complex deposits, containing plasmodial antigens, are seen with electron microscopy (Fig. 57-4).

Another malarial species, *Plasmodium malariae,* infects only aging erythrocytes and is therefore associated with a less severe form of malaria (quartan malaria). Epidemiologic studies suggest that chronic quartan malaria may be associated with a corticosteroid-resistant nephrotic syndrome, referred to historically as tropical nephritis[49] and more recently as tropical nephrotic syndrome. The disease typically affects children, usually 4 to 8 years old, and only rarely adults. It causes heavy proteinuria and overt nephrotic

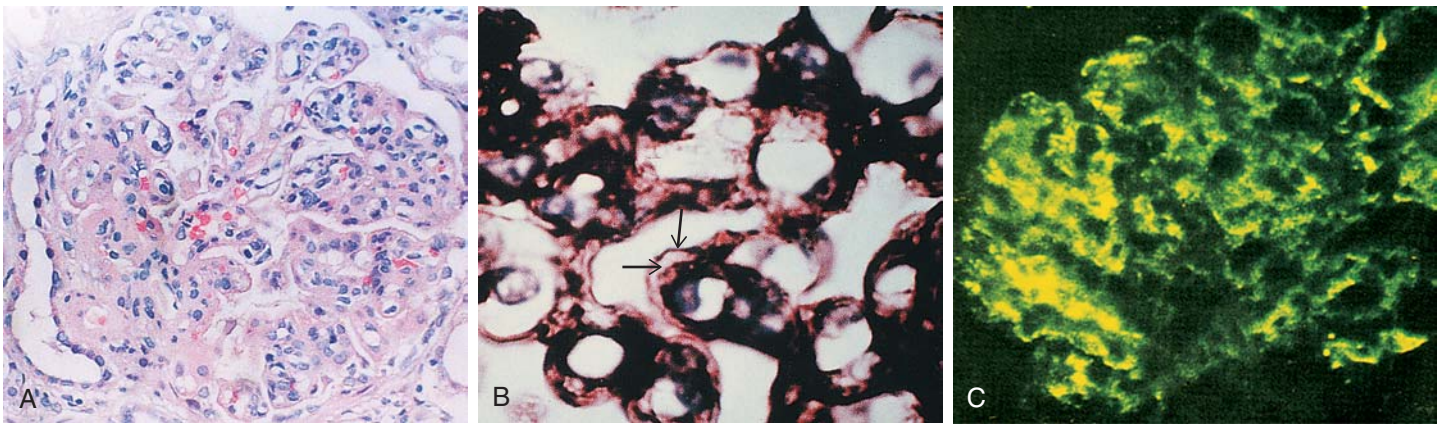

Figure 57-5 Quartan malarial nephropathy. A, Light microscopy shows a sclerosing membranoproliferative glomerulonephritis. **B,** Silver stain shows a double contour *(arrows)* of the basement membrane. **C,** Malarial antigens are present on immunofluorescence. *(From reference 50.)*

syndrome, late-onset hypertension, and progressive kidney impairment. Despite the severe hypoproteinemia, blood cholesterol is often normal, presumably because of associated nutritional deficiency. Renal biopsy shows MPGN with intramembranous lacunae (from reabsorption of immune complexes). Immunofluorescence shows coarsely granular IgG, IgM, and C3 deposits, and electron microscopy displays subendothelial deposition of dense material (Fig. 57-5).[50] As mentioned earlier, the disease is steroid resistant and progresses to end-stage CKD in a few years, even with successful treatment of the malarial infection, which is often attributed to the involvement of autoimmune mechanisms in progression.

The identity of quartan malarial nephropathy as a specific disease entity is largely based on experimental and epidemiologic evidence.[45] Most impressive is the declining incidence of steroid-resistant nephrotic syndrome in Nigeria with the control of malaria; but simultaneous improvement of health care in general may have the same effect.

The lack of hard evidence continues to invite challenges to the presumed cause-and-effect relationship between malaria and CKD.[51] The most significant argument is the inconsistency of the immunohistochemical profile in different geographic regions. Even at an epidemiologic level, it is not understood why quartan malarial nephropathy is limited to Nigeria among the West African countries and Uganda in the East, despite similar endemicity of the same malarial species in neighboring countries. Concomitant infection with other parasites (e.g., schistosomiasis) or viral infection (e.g., EBV) may be involved in the pathogenesis of kidney injury, thereby having a potential influence on geographic variations. The recently discovered *APOL1* gene mutations in African Americans may turn out to be a risk factor in this context, yet this possibility remains to be investigated.

Filariasis

Filariae are nematodes that infect humans as well as several animal species. Of hundreds of known filarial parasites, eight species affect humans. Only three, *Wuchereria bancrofti, Onchocerca volvulus,* and *Loa loa,* are associated with kidney disease. Like all filarial species, these are transmitted by arthropod vectors, namely black flies and mosquitoes.

W. bancrofti affects more than 90 million people mainly in sub-Saharan Africa, Southeast Asia, India, and the Pacific Islands. It is responsible for several clinical syndromes, the best known of which include tropical eosinophilic pneumonia, elephantiasis, and chyluria. The latter has typically been blamed for the occurrence of proteinuria, hypoproteinemia, and even hematuria in infected patients. It was not until the late 1970s that the urinary abnormalities in a small proportion of patients were attributed to parenchymal kidney disease, mesangial proliferative GN being the predominant lesion. Immune complex deposits containing worm antigens were demonstrated in the glomeruli a few years later.[52] Acute proliferative and exudative GN with eosinophilic predominance was occasionally described in association with *W. bancrofti* infection.[53]

Bancroftiasis is often associated with bacterial infection, usually staphylococci and certain streptococci, the impact of which in the pathogenesis of "filarial" GN is unclear. Even less understood is the role of rickettsiae-like bacteria, *Wolbachia,* recently discovered within filarial nematodes and blamed for activation of innate immune pathways.[54]

O. volvulus is less widely spread, yet it affects 21 million people in West Africa, particularly Cameroon, Burkina Faso, and Ghana, as well as in Central and South America, with a few foci in Southern Arabia and Yemen. The adult worms settle in the subcutaneous tissues, leading to a variety of skin manifestations including papular and lichenified dermatitis, hyperpigmentation and depigmentation, and atrophy. It also parasitizes the inguinal lymph nodes, which causes obstruction of the scrotal lymphatics, leading to a characteristic "hanging scrotum." Onchocercosis is associated with a number of immune-mediated manifestations, the most significant of which are keratitis, anterior uveitis, and optic atrophy. These lesions may lead to blindness in large populations living around the rivers where the mosquito vector breeds, hence the term "river blindness."

In a large study of 1011 infected individuals in Cameroon, proteinuria was over fivefold more frequent than in controls.[55] Steroid-resistant nephrotic syndrome with progressive kidney impairment was the usual clinical presentation in this and other series. Minimal change, MPGN, and chronic sclerosing GN lesions were most often encountered on renal biopsy. Subendothelial and mesangial immune complexes containing IgM, IgG, and C3. Onchocercal antigens were detected by immunofluorescence, and mesangial electron-dense deposits by electron microscopy. Onchocercal GN is known to recur in transplanted kidneys.[45]

L. loa is the least prevalent of nephritogenic filariae, being localized in Central America, where about 3 million individuals are infected. Like *Onchocerca, L. loa* lives in the subcutaneous tissues; infection may lead to transient and nonerythematous swellings on the extremities, particularly overlying the joints (Calabar swellings). These may be associated with localized pain, pruritus, and urticaria.

Adult worms may be seen migrating under the conjunctiva. Kidney disease associated with this infection includes membranous nephropathy and less commonly MPGN and FSGS.[56]

Leishmaniasis

Leishmaniae are obligatory intracellular protozoa that infect 12 million humans and many animals. The latter serve as reservoir hosts, the types of which vary according to geographic location: dogs in the Mediterranean and China, rodents in Africa, and foxes in Brazil and Central Asia. Humans may serve as a reservoir for transmission, particularly in India. Infection is transmitted by female sand flies *(Phlebotomus)*. Of 30 known leishmanial species, 21 are pathogenic to humans, the best known being *Leishmania donovani, Leishmania infantum, Leishmania chagasi, Leishmania tropica, Leishmania major, Leishmania mexicana,* and *Leishmania braziliensis*.

Kidney involvement may occur only with visceral leishmaniasis (kala-azar), the systemic illness induced by *L. donovani* in Bangladesh, China, India, Nepal, and Sudan; by *L. infantum* in North Africa and southern Europe; and by *L. chagasi* in Latin America. The disease is characterized by fever, malaise, anorexia, weight loss, and massive hepatosplenomegaly. Generalized lymphadenopathy may occur in a few geographic locations. Although many reports have described different frequencies and profiles of CKD in visceral leishmaniasis, the global incidence remains unknown. Urinary concentration and acidification defects are present in one third of the patients.[57] Reported lesions include chronic interstitial nephritis, MPGN, and renal amyloidosis.[58] The latter has been most frequently described in patients with associated HIV infection.[59] Leishmania-induced AKI has been mostly reported in children with visceral leishmaniasis,[60] and reactivation of leishmaniasis is a potential complication in transplant patients.[61]

CHAPTER 58

Human Immunodeficiency Virus Infection and the Kidney

Jeffrey B. Kopp and Saraladevi Naicker

Human immunodeficiency virus (HIV) infection is the defining infectious disease of our era. The 2012 UNAIDS report estimated that there are 35.3 million people living with HIV infection and 2.3 million new infections[1]; there have been 16 million deaths since the start of the epidemic. With regard to nephrologic issues, HIV-1 infection is associated with glomerular and tubulointerstitial disease, and patients with HIV infection are also at risk for nephrotoxicity from antiretroviral therapy (ART) as well as from other medications. Coinfections with other pathogens, in particular hepatitis B virus (HBV) and hepatitis C virus (HCV), can complicate the clinical picture. Acute kidney injury (AKI) and interstitial nephritis, resulting from medication and opportunistic infection, are not uncommon. As patients with HIV disease live longer with ART, patients are experiencing the complex, interacting effects of HIV infection itself, ART, and the worldwide diseases of development, including atherosclerosis, metabolic syndrome, type 2 diabetes, and end-stage renal disease (ESRD). Patients with HIV disease and chronic kidney disease (CKD) and ESRD, those undergoing chronic dialysis therapy, and those undergoing kidney transplantation face particular issues and concerns.

In addition to HIV-1, HIV-2 can cause immunodeficiency but rarely causes kidney disease. In this chapter, we use HIV to refer to HIV-1.

HUMAN IMMUNODEFICIENCY VIRUS–ASSOCIATED KIDNEY DISEASE

The evaluation of AKI or CKD in a patient with HIV infection resembles that in other settings: history, focused particularly on medication use and other infections; physical examination; examination of the urine sediment; serum and urine chemistries; and, in many cases, renal imaging studies. Urine chemistries may include 24-hour timed or spot urine measurement of protein and albumin (for suspected glomerular disease), glucose, phosphate, and uric acid (for suspected proximal tubular disease). Indications for kidney biopsy include AKI without clear associated cause, especially with a nephritic sediment; nephrotic proteinuria; clinical evidence of thrombotic microangiopathy (TMA); and unexplained CKD. In the past, some clinicians argued that nephrotic proteinuria in an individual of African descent is likely to be HIV-associated collapsing glomerulopathy (CG) and that a biopsy is not necessary. The widespread use of ART in the current era makes this decision less tenable, and renal biopsy appears to be indicated to guide prognosis and therapy, particularly when substantial proteinuria is present.

GLOMERULAR DISORDERS

Human Immunodeficiency Virus–Associated Collapsing Glomerulopathy

Human immunodeficiency virus infection is associated with various glomerular disorders (Table 58-1). The classic glomerulopathy of HIV infection is CG. The pathologic changes were described in early reports as focal segmental glomerulosclerosis (FSGS) and more recently as HIV-associated nephropathy (HIVAN), but the latter term has also been used to describe other glomerular pathologic processes associated with HIV infection.

Etiology and Pathogenesis

Human immunodeficiency virus–associated CG occurs with both acute infection and chronic infection; in the latter case, it is associated with higher viral RNA levels and lower CD4 T lymphocyte counts. It appears that HIV can infect glomerular and tubular cells, setting up a chronic and possibly latent infection.[2] Specific HIV accessory proteins such as Vpr and Nef can damage renal cells independent of direct infection. In transgenic mice, the expression of HIV-1 accessory protein Vpr or Nef in podocytes is associated with progressive CKD, leading to ESRD, loss of podocyte differentiation markers, and features suggestive of human CG and segmental glomerulosclerosis. Transgenic mouse experiments also suggest that HIV-1 gene products are toxic to tubular epithelial cells, resulting in apoptosis and blocking cell proliferation.

Host factors also determine susceptibility to HIV-associated CG, especially in individuals of African descent when compared with those of European descent. This 20-fold predilection was originally linked with genetic polymorphisms in MYH9, encoding myosin heavy chain 9, a component of nonmuscle myosin IIA. More recently, much of the risk attributed to *MYH9* genetic variation has been shown to more closely associate with coding-region polymorphisms in *APOL1* (encoding apolipoprotein L1), which is in linkage disequilibrium with *MYH9* polymorphisms. Apolipoprotein L1 is a constituent of high-density lipoprotein. The ApoL1 codon-changing variants confer an odds ratio of 29, a strikingly high effect for a complex disease.[3] It remains unknown whether these *APOL1* polymorphisms cause CKD, and by what molecular mechanism. Nevertheless, homozygosity or dual heterozygosity for two risk alleles (labeled G1 and G2) are observed in approximately 50% of African Americans with HIV-associated CG, compared with only 12% of African American controls. It is interesting to note that these variants appear to protect individuals from African sleeping sickness caused by *Trypanosoma brucei rhodesiense,* and this may explain the

Kidney Diseases Associated with HIV Infection

	Entity	Frequency	Associations
Glomerular	Collapsing glomerulopathy	Common	African descent; particularly advanced HIV disease
	Immune complex glomerulonephritis	Common	European, Asian descent, and black Africans in Africa
	Thrombotic microangiopathy	Uncommon	
	Membranoproliferative glomerulonephritis, with or without cryoglobulin-associated vasculitis	Rare*	Hepatitis C; enfuvirtide
	Membranous nephropathy	Rare*	Hepatitis B
	Fibrillary and immunotactoid glomerulopathies	Rare*	
	Amyloid nephropathy (AA type)	Rare*	
	Minimal change nephropathy	Rare*	Nonsteroidal anti-inflammatory medication
Tubular	Acute kidney injury	Moderately common	Aminoglycosides, cidofovir foscarnet
	Proximal tubule injury (Fanconi syndrome)	Moderately common	Tenofovir, adefovir, cidofovir, didanosine
	Diabetes insipidus	Uncommon	Amphotericin, tenofovir, didanosine, abacavir
	Chronic tubular injury	Moderately common	Amphotericin, cidofovir, adefovir, tenofovir
	Crystal nephropathy	Uncommon	Indinavir, atazanavir; sulfadiazine, ciprofloxacin, intravenous acyclovir
Interstitial	Interstitial nephritis	Uncommon	Allergy to β-lactam, sulfa, ciprofloxacin, rifampin, proton pump inhibitor, allopurinol, phenytoin; also causes of crystal nephropathy listed above
			BK virus; generally advanced disease
			Immune reconstitution inflammatory syndrome; generally advanced disease; following initiation of ART

Table 58-1 Kidney diseases associated with human immunodeficiency virus (HIV) infection. Shown are diseases that are associated with HIV infection or its treatment. *ART,* Antiretroviral therapy. *Certain glomerular diseases are commonly associated with other viral infections or may occur on an idiopathic basis; a true association with HIV disease is uncertain or doubtful. Collapsing glomerulopathy is notable for glomerular, tubular, and interstitial disease but is classified under glomerular disease for simplicity.

rapid rise in allele frequency in certain African populations, particularly West African populations, that has occurred during the past 40,000 years.[4,5]

Clinical Manifestations

Patients with HIV-associated CG typically present with laboratory abnormalities, including proteinuria and renal impairment; some patients present with edema, although edema is less common than with other conditions associated with nephrotic range proteinuria or with uremia. Imaging studies may reveal increased kidney size despite reduced glomerular filtration rate (GFR) and, in some cases, increased echogenicity; this unusual feature is shared with diabetic nephropathy and amyloid nephropathy. However, no radiologic features predict the renal histology, and renal biopsy is required for diagnosis.

Pathology

Human immunodeficiency virus–associated CG is indistinguishable from idiopathic CG, with pathologic changes in glomeruli (proliferation and dysregulation of podocytes or podocyte stem cells, together with glomerular collapse), tubules (acute and chronic injury, sometimes with microcystic tubular changes), and interstitium (chronic inflammation, fibrosis) (Fig. 58-1). Both HIV-associated CG and idiopathic CG may cause tubuloreticular inclusions within dilated endosomal compartments within glomerular endothelial cells, which is believed to be a marker for cytokine (interferon) injury. Some pathologists diagnose classic FSGS in the setting of HIV infection, and others see this rarely; it is unclear whether these differences are a result of population differences or of different diagnostic standards in distinguishing FSGS from CG. Some patients with progressive loss of kidney function (e.g., from immune complex glomerulonephritis [ICGN] or interstitial nephritis) may develop adaptive FSGS from the consequence of glomerular hyperperfusion and hyperfiltration.

Diagnosis and Differential Diagnosis

Diagnosis of HIV-associated CG is made by renal biopsy. Among individuals of African descent, nephrotic proteinuria and low CD4 count are consistent with HIV-associated CG; plasma HIV RNA of less than 400 copies/ml suggests another disease. Among individuals of African descent, other possible diagnoses include primary or adaptive FSGS (although a pathogenic role for HIV cannot be excluded in conferring susceptibility) and arterionephrosclerosis (see later). In all individuals, diabetic nephropathy and HIV-related ICGN should be considered (see later discussion and Table 58-1).

Treatment

Human immunodeficiency virus–associated nephropathy is an indication for the initiation of ART in patients who are not currently receiving these medications; this is regardless of T-lymphocyte count.[6] It is reasonable to extend this recommendation to HIV-associated ICGN, despite an absence of specific evidence.

In the era before ART therapy, HIV-associated CG progressed rapidly, with patients reaching ESRD in months to a few years. The marked decline in HIV-associated ESRD in the United States after the introduction of ART in 1995 suggests that effective control of viral replication with ART may prevent HIV-associated CG. Retrospective studies also suggest that ART treatment of HIV-associated CG may prolong renal survival.[7] The Development of Anti-Retroviral Therapy in Africa (DART) study, conducted in Uganda and Zimbabwe, demonstrated improvement of kidney function of 2 to 6 ml/min/1.73 m^2 after 4 to 5 years of ART.[8] Other studies suggest that ART is most effective when it is initiated before the onset of severe renal disease.[9-12] In a few cases, regression of histologic lesions with ART has been demonstrated.[12,13] The current guidelines from the Infections Disease Society of America suggest starting ART when HIVAN is diagnosed, if therapy was not used before.[14] The guidelines do not address the role of ART in other renal histologies, but

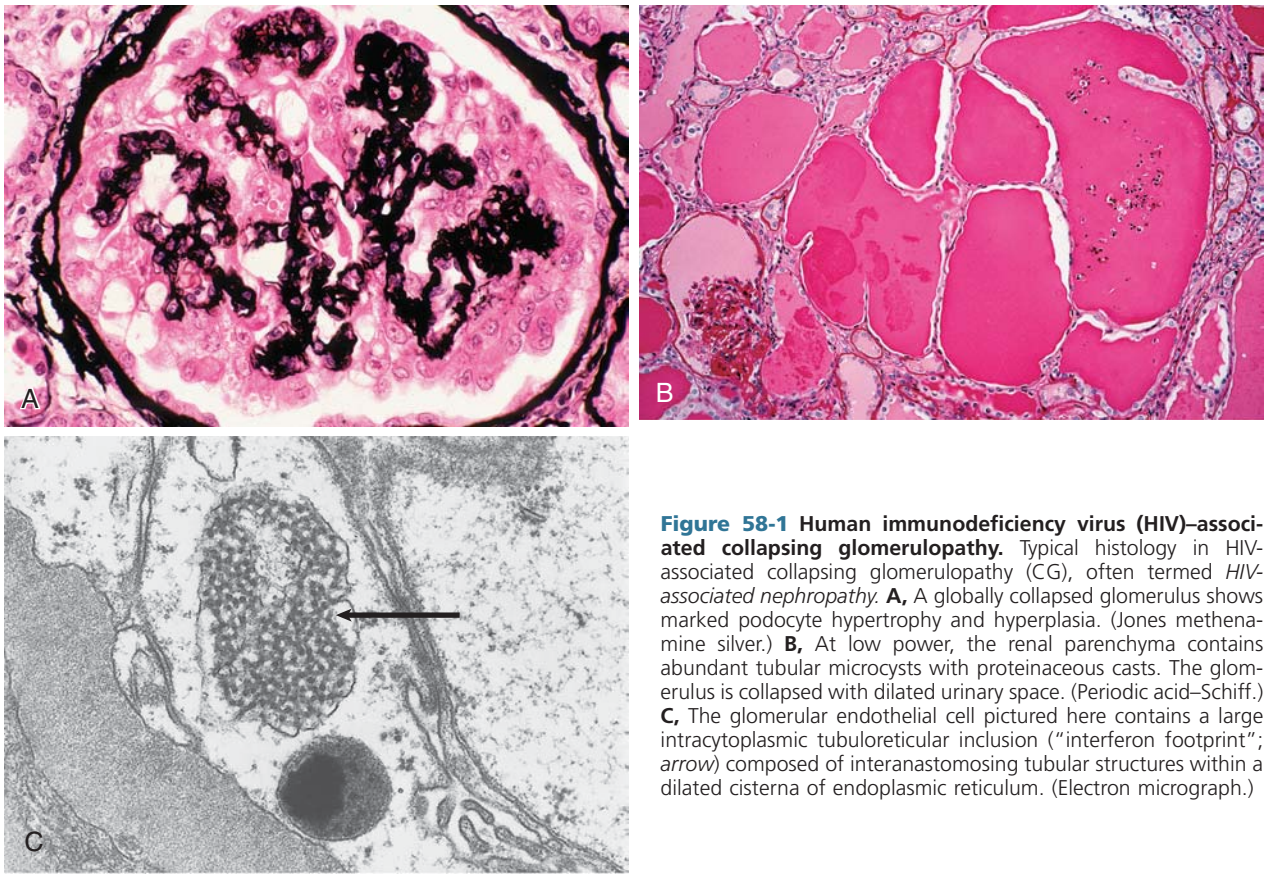

Figure 58-1 Human immunodeficiency virus (HIV)–associated collapsing glomerulopathy. Typical histology in HIV-associated collapsing glomerulopathy (CG), often termed *HIV-associated nephropathy.* **A,** A globally collapsed glomerulus shows marked podocyte hypertrophy and hyperplasia. (Jones methenamine silver.) **B,** At low power, the renal parenchyma contains abundant tubular microcysts with proteinaceous casts. The glomerulus is collapsed with dilated urinary space. (Periodic acid–Schiff.) **C,** The glomerular endothelial cell pictured here contains a large intracytoplasmic tubuloreticular inclusion ("interferon footprint"; *arrow*) composed of interanastomosing tubular structures within a dilated cisterna of endoplasmic reticulum. (Electron micrograph.)

the authors believe it is prudent to initiate ART for any glomerular disease that is plausibly linked to HIV infection.

Treatment of HIV-associated renal disease also includes standard therapies for CKD, including control of blood pressure to below 130/80 mm Hg and the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs). Nonrandomized studies in HIV-associated renal disease suggest benefit from these interventions, but randomized controlled studies have not been performed. Several nonrandomized studies have suggested a benefit from corticosteroid therapy, but because the efficacy appears to be modest and often short-lived, this is not considered standard therapy.

Natural History

Progression of CKD is more rapid in HIV-infected individuals of African descent, probably reflecting the effect of the *APOL1* variants.[9] This is of particular relevance to the African population in sub-Saharan Africa that has the highest prevalence rates of HIV infection.

Patients with HIVAN may also progress to ESRD in spite of ART.[15,16] Predictors of progression are a high degree of chronic damage on histology[15] as well as severe renal dysfunction at baseline, high-grade proteinuria, and presence of large numbers of sclerotic glomeruli.[16] Concomitant use of renin-angiotensin blockade results in improved renal survival.[16]

Human Immunodeficiency Virus–associated Immune Complex Glomerulonephritis

In populations of European and Asian ancestry, the most common glomerular disease associated with HIV disease is ICGN; this is true among developed countries (e.g., European Union) and developing countries (e.g., Thailand). HIV-associated ICGN is also seen in populations of African descent.[17] The pathogenesis of HIV-associated ICGN is not well understood. In some cases, immune complexes include HIV antigens. Other cases may represent generalized polyclonal B-cell expansion that accompanies HIV disease. Clinically, patients typically present with nephrotic proteinuria and hematuria that are clinically indistinguishable from HIV-associated CG. Renal biopsy findings may vary from mesangial proliferative glomerulonephritis (GN) to focal or diffuse proliferative GN with endocapillary proliferation (Fig. 58-2). In some cases, changes consistent with HIV-associated CG may also be present, and tubuloreticular inclusions may be present within glomerular capillary endothelial cells. Immune deposits may be in mesangial, subendothelial, and in some cases subepithelial locations and may include IgG and IgM or IgG, IgM, and IgA (so-called "full house deposits"), often with C3. These forms resemble lupus nephritis, although lupus serologic test results are typically negative. Patients who have coinfection with HCV may manifest membranoproliferative glomerulonephritis (MPGN), with double glomerular capillary basement membrane contours. Other patients may have only mesangial IgA deposits, and this is observed especially in the setting of microhematuria and non-nephrotic proteinuria, resembling idiopathic IgA nephropathy. The long-term outcome of HIV-associated ICGN is not well defined but appears to be more favorable when histologic changes resemble IgA nephropathy as opposed to lupus-like GN. There are few studies of therapy; presumably, control of HIV infection and conservative measures to control blood pressure and proteinuria are indicated.

OTHER GLOMERULAR DISORDERS

In addition to HIV-associated CG, FSGS, and HIV-associated immune complex disease, mentioned earlier, other glomerular

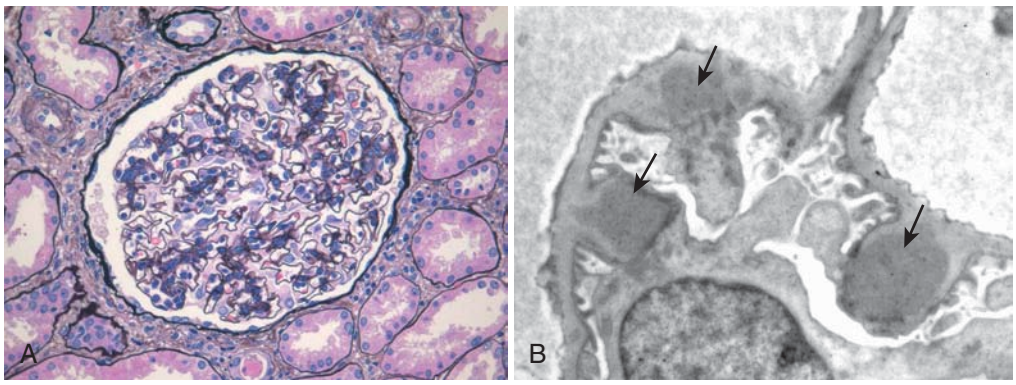

Figure 58-2 Human immunodeficiency virus (HIV)–associated GN. This HIV-infected patient presented with microhematuria and non-nephrotic proteinuria with normal renal function. Renal biopsy shows mild mesangial expansion **(A),** with mesangial and paramesangial deposits, together with varying numbers of subepithelial-based deposits *(arrows),* resulting in the "ball-and-cup" appearance **(B).** *(Courtesy Professor Stewart Goetsch, University of the Witwatersrand, Johannesburg, South Africa.)*

disorders have been seen with HIV infection. TMA may occur with HIV infection and is associated with lower CD4 cell counts, higher viral burden, and acquired immunodeficiency syndrome (AIDS). Membranous nephropathy (MN), fibrillary GN, immunotactoid GN, and amyloidosis have also been reported in HIV infection, but a causal role for HIV infection has not been firmly established.

ARTERIONEPHROSCLEROSIS

As HIV has become a chronic disease, extending over a period of decades, it has become apparent that chronic HIV disease is associated with premature aging, affecting various organ systems. In the kidney, this takes the form of arterionephrosclerosis, which is the constellation of arterial intimal thickening, medial hypertrophy, and duplication of the internal elastic lamina, together with global glomerulosclerosis, and is traditionally ascribed to hypertension. However, increasing evidence suggests that afferent arteriolar lesions may not only predispose to glomerulosclerosis by altering renal autoregulation, but may also have a role in the pathogenesis of hypertension. In this view, arteriosclerosis is a disorder associated with genetic mutations (e.g., *APOL1*), metabolic disorders (e.g., diabetes, obesity, hyperlipidemia, metabolic syndrome, and HIV infection), and chronic inflammation (smoking, oxidative stress, hemodynamic shear stress, and renin-angiotensin system activation).[18] Many of these factors arise as result of lifestyles, activity patterns, diets, and habits that have been adopted throughout the world. Certain of these pathogenic factors are exacerbated in HIV infection and its therapy, including chronic inflammation, metabolic disorders, and premature aging. In a recent series of biopsies performed on HIV patients in the United States, isolated arteriosclerosis with glomerulosclerosis was the most common single pathology noted,[19] and this is a trend that is likely to grow stronger.

TUBULAR DISORDERS

Human immunodeficiency virus infection is associated with several tubular disorders, many of which are secondary to drugs commonly used in this disease (see Table 58-1).[20] HIV-associated AKI, as defined by the AIDS Clinical Trials Group, is a creatinine concentration equal to or greater than 1.5 mg/dL or an increase of 1.3-fold over the upper limit of normal, that resolves within 3 months.[21] Most HIV-associated AKI occurs outside hospitals, with major causes being pre-renal or post-renal impairment (including obstruction as a result of prostate disease, kidney stone, or crystalluria), medication toxicity (including interstitial nephritis caused by antibiotics or indinavir, tubular injury caused by tenofovir or other agents, and statin-associated rhabdomyolysis), and less commonly acute presentations of glomerular diseases. Risk factors for HIV-associated AKI include male sex, black race, low CD4 count, high viral load, diabetes, CKD, and hepatic disease.[22]

Proximal tubular injury is moderately common, manifesting as various combinations of glycosuria, phosphaturia (sometimes associated with clinically significant hypophosphatemia), uricosuria, proteinuria, and aminoaciduria. Diabetes insipidus may also be present, indicating that the distal nephron is also involved. The most common cause is tenofovir, which is taken up by proximal tubular cells by one or more organic anion transporters and causes mitochondrial injury (mitochondrial depletion, enlargement, and dysmorphic changes) and also inhibits DNA repair and replication.[23,24] A mild decrease in GFR has also been associated with tenofovir use, but usually it is not severe enough for treatment to be discontinued.[23] Although three controlled studies have suggested minimal nephrotoxicity (perhaps 1%) when tenofovir is used for periods up to 48 weeks, a growing number of case series suggest that some patients manifest tubular injury that may resolve over a period of months to years[25]; others have described partial recovery or progression to CKD.[24,26] This apparent incongruity may be explained by the use of tenofovir in clinical practice in patients with other renal injury risk factors and by its frequent long-term use. Risk factors for tenofovir-induced renal toxicity include low CD4 count, prior renal impairment, and possibly combined therapy with didanosine and protease inhibitors (lopinavir and ritonavir). Five gene products may mediate tenofovir handling by the proximal tubular cells: *SLC22A6* (organic anion transporter 1 [OAT1]) and to a lesser extent *SLC22A8* (OAT3) are responsible for tubular cell uptake of tenofovir from the tubular fluid; and *ABCC2* (encoding MRP2 [multidrug resistance protein 2]), *ABCC4* (encoding MRP4), and *ABCC10* (encoding MRP10) may contribute to tenofovir efflux on the apical side. Mutations in *ABCC4* are associated with increased plasma tenofovir concentrations,[27] and mutations in *ABCC10* are associated with increased risk of phosphate wasting.[28]

Other protease inhibitors are also associated with variable risk for nephrotoxicity (Table 58-2). Nucleotide and nucleoside reverse transcriptase inhibitors (NRTIs) may have variable effects on tubular function. In addition to tenofovir, the most common renal toxicities are seen with indinavir, which is associated with crystalluria, nephrolithiasis, and AKI (see Table 58-2). Most other case reports involving protease inhibitors have been associated with multiple

Renal Toxicity of Antiviral Therapy

Antiretroviral Class	Antiretroviral Therapy	Renal Effect	Clinical Recommendations
Protease inhibitors	Indinavir	Nephrolithiasis, crystalluria, dysuria, papillary necrosis, acute kidney injury, interstitial nephritis Ritonavir and lopinavir may increase toxicity of indinavir	Daily fluid intake of >2 l/day
	Ritonavir	Reversible AKI (usually in combination with nephrotoxic drugs)	
	Saquinavir, nelfinavir	Renal calculi (rare)	Increased fluid intake
Reverse transcriptase inhibitors	Tenofovir, abacavir	Renal tubular damage: proximal tubular dysfunction, Fanconi syndrome, nephrogenic diabetes insipidus, acute tubular necrosis, AKI	Patients taking tenofovir should be monitored for signs of tubular dysfunction (elevated serum creatinine, hypophosphatemia, low serum uric acid, acidosis glycosuria, proteinuria)
	Didanosine, lamivudine, stavudine	Isolated case reports of tubular dysfunction	
Other	Cidofovir, adefovir	Renal tubular damage, proximal tubular dysfunction (cidofovir)	

Table 58-2 Renal toxicity of antiviral therapy. The toxicity of these agents has been the subject of a recent review. *AKI,* Acute kidney injury. *(From reference 23.)*

confounding factors (sepsis, concomitant nephrotoxic agents), and most of these factors are reversible.[23] Lopinavir and ritonavir may increase plasma concentrations of tenofovir by 30%. NRTIs have a good renal safety profile.[23] Non-nucleoside reverse transcriptase inhibitors (NNRTIs) also have a good safety profile, with an isolated case report of AKI from interstitial nephritis caused by a hypersensitivity reaction to efavirenz. The fusion inhibitor enfuvirtide has been associated with an isolated case report of MPGN in a diabetic patient.

CHRONIC KIDNEY DISEASE AND END-STAGE RENAL DISEASE IN HUMAN IMMUNODEFICIENCY VIRUS–INFECTED PATIENTS

Epidemiology

The Developed World

With the advent of ART, the range of common renal diagnoses has expanded from HIV-associated CG in individuals of African descent and ICGN associated with either IgA or all immunoglobulins to include diseases such as FSGS, diabetic nephropathy, and arteriosclerosis. In patients with hepatitis, MN associated with hepatitis B and MPGN associated with hepatitis C should be considered. Uncommon but important diagnoses include MN (presumably idiopathic, but possibly related to the polyclonal B cell expansion typical of HIV disease) and amyloid. Chronic tubular injury, especially associated with tenofovir therapy but possibly associated with other ART, is not uncommon; but when early diagnosis leads to cessation of the offending medication, CKD is usually averted. Despite the plethora of diagnoses, HIV-associated CG remains the leading cause of ESRD in patients with HIV disease.

There are few data on the worldwide prevalence of CKD in HIV infection. In a cross-sectional study from 31 European countries, Israel, and Argentina, CKD stages 3 to 5 was present in 4.7% of HIV-infected patients by use of the Modification of Diet in Renal Disease (MDRD) formula. A study from Hong Kong showed CKD (defined as estimated glomerular filtration rate [eGFR] ≤60 ml/min/1.73 m^2 or proteinuria for more than 3 months) in 18% of HIV-infected Chinese patients, but this study excluded those with ESRD.

The United States Renal Data System (USRDS) reports that for the period 2006 to 2010, there were 3834 cases of AIDS nephropathy (0.7% of total ESRD); the racial breakdown was 86% African American and 15% Caucasian.[29] The Department of Health and Human Services reported that in 2009 there were an estimated 787,701 Americans living with HIV disease, of whom 43% were African American and 35% were Caucasian.[30] Thus the unadjusted relative risk for ESRD was 4.7 for those of Black race. This relative risk is less than previously estimated for HIV-associated CG and supports the idea that the distribution of kidney diseases associated with HIV infection is shifting.

The Developing World

More than two thirds (69%) of the total HIV-infected population in the world live in sub-Saharan Africa, and the majority infected are women (58%). Transmission of HIV infection is largely by heterosexual contact in most of the region. Of HIV-infected individuals in sub-Saharan Africa, 56% have access to ART.[1] Access to renal replacement therapy (RRT), however, is frequently limited. Reported prevalence of CKD has been assessed by the presence of proteinuria or eGFR (based on serum creatinine measurements) and ranges widely from 6% to 48.5% in Africa.[31] This wide variation may be partly ascribed to differences in study design, populations studied, and definitions used for CKD based on dipstick proteinuria and quantitative measure of proteinuria or serum creatinine. Isolated screening studies with relatively small numbers using persistent proteinuria as a marker of CKD have been done in various countries with the following prevalence rates: 1% to 6% in Brazil, 27% in India, and 20% in Iran.

Human immunodeficiency virus–associated CG is the dominant disease documented in up to 80% of kidney biopsy specimens, which is consistent with findings in the United States. As in developed countries, other renal causes are also observed, including ICGN from postinfectious and other causes, MN, and interstitial nephritis. There are nonspecific histologic changes, such as mesangial hyperplasia and chronic active interstitial nephritis, that do not necessarily fulfill the diagnostic criteria for HIV-associated CG but show regression on ART, which suggests that the histologic criteria for HIV-associated CKD may need to be revised.[32-34]

A significant response of HIV-associated CKD to ART has been shown, with the median eGFR improving by 21% after 2 years on

ART.[35] A recent study of 221 HIV-positive patients in South Africa with renal histology reported that both HIV-associated CG and ICGN showed response to ART.[36] The presence of kidney dysfunction, in the setting of HIV infection, acts as an independent predictor of poor outcome, with an increased mortality after 90 days.[37]

Dosage of Antiretroviral Therapy in Chronic Kidney Disease

Many antiretroviral medications are partially or completely eliminated by the kidney and require dosage adjustment in CKD (Table 58-3). Certain drug classes, such as the protease inhibitors and the NNRTIs, are extensively metabolized by the liver and do not require dosage adjustment.[38] Most of the NRTIs are excreted unchanged in the urine and require dosage adjustment, with the exception of zidovudine and abacavir, which both have substantial extrarenal biotransformation that requires less or no dosage adjustment. In uremia, drug dosages may be affected by altered gastric pH and variable volumes of distribution.[39] Factors that influence dialyzability of antiretroviral medications relate to the properties of the dialysis membrane and molecular weight, degree of protein binding, molecular charge, and water solubility of the drug. If removal of the drug occurs during hemodialysis (HD), it should be taken after dialysis. If the drug is removed in peritoneal dialysis (PD) effluent, the dose may have to be supplemented.[39] Dosage recommendations in both HD and PD are limited by the lack of reliable data. Fixed drug combinations should not be used in patients with eGFR below 30 to 50 ml/min.[38]

Dose Adjustments for ART in CKD and ESRD

Name	CKD (Adjusted According to Creatinine Clearance [CrCl] by eGFR)		Dialysis
Nucleoside or nucleotide analogues			
Abacavir	No adjustment		No adjustment HD: dosing independent of dialysis sessions
Azidothymidine (AZT), zidovudine*	CrCl ≥15 ml/min: no adjustment CrCl <15 ml/min: 100 mg PO q6-8h		HD:100 mg PO q6-8h* or 300 mg PO qd PD: no data
Didanosine (ddi)	Weight >60 kg CrCl 30-59 ml/min: 200 mg PO qd CrCl 10-29 ml/min: 150 mg PO qd CrCl <10 ml/min: 125 mg PO qd	Weight <60 kg 150 mg PO qd 100 mg PO qd 75 mg PO qd	Dosage for CrCl <10 ml/min† HD, PD: same dose
Emtricitabine‡	CrCl >50 ml/min: no adjustment CrCl 30-49 ml/min: 200 mg PO q48h CrCl 15-29 ml/min: 200 mg PO q72h CrCl <15 ml/min: 200 mg PO q96h		HD: 200 mg PO q96h† PD: no data
Lamivudine* (3TC)	CrCl >50 ml/min: no adjustment CrCl 30-49 ml/min: 150 mg PO qd CrCl 15-29 ml/min: 150 mg first dose, then 100 mg PO qd CrCl 5-14 ml/min: 150 mg first dose, then 50 mg PO qd CrCl <5 ml/min: 50 mg first dose, then 25 mg PO qd		HD: 50 mg first dose, then 25 mg PO qd†
Stavudine (d4T)	CrCl >50 ml/min: no adjustment CrCl 26-50 ml/min: 15-20 mg PO bid CrCl ≤25 ml/min: 15-20 mg PO qd		20 mg PO qd† PD: has been used safely
Tenofovir‡	CrCl >50 ml/min: no adjustment CrCl 30-49 ml/min: 300 mg q48h CrCl 10-29 ml/min: 300 mg q72h		300 mg PO every 7 days†
Zalcitabine	CrCl ≥40 ml/min: no adjustment CrCl 10-40 ml/min: 0.75 mg q12h CrCl <10 ml/min: 0.75 mg q24h		HD: dosage for CrCl <10 ml/min† PD: no data
Non-nucleoside reverse transcriptase inhibitors§	No adjustment		
Protease inhibitors§	No adjustment		No adjustment
Entry or fusion inhibitor Enfuvirtide	CrCl ≥35 ml/min: no adjustment CrCl <35 ml/min: unknown, use with caution		Unknown, use with caution
CCR5 antagonist Maraviroc	No dosage recommendations Patients with CrCl <50 ml/min should receive maraviroc and CYP3A inhibitor only if potential benefit outweighs the risk		No data
Integrase inhibitor§ Raltegravir	No adjustment		No adjustment

Table 58-3 Dose adjustments for ART in CKD and ESRD. U.S. Food and Drug Administration (FDA) recommendations are based on CrCl or eGFR calculated as ml/min, but are likely valid for these expressed as ml/min/1.73 m^2. Atripla (efavirenz, tenofovir, and emtricitabine) is not recommended for CrCl < 5 ml/min. *ART,* Antiretroviral therapy; *CCR5,* cysteine-cysteine chemokine receptor 5; *CKD,* chronic kidney disease; *CrCl,* creatinine clearance; *eGFR,* estimated glomerular filtration rate; *ESRD,* end-stage renal disease; *HD,* hemodialysis; *PD,* peritoneal dialysis. *Combination AZT/lamivudine tablets (300 mg/150 mg) should be administered separately when eGFR < 50 ml/min. †Defer daily dose(s) until after hemodialysis (removal of drug occurs on dialysis). ‡Combination emtricitabine-tenofovir tablets (200 mg/300 mg): if CrCl = 30-49 ml/min, 1 tablet PO q48h; if CrCl <30 ml/min, the combination tablet should not be prescribed. §No dose adjustment necessary for any drug from this class in patients with renal dysfunction, hemodialysis, or peritoneal dialysis.

RENAL REPLACEMENT THERAPY IN THE PATIENT WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION

With the increasing survival of HIV-infected patients with treatment and the declining cost of ART, the magnitude of HIV-associated ESRD will likely increase worldwide, as it has in developed countries.[40] Life expectancy in HIV infection with ART has increased by 10 to 20 years in developed countries, and many of these patients are now dying of the complications of ESRD rather than of HIV infection. Currently, HIV-infected patients requiring either HD or PD, who are stable on ART, are achieving survival rates comparable to those of dialysis patients without HIV infection, and choice of dialysis modality does not have an impact on survival.

Immunization schedules are the same as for non–HIV-infected dialysis patients and should include vaccinations against *Streptococcus pneumoniae,* influenza virus, hepatitis A virus, and hepatitis B virus.[21] In both CKD and HIV infection, the presence of anemia is independently associated with shorter survival. The response to recombinant erythropoietin (EPO) in HIV-infected patients with ESRD is similar to that in HIV-negative patients.[41] Measurements of iron indices are complicated in HIV-infected patients, resembling those of the anemia of chronic disease, especially because levels of ferritin (an acute phase reactant) are often elevated in patients with HIV infection.

Elevated soluble transferrin receptor concentrations are more reliable than serum ferritin to distinguish iron deficiency in inflammatory disease states.[42]

Hemodialysis

Strict use of universal precautions is the best form of prevention of HIV transmission in dialysis units. Although HIV-infected patients do not have to be isolated from other patients or dialyzed on separate machines, concerns of staff and patients result in these patients being dialyzed in separate facilities in some institutions. Reprocessing of dialyzers from HIV-positive patients should not place staff members at increased risk for infection if necessary sterile precautions are undertaken. The risk of HIV seroconversion after a needlestick injury from an infected patient is estimated to be approximately 0.2% to 0.5% lower than that of HBV and HCV (5% to 40% and 3% to 10%, respectively). ART may reduce the risk of transmission after a needle stick injury, and postexposure prophylaxis with a combination of two reverse transcriptase inhibitors and one protease inhibitor is recommended.

Native arteriovenous fistulas are the preferred types of access because of better patency rates once established and lower complication rates compared with those associated with other access options.

Peritoneal Dialysis

Human immunodeficiency virus has been shown to survive in peritoneal effluents at room temperature for up to 7 days and in PD exchange tubing for up to 48 hours. Dialysate should therefore be handled as a contaminated body fluid.[43] Sodium hypochlorite (50% solution) and household bleach (10% solution), each further diluted 1:512, are effective at killing HIV in dialysate. PD patients should be instructed to pour dialysate into the home toilet and to dispose of dialysate bags and lines by tying them in plastic bags and disposing of the plastic bags in conventional home garbage.[21,43,44]

Kidney Transplantation

Kidney transplantation has been performed with success in HIV-infected patients. Preliminary short-term data in liver, kidney, and heart transplant recipients suggest that patient survival rates are similar to those of HIV-uninfected transplant recipients, and there has been no increase in the prevalence of opportunistic infection.[45] The largest series to date of 150 kidney transplants in the United States has reported patient and graft survival of 88% and 74%, respectively, at 3 years. In spite of high rates of acute graft rejection, survival appears to be similar to that of HIV-uninfected recipients, falling between that of older kidney transplant recipients and all kidney transplant recipients.[46] In areas with high endemic rates of HIV infection, it has been proposed that HIV-infected cadaveric donor organs may be transplanted into HIV-infected recipients with ESRD.[47] Four such transplantations have been reported with good graft and recipient survival.[48] With the series currently at 20 kidney transplants from HIV-positive deceased donors, 1- and 4-year graft survival rates have been 88% and 83%, respectively, and patient survival rates have been 94% and 89% (E. Muller, personal communication).

SCREENING FOR CHRONIC KIDNEY DISEASE

As noted previously, treatment of HIV-associated CG, and possibly HIV-associated ICGN, may slow progression of renal functional decline. Studies suggest that creatinine clearance and the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) creatinine eGFR equation provide suitable estimates of true GFR as assessed by iothalamate GFR.[45]

Patients with HIV disease are at increased risk for CKD and should receive regular screening. A committee of the Infectious Diseases Society of America has laid out a proposal for screening.[21] Annual screening should include assessment of blood pressure, assessment of serum creatinine and/or cystatin C, and a quantitative measure of urine protein. In a resource-limited setting, this might be a urine protein-creatinine measurement. In other settings, adding the urine albumin-creatinine ratio (ACR) provides additional information about cardiovascular risk and also the source of proteinuria, as the ACR gives an indication of glomerular versus tubular disease.[50] Support for screening has come from published data confirming that CKD in HIV infection is common, can occur at any stage of HIV infection (even before seroconversion), and can progress rapidly to ESRD if it is untreated.

The role of microalbuminuria in the natural history of HIV-associated CKD and screening is an area of active investigation. Microalbuminuria may indicate early glomerular disease, including in diabetes, arterionephrosclerosis, HIV-associated glomerular disease, tubular disease (drug toxicity), metabolic syndrome, or systemic inflammation.[51] Its role in diagnosis and screening in the setting of HIV infection remains to be determined. Microalbuminuria is associated with an increased risk of cardiovascular disease and mortality in patients with diabetes and hypertension, and also in the general population.[52] Han and colleagues[32] found that six of seven South African patients with persistent microalbuminuria had HIV-associated CG; these findings tell us that HIV-associated CG can present insidiously, at a stage when therapy may slow its progression. Nevertheless, these patients were ART naive, and this HIV-infected population may lack the high prevalence of diabetes, hypertension, and drug-induced renal toxicity that characterizes patients with HIV disease in developed countries. Szczech and colleagues[53] found microalbuminuria in 11% of patients with HIV disease compared

with 2% of controls; the presence of microalbuminuria was associated with insulin resistance, systolic hypertension, and advanced HIV disease characterized by a low CD4 count. Whether this association predicts increased risk of cardiovascular disease and mortality in HIV disease needs to be investigated. Hadigan and colleagues reported recently that the period of prevalence of persistent microalbuminuria, defined as the mean of three samples over 6 to 9 months, was 14% in an HIV population from which those with diabetes, chronic viral infection, and cancer had been excluded; furthermore, a single urine ACR result had a 98% negative predictive value but only a 74% positive predictive value to identify those with persistent microalbuminuria.[47]

Screening, early detection, and treatment of HIV-associated CKD are strongly recommended (Fig. 58-3). In the algorithm, management of leukocyturia, in addition to proteinuria, has been included because it occurs commonly and the presence of sterile pyuria may

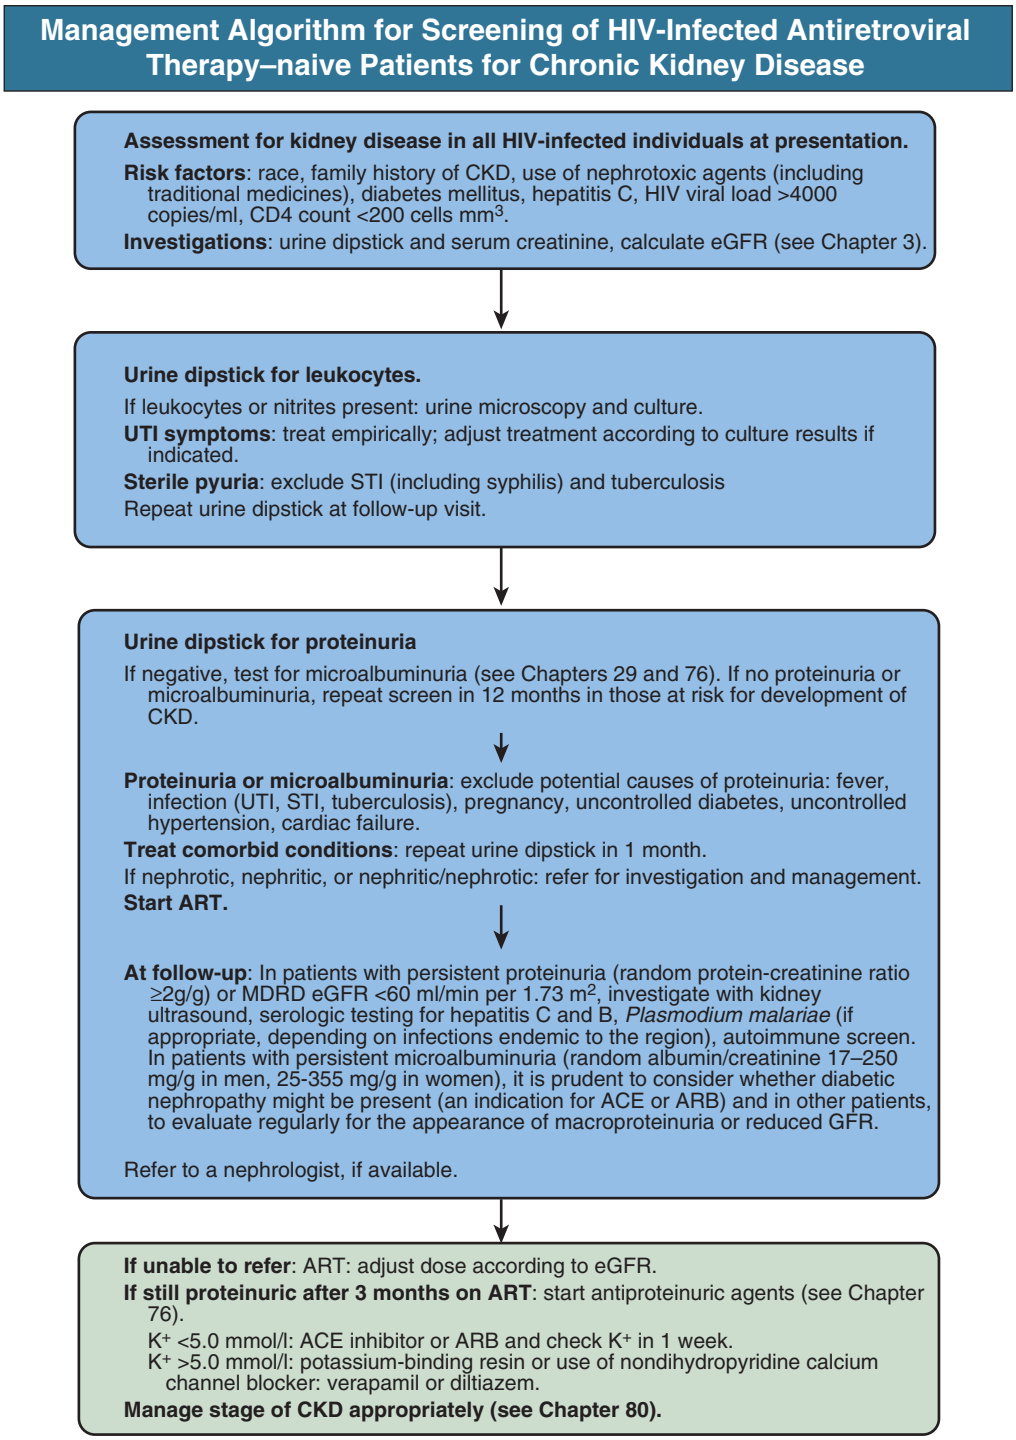

Figure 58-3 Management algorithm for screening of human immunodeficiency virus (HIV)–infected antiretroviral therapy–naive patients for chronic kidney disease. Tuberculosis may be pulmonary or extrapulmonary. Antiproteinuric agents may be used in normotensive individuals with gradual uptitration of dose, depending on tolerance and severity of proteinuria. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin II receptor blocker; *ART,* antiretroviral therapy; *CKD,* chronic kidney disease; *eGFR,* estimated glomerular filtration rate, calculated by the Cockcroft-Gault formula or the modified Modification of Diet in Renal Disease (MDRD) formula; *STI,* sexually transmitted infection; *UTI,* urinary tract infection.

be associated with comorbid disease. Urinary screening is inexpensive and easy to perform and to interpret, provided guidelines are given to staff at the primary health care level to initiate treatment, to investigate, and, if necessary, to refer. Effective screening programs are more realistic in resource-limited developing countries when the alternative is considered, which is that access to RRT is extremely limited and progression of CKD to ESRD is ultimately fatal for most patients.

SECTION X

Urologic Disorders

CHAPTER 59

Nephrolithiasis and Nephrocalcinosis

David A. Bushinsky and Rebeca D. Monk

Kidney stones are common and are associated with significant morbidity. *Nephrolithiasis* refers to stone formation within the renal tubules or collecting system, although calculi are often found within the ureters or in the bladder.[1-3] Most renal calculi are calcium oxalate, calcium phosphate, struvite, uric acid, and cystine. Clinical presentation varies from asymptomatic small stones to large, obstructing staghorn calculi that impair renal function and cause chronic kidney disease (CKD). The severity of stone disease depends on the pathogenesis as well as stone type, size, and location. *Nephrolithiasis* classically presents as ureteral colic, but may also commonly present with hematuria or urinary tract infection (UTI). Diffuse renal parenchymal calcification is termed *nephrocalcinosis.* These calcifications are usually calcium phosphate or calcium oxalate and may deposit in the renal cortex or medulla, depending on the cause.

NEPHROLITHIASIS

Epidemiology

Kidney stones are common in industrialized nations, with an annual incidence of over 1/1000 persons and a lifetime risk of forming stones of approximately 5% in women and approximately 13% in men.[1,3,4] In the United States the prevalence of nephrolithiasis increased from 3.2% in the late 1970s to 5.2% in the 1990s[5] and further to 8.8% in the 2000s, in parallel with the rising incidence of obesity, insulin resistance, and type 2 diabetes mellitus.[6-8] Incidence peaks in the third and fourth decades and prevalence increases with age until approximately 70 years in men and 60 years in women.[5] Factors that determine renal stone prevalence include age, sex, race, and geographic distribution. In the United States, Caucasians are more likely to develop renal stones than African Americans, Hispanics, or Asian Americans, but the prevalence is rising in non-Caucasians as well.[8] Men are more prone to stone formation than women.[8] In the United States the tendency for the development of stones also depends on geographic location, with an increasing prevalence from north to south and, to a lesser degree, from west to east. Increased environmental temperatures have been associated with increased stone formation rates.[9] The increase in nephrolithiasis rates may be a result of the greater sunlight exposure leading to an increase in insensible losses through sweating, and more concentrated urine.[4,10] The higher urine calcium excretion in a smaller urine volume will increase the risk for supersaturation for calcium-containing crystals, thereby promoting stone formation.

Stone type varies with worldwide geography and genetic predisposition. In the Mediterranean and Middle East, 75% of stones are composed of uric acid, whereas in the United States the majority of stones are calcium oxalate or calcium phosphate (>70%), with less than 10% being pure uric acid stones. Magnesium ammonium phosphate (struvite) stones account for 10% to 25% of stones formed (with a higher incidence in the United Kingdom), and cystine stones constitute 2% of all stones formed (Fig. 59-1).[11]

Outbreaks of kidney stones can also occur as a result of dietary supplements or medications. A large number of Chinese infants and toddlers developed kidney stones, and in some, renal failure, because of obstruction caused by stones. This outbreak was associated with melamine contamination in infant formulas and powdered milk as a means of raising the apparent concentration of protein in the products.[12]

Pathogenesis

Stones occur in urine that is supersaturated with respect to the ionic constituents of the specific type of stone. Supersaturation is dependent on the product of the free ion activities of stone components rather than on their molar concentrations. Whereas an increasing concentration of crystal components increases their free ion activity, other factors diminish it. When calcium and oxalate are dissolved in pure water, for example, the solution becomes saturated when the addition of any more calcium or oxalate does not result in further dissolution. However, urine, unlike pure water, contains numerous ions and molecules that can form soluble complexes with the ionic components of the stone. The interactions with these other solutes (e.g., citrate) may result in a decrease in free ion activity, which allows the stone constituents to increase in total concentration to levels that would normally cause stone formation in water. Urinary pH also influences free ion activity. The level of chemical free ion activity in which stones will neither grow nor dissolve is referred to as the *equilibrium solubility product,* or the upper limit of metastability. Above this level, the urine will be supersaturated and any stone present will grow in size.

When the solution becomes supersaturated with respect to a solid phase, ions can join together to form the more stable, solid phase, a process termed *nucleation.* Homogeneous nucleation refers to the joining of similar ions into crystals. The more common and thermodynamically favored heterogeneous nucleation results when crystals grow adjacent to crystals or other substances in the urine such as sloughed epithelial cells. Calcium oxalate crystals, for example, can nucleate with uric acid crystals. These small crystals may then aggregate to form larger stones, which would pass into the urine, causing crystalluria, if they did not anchor to the urothelium.

Calcium oxalate crystals anchor on areas of calcium phosphate deposits termed *Randall plaques*, which are located in the renal papillae and are composed of apatite (a complex of mostly calcium and phosphate) crystals. The apatite appears to originate around the thin loop of Henle, in the tubular basement membrane, and extends into the interstitium without filling the tubular lumen or damaging the tubular cells. Calcium oxalate crystals attach to Randall plaques, allowing significant stone growth.[13-15] Clinically apparent stone

Clinical Presentations of Nephrolithiasis

Presentation	Characteristics
Pain	Ureteral colic, loin pain, dysuria
Hematuria	—
Urinary tract infection	Recurrent, chronic infection, pyelonephritis
Asymptomatic urine abnormality	Microhematuria, proteinuria, sterile pyuria
Interruption of urinary stream	—
Calculus anuria	—

Table 59-1 **Clinical presentations of nephrolithiasis.**

Causes of Hematuria

- Nephrolithiasis
- Infection: cystitis, prostatitis, urethritis, acute pyelonephritis, tuberculosis, schistosomiasis
- Malignancy: renal cell carcinoma, transitional cell carcinoma, prostatic carcinoma, Wilms tumor
- Trauma
- Glomerular disease
- Interstitial nephritis
- Polycystic kidney disease
- Papillary necrosis
- Medullary sponge kidney
- Coagulopathy: bleeding disorders, anticoagulation therapy
- Miscellaneous: loin pain–hematuria syndrome, arteriovenous malformation, chemical cystitis, caruncle, factitious

Box 59-1 **Causes of hematuria.**

disease occurs when the calcium oxalate crystals break off from the Randall plaques and cause injury or obstruction.

Clinical Manifestations

The two most characteristic symptoms of nephrolithiasis are pain and hematuria. Other presentations include UTIs and acute kidney injury (AKI) caused by obstructive uropathy if stones cause bilateral renal tract obstruction or unilateral obstruction in a single functioning kidney (Table 59-1).

Pain

The classic presentation of pain in patients with nephrolithiasis is ureteral colic. Pain is of abrupt onset and intensifies over time into an excruciating, severe flank pain that resolves only with stone passage or removal. The pain may migrate anteriorly along the abdomen and inferiorly to the groin, testicles, or labia majora as the stone moves toward the ureterovesical junction. Gross hematuria, urinary urgency, frequency, nausea, and vomiting may occur. Stones smaller than 5 mm usually pass spontaneously with hydration, whereas larger stones often require urologic intervention (Fig. 59-2).[14,16] Ureteral colic may also occur with the passage of clots from hematuria of any cause ("clot colic"), or with papillary necrosis. As well as colic, nephrolithiasis may provoke less-specific loin pain that poorly localizes to the kidney and therefore has a wide differential diagnosis, particularly if not associated with other urinary symptoms. The finding of a stone on radiologic examination does not preclude a coincidental cause of pain from another source.

Hematuria

Stone disease is a common cause of hematuria. Macrohematuria occurs more commonly with large calculi and during UTI and colic. Although typically associated with loin pain or ureteral colic, the hematuria of nephrolithiasis may also be painless. The clinical differential diagnosis of hematuria is therefore wide (Box 59-1). Painless microhematuria in children may occur with hypercalciuria in the absence of demonstrable stones.

Loin Pain–Hematuria Syndrome

Loin pain–hematuria syndrome is a poorly understood condition that must always be considered in the differential diagnosis of nephrolithiasis. It is diagnosed by exclusion when patients (most typically young and middle-aged women) present with loin pain and persistent microhematuria or intermittent macrohematuria.[17,18] Careful evaluation is required to exclude small stones, tumor, UTI, and glomerular disease. Angiographic abnormalities implying intrarenal vasospasm or occlusion have been reported, as have renal biopsy abnormalities typified by deposition of complement C3 in arteriolar walls. However, these findings are not consistent, nor do they provide a coherent framework to explain the pathogenesis of this condition.

In one study, 43 consecutive patients with clinical manifestations of loin pain–hematuria syndrome were evaluated by renal biopsy

after other causes of their symptoms had been excluded with at least two imaging studies.[17] Thirty-four patients were considered to have idiopathic loin pain–hematuria syndrome after nine with histologic evidence of IgA nephropathy were excluded. Of these, 66% had glomerular basement membranes that were either unusually thick or thin on electron microscopy, and 47% had a history of kidney stones, though none had obstructing stones at the time of assessment. Evidence of glomerular hematuria was more common in biopsies of patients with loin pain–hematuria syndrome compared with those of healthy living kidney donors who also underwent renal biopsy. The investigators postulated that the structurally abnormal glomerular basements in the majority of these patients may lead to rupture of the glomerular capillary walls, with consequent hemorrhage into the renal tubules. Tubular obstruction by red blood cells or potentially by microcrystals ensues. Local and global renal parenchymal edema follow, ultimately resulting in stretching of the renal capsule and in severe flank pain.

Loin pain–hematuria syndrome is a chronic condition requiring reassurance, careful management of analgesia, and ongoing psychological support. The condition usually remits after several years. Denervation of the kidney by autotransplantation is rarely successful.[18] The extreme measure of nephrectomy has been used, but pain often recurs promptly in the contralateral kidney. Bilateral nephrectomy and renal replacement therapy has been reported as an approach of very last resort. Referral to a pain clinic can assist in providing psychiatric counseling, analgesia, and exclusion of other disorders. In one retrospective study, patients who eventually came to accept a nonsurgical approach along with pain-coping strategies that did not involve narcotic analgesics had the most successful outcomes.[19]

Asymptomatic Stone Disease

Even large staghorn calculi may be asymptomatic and discovered only during the investigation of unrelated abdominal or musculoskeletal symptoms. Obstructive uropathy caused by calculi may also be painless; therefore, nephrolithiasis should always be considered in the differential diagnosis of unexplained renal failure.

In the outbreak of melamine-associated nephrolithiasis in Chinese infants, the majority of patients brought to a screening clinic had no symptoms or signs of stones, and the diagnosis of nephrolithiasis was made only by ultrasound in at-risk infants and toddlers.[12]

Clinical Evaluation of Stone Formers

All patients with recurrent nephrolithiasis merit metabolic evaluation to determine the cause of their kidney stones. Complete evaluation of patients who have formed only a single stone is controversial because of the undetermined cost-benefit ratio. A National Institutes of Health Consensus Development Conference on the Prevention and Treatment of Kidney Stones determined that all patients, even those with a single stone, should undergo a basic evaluation, which need not include a 24-hour urine collection. Those with metabolically active stones (stones growing in size or number within 1 year), all children, noncalcium stone formers, and patients in demographic groups not typically prone to stone formation warrant a more complete evaluation, which includes a 24-hour urine collection made with the patient taking his or her typical diet.[20]

Basic Evaluation

The clinic evaluation of stone formers includes a general history and physical examination and requires specific data gathering on stone formation, diet, and specific laboratory studies, as shown in Box 59-2.

The Basic Evaluation of Nephrolithiasis

- Stone history
  - Number of stones formed
  - Frequency of stone formation
  - Age at first onset
  - Size of stones passed or still present
  - Kidney involved (left, right, or both)
  - Stone type, if known
  - Need for urologic intervention: ESWL, percutaneous nephrolithotomy, and so on
  - Response to surgical procedure
  - Are stones associated with urinary tract infections?
- Medical history
- Medications
- Family history
- Occupation and lifestyle
- Fluid intake and diet
- Physical examination
  - Evidence of systemic causes of stones (e.g., tophi)
- Laboratory data
  - Urinalysis
  - Urine culture
  - Stone analysis
- Blood chemistry
  - Sodium, potassium, chloride, bicarbonate
  - Creatinine, calcium, phosphorus, uric acid
  - Intact parathyroid hormone level if calcium elevated
- Radiologic evaluation
  - Abdominal radiograph (no contrast)
  - Noncontrast CT
  - IVU
  - Ultrasound

Box 59-2 The basic evaluation of nephrolithiasis. *CT,* Computed tomography; *ESWL,* extracorporeal shock wave lithotripsy; *IVU,* intravenous urography.

History The history serves to uncover a systemic cause for nephrolithiasis. Any disease that can lead to hypercalcemia (including malignancy, hyperparathyroidism, and sarcoidosis) can result in hypercalciuria and increase the risk for calcium stone formation. A number of malabsorptive gastrointestinal disorders (including Crohn disease and sprue [celiac disease]) can result in calcium oxalate stone formation as a result of volume depletion and hyperoxaluria. Uric acid stones often occur in patients with a history of gout and, increasingly, in patients with insulin resistance.[11]

The stone history (see Box 59-2) includes the number and frequency of stones formed, patient age at incidence of first stone, size of stones, stone type (if known), and whether the patient required surgical removal of the calculi. This information indicates the severity of the stone disease and provides clues to the cause of the stone formation. For example, large staghorn calculi that do not pass spontaneously and recur despite frequent surgical intervention are more consistent with struvite than calcium oxalate stones. Stones that develop at a young age may be caused by cystinuria or primary hyperoxaluria. Stone response to intervention is also significant; cystine stones, for example, do not fragment well with lithotripsy. If stones recur frequently in a single kidney, a congenital abnormality in that kidney, such as megacalyx or medullary sponge kidney, should be explored.

Family history is important because a number of stone types have a genetic basis. Idiopathic hypercalciuria is most likely a polygenic disorder. Mutations in the claudins, which regulate calcium reabsorption in the thick ascending limb of the loop of Henle, cause familial hypercalciuria and nephrocalcinosis. A genome-wide association study in kidney stone patients identified sequence variants in the gene encoding claudin 14 that were associated with hypercalciuria.[21]

Cystinuria is usually autosomal recessive, and hyperuricosuria has been associated with rare inherited metabolic disorders. Nephrolithiasis and nephrocalcinosis can also result from a variety of monogenic disorders, such as Dent disease (X-linked recessive nephrolithiasis), McCune-Albright syndrome, osteogenesis imperfecta type 1, and congenital lactate deficiency. The various genetic disorders can lead to hypercalciuria by increasing bone resorption, affecting intestinal absorption, or decreasing renal tubular reabsorption transport, or through other, as yet unknown mechanisms.[4,14,15,22,23]

A number of medications are known to potentiate calcium stone formation (e.g., loop diuretics are calciuric) or may predispose to uric acid lithiasis (salicylates, probenecid) (Box 59-3). Certain drugs can precipitate into stones themselves, such as rapidly infused intravenous acyclovir, high-dose sulfadiazine, triamterene, and the antiretroviral agents indinavir and nelfinavir.[24] In addition, some medications, such as acetazolamide and topiramate (a medication used for seizures and migraine headaches), promote nephrolithiasis by inhibiting carbonic anhydrase activity. In this setting the metabolic acidosis that ensues, along with lower urine citrate, higher urine pH, and increased urinary calcium excretion, predisposes to calcium phosphate stone formation.[25]

The social history should include details regarding occupation and lifestyle. Cardiothoracic surgeons and real-estate agents, for example, may minimize fluid intake to avoid bathroom breaks during the workday. Those who engage in vigorous physical activities, such as running, may not rehydrate adequately to keep up with insensible losses, producing excessively concentrated urine and precipitation of stone crystals in those prone to nephrolithiasis.

A dietary history and review of fluid intake are essential in determining potential causes or contributors to stone formation. The patient should be asked about commonly consumed foods, with attention paid to sodium-containing foods, as well as quantities of calcium, animal protein, purine, and oxalate (Box 59-4). Dietary calcium intake should be reviewed, because many patients with nephrolithiasis are erroneously instructed to eliminate all calcium from their diet, a suggestion that can result not only in bone demineralization, particularly in women and children, but also in an *increase* in stone formation.[1-3,26-28] Sugar-sweetened soda appears to be associated with a greater risk of stone formation, whereas consumption of coffee, tea, beer, wine, and orange juice appears to be associated with a lower risk.[29] The exact mechanism of nephrolithiasis from soda is not known but is likely related to the high fructose content of soda which may alter urinary composition and pH.[30]

Physical Examination Most patients with idiopathic hypercalciuria are healthy and have normal physical examination findings. Patients with hyperuricosuria and uric acid stone formation may display tophi. Central obesity is associated with a predisposition to metabolic syndrome and uric acid stones. Paraplegic patients with a chronic indwelling bladder catheter may be predisposed to chronic UTI and struvite stones.

Laboratory Findings Urine pH is generally high in patients with struvite and calcium phosphate stones but low in patients with

Medications Associated with Nephrolithiasis and Nephrocalcinosis

Calcium Stone Formation
Loop diuretics
Vitamin D
Corticosteroids
Calcium supplements
Antacids (calcium and noncalcium antacids)
Theophylline

Box 59-3 Medications associated with nephrolithiasis and nephrocalcinosis. *Associated with nephrocalcinosis.

Foods High in Oxalate and Purine

High-Oxalate Foods (Avoid in Setting of Hyperoxaluria)
Green beans
Beets
Celery
Green onions
Leeks
Leafy greens: collard greens, dandelion greens, Swiss chard, spinach, escarole, mustard greens, sorrel, kale, rhubarb
Cocoa
Chocolate
Black tea
Berries: blackberries, blueberries, strawberries, raspberries, currants, gooseberries
Orange peel
Lemon peel
Dried figs
Summer squash
Nuts, peanut butter
Tofu (bean curd)

High-Purine Foods (Avoid in Setting of Hyperuricosuria)
Organ meats: sweetbreads, liver, kidney, brains, heart
Shellfish
Meat: beef, pork, lamb, poultry
Fish: anchovies, sardines (canned), herring, mackerel, cod, halibut, tuna, carp
Meat extracts: bouillon, broth, consommé, stock
Gravies
Certain vegetables: asparagus, cauliflower, peas, spinach, mushrooms, lima and kidney beans, lentils

Box 59-4 Some foods high in oxalate and purine.

uric acid and calcium oxalate stones. The specific gravity, if high, will confirm inadequate fluid intake in many patients. Hematuria may imply active stone disease with crystal or stone passage. Examination of the urine may reveal red blood cells along with characteristic crystals (Fig. 59-3). Bacteriuria with urine pH of 6 to 6.5 suggests struvite stones. Urine should be cultured, and because many bacteria produce urease even when urine bacterial colony counts are low, the microbiology laboratory should be instructed to type the organism even if there are fewer than 100,000 colony-forming units/ml.

Blood tests required in the basic evaluation are serum electrolytes (sodium, potassium, chloride, and bicarbonate), creatinine, calcium, phosphorus, and uric acid. If the serum calcium is elevated or at the upper limit of normal, especially if the serum phosphorus is low, a serum parathyroid hormone level should be measured. A low potassium or bicarbonate level may indicate a cause for hypocitraturia, such as distal renal tubular acidosis.

Stone Analysis Patients should be encouraged to retrieve any stone they excrete for chemical analysis, which may help define the underlying metabolic abnormality and guide therapy.

Imaging Patients should have a plain film of the abdomen performed with views of the kidneys, ureters, and bladder (KUB). This may reveal opacifications in the areas of the kidneys and ureters that could be a result of calcium, cystine, or struvite stones (Fig. 59-4). Uric acid and xanthine calculi are radiolucent and will not be visible on plain films. The unenhanced helical computed tomography (CT) scan, also known as spiral CT, or CT urography, has replaced contrast intravenous urography (IVU) as the diagnostic test of choice for acute ureteral colic; it has a higher sensitivity and specificity than IVU for detecting ureteral stones and ureteral obstruction[16] and avoids the need for contrast. CT scanning is more likely to reveal causes of colic other than stones. It is more rapid, with results being available in minutes rather than hours, an advantage in the emergency room setting. However, an experienced radiologist, required for optimal interpretation of the images, may not be available at all times in urgent care facilities. Disadvantages of CT imaging include a radiation dose approximately three times that of a conventional IVU, and higher cost. Both tests should be avoided or limited in patients at risk for radiation exposure such as children and pregnant women.[31,32] The role of CT urography is also discussed in Chapter 5.

Contrast should generally be avoided in patients with renal impairment or other contraindications to the use of contrast. The IVU generally demonstrates urinary tract obstruction caused by calculi and can identify abnormalities of the genitourinary tract that may predispose to stone formation, such as medullary sponge kidney (see Chapter 47) or calyceal anomalies (see Chapter 52) (Fig. 59-5). During acute colic, the radiographic contrast used in the IVU, by creating a strong osmotic diuresis, may assist in moving the stone along the ureter. If stones are radiopaque, a KUB can be obtained if a patient develops symptoms suggestive of recurrent stone disease.

Renal ultrasound provides great specificity in the evaluation of stones, but is not a sensitive screening test. Both radiolucent and radiopaque stones within the kidneys should be detectable on ultrasound, but ureteral stones are often missed. Nonetheless, this is the test of choice for those patients who must avoid radiation exposure.

Periodic monitoring, if deemed necessary, should be obtained with a KUB and/or ultrasound scan rather than CT, whenever possible, to minimize radiation exposure. The combination of ultrasound and KUB has been found to be more sensitive in detecting stones than either test alone, while minimizing radiation compared with CT.[33] Many stone patients have recurrent disease and are therefore at risk for repeated exposure to radiation. Especially when

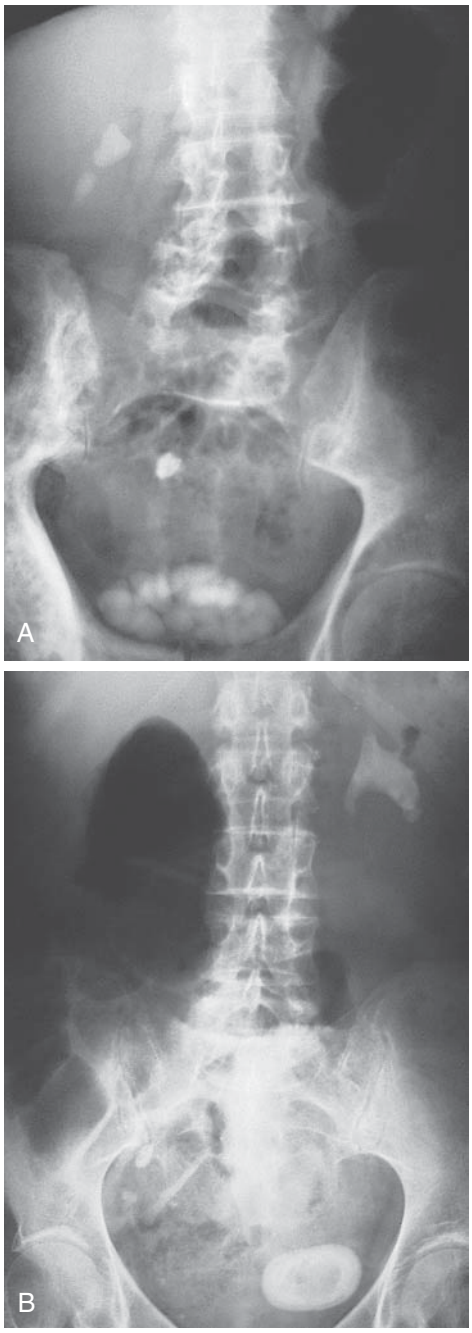

Figure 59-4 Radiopaque renal calculi. A, X-ray film showing multiple cystine stones in the right kidney, right ureter, and bladder. **B,** Struvite stones: left staghorn calculus and a single bladder stone.

caring for patients who may father or subsequently carry offspring, every effort should be made to limit radiation exposure. In general, we do not order routine follow-up x-ray examinations and do not order x-ray examinations unless the results will alter subsequent care. If x-ray films are ordered, every effort should be made to limit radiation exposure—for example, by not routinely ordering both a noncontrast and a contrast study. Often the results of the noncontrast study alone are sufficient to guide therapy.

Complete Evaluation

A complete evaluation should be undertaken in patients with multiple or metabolically active stones (i.e., stones that grow in size or increase in number within a year), in all children, in patients from

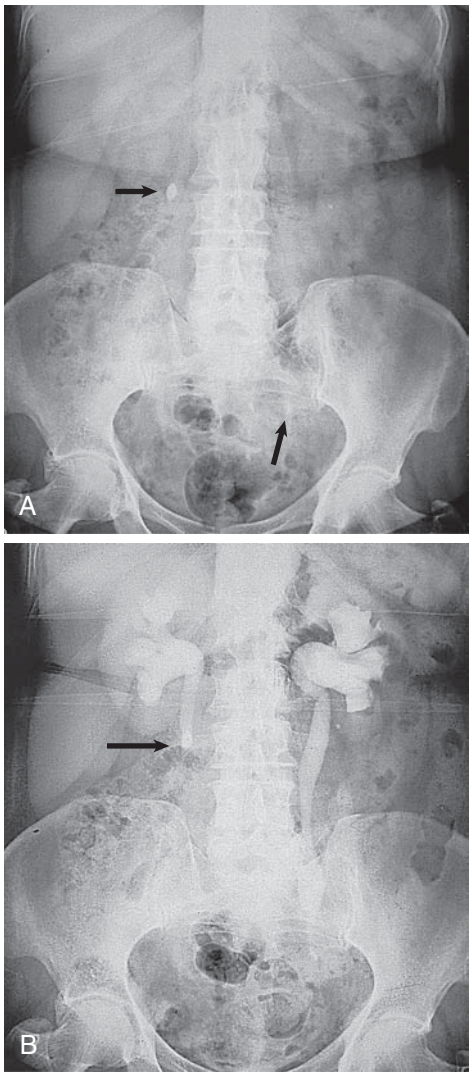

Figure 59-5 Obstructive uropathy resulting from nephrolithiasis in a patient with acute renal impairment. A, X-ray film showing a stone in the right upper ureter and a very small stone in the lower left ureter *(arrows).* **B,** Intravenous urogram at the same time showing bilateral hydronephrosis caused by ureteral obstruction.

demographic groups not typically prone to stone formation, and in those with stones other than those containing calcium.

The complete evaluation should include a measure of urine volume and the quantity of calcium, oxalate, phosphorus, uric acid, sodium, citrate, and creatinine excreted in a 24-hour urine collection (Table 59-2). Urine creatinine is useful in assessing adequacy of the collection; men should excrete more than 15 mg/kg (132.6 µmol/kg) and women should excrete more than 10 mg/kg (88.4 µmol/kg) daily. Patients should be encouraged to perform the urine collection on a typical day while eating a typical diet, although many patients prefer to collect the urine on weekends when their diet and habits may differ from those during usual workdays. Specialized testing, such as the use of high- or low-calcium diets, is not recommended.[20] Careful instructions should be given to avoid overcollection or undercollection. Patients should be instructed to flush the first morning urine and collect all urine for the next 24 hours including the second morning urine.

A disadvantage of the standard 24-hour urine collection is that laboratories vary in the preservatives required to process the various constituents. Many require more than one collection to measure all

Optimal 24-Hour Urine Values in Recurrent Nephrolithiasis	
24-Hour Urine Values	
Volume	>2 to 2.5 l
Calcium	<4 mg/kg (0.1 mmol/kg), ~300 mg (7.5 mmol) in men, ~250 mg (6.3 mmol) in women
Oxalate	<40 mg (0.36 mmol)
Uric acid	<750 mg (4.5 mmol) in women and <800 mg (4.7 mmol) in men (can be pH dependent)
Citrate	>320 mg (17 mmol)
Sodium	<3000 mg (<130 mmol)
Phosphorus	<1100 mg (35 mmol)
Creatinine	>10 mg/kg (88 µmol/kg) in women and >15 mg/kg (132 µmol/kg) in men, if specimen is a complete collection
Urine Supersaturation Values	
Calcium oxalate supersaturation	<5
Calcium phosphate supersaturation	0.5-2
Uric acid supersaturation	0-1

Table 59-2 Evaluation of nephrolithiasis: optimal 24-hour urine values.

the urinary constituents, reducing compliance and therefore the accuracy of the results.

A better approach available in some laboratories is to undertake a 24-hour urine collection for quantification of supersaturation for the common solid phases of calcium oxalate, brushite (calcium phosphate), and uric acid (see Table 59-2). Urine for supersaturation analysis has been shown to correlate well with stone composition.[34] Determination of supersaturation is far more informative than evaluation of the individual urinary constituents.

Patients can bring their specimens to a local laboratory or may directly mail them to specialized laboratories that measure calcium, oxalate, citrate, uric acid, creatinine, sodium, potassium, magnesium, sulfate, phosphorus, chloride, urine urea nitrogen, and pH. Supersaturation is calculated with a computer program such as EQUIL2.[35] Calculation of supersaturation from a 24-hour urine specimen will provide values lower than the peak postprandial supersaturation and peak nighttime supersaturation, either of which may initiate stone formation. Patients should stop taking any vitamin C or multivitamins containing more than 100 mg of vitamin C for at least 5 days before the urine collection because the antioxidants in the vitamin may interfere with the assay. Only undersaturated urine ensures that stones will not recur; the risk of stone formation rises with increasing supersaturation.

JESS (Joint Expert Speciation System) is another program that measures the concentration of the various complexes in solution under many different conditions. It may prove to be more accurate than supersaturation analysis but is currently used for research purposes only.[36,37]

General Treatment

Intervention for stone removal may be required when pain, obstruction, and/or infection resulting from nephrolithiasis do not respond to conservative management. Surgical management of stones includes extracorporeal shock wave lithotripsy and both endoscopic and percutaneous surgical removal of stones (see Chapter 60). The risk for developing renal impairment varies with the type of stone, and this must be considered in planning management.[38]

Medical Management

Patients who are seen by stone "specialists" often have a decrease in stone recurrence even without pharmacologic intervention.[39] This phenomenon, termed the "stone clinic effect," is likely a result of modifications in diet and fluid intake. These nonpharmacologic measures include an increase in fluid intake, which increases urine volume; restriction of dietary sodium, which leads to a reduction of urine calcium excretion; restriction of animal protein, which also leads to a reduction of urine calcium excretion and an increase in excretion of the calcification inhibitor citrate; and ingestion of an age- and gender-appropriate amount of dietary calcium. Although dietary calcium restriction continues to be prescribed by many physicians, increasing evidence indicates that this is not beneficial and can actually increase the rate of stone formation (see the later discussion of calcium stones).[3,26]

Fluid Intake An increase in urine volume to more than 2 to 2.5 L daily has been proven to reduce the incidence of stones.[39-41] Large urine volumes will reduce calcium oxalate supersaturation, as well as precipitation of other crystals. Increased fluid intake to augment urine volume is also a mainstay of therapy for patients with uric acid and cystine stones. The period of maximum risk for stone formation is at night, when urine concentration is physiologically increased. Patients should be encouraged to drink enough fluid in the evening to provoke nocturia and then drink further fluid before returning to bed.

Salt Intake Urine sodium excretion directly correlates with urine calcium excretion[1,2]; thus, dietary salt restriction is associated with decreased urine calcium excretion. Patients should be instructed to limit daily sodium intake to 2 g (87 mmol sodium).

Dietary Protein Animal protein ingestion increases the frequency of renal stone formation by a number of mechanisms. Metabolism of certain amino acids leads to generation of sulfate ions, which render urinary calcium ions less soluble.[42,43] The metabolic acidosis that results from protein ingestion causes calcium release from bone and a consequent increase in the filtered load of calcium.[42,43] Acidosis also decreases tubular calcium reabsorption, resulting in hypercalciuria. Urinary citrate excretion is also pH dependent, with acidosis leading to a decrease in citrate excretion. The result of increased animal protein intake is an increase in urinary calcium excretion that is rendered less soluble because of concomitant sulfate excretion and hypocitraturia. Low urine pH, coupled with increased uric acid excretion from the metabolism of animal protein, can result in uric acid lithiasis. For these reasons stone formers should consume only a moderate-protein diet (0.8 to 1.0 g/kg daily).[1] Dietary fructose may also increase uric acid lithiasis.[30]

Dietary Calcium Despite conventional wisdom, several studies have demonstrated a decrease in stone incidence when people consume diets adequate in calcium.[41,44-46] This beneficial effect has been attributed to intestinal binding of ingested oxalate (which is highly lithogenic) by dietary calcium. Although women have reduced stone formation while ingesting an age-appropriate amount of dietary calcium, this benefit may not extend to those taking calcium in the form of calcium supplements.[47] The data are inconsistent as to whether calcium supplements increase the risk of nephrolithiasis.[48,49] Some have postulated that any increased risk may be a result of timing the supplemental calcium ingestion apart from meals, which would enhance calcium absorption without reducing oxalate

absorption. In addition, the calcium supplements may dissociate rapidly, leading to rapid absorption, increased filtered calcium load, and transitory hypercalciuria, leading to increased supersaturation. We advise patients that it is best to obtain calcium from dairy products rather than supplements.

Some, but not all, recent studies have demonstrated that women ingesting calcium supplements have a great risk of cardiovascular disease and death.[51-52] In one long-term study of more than 60,000 Swedish women, those with a dietary calcium intake exceeding 1400 mg/day had an increased risk of cardiovascular mortality with a hazard ratio of 1.49 (1.09-2.02, 95% confidence interval [CI]). The risk for all-cause mortality rose to 2.57 (1.19-5.55, 95% CI) when any calcium tablet supplements were added to this high dietary intake.[50] Bolland and colleagues reviewed cardiovascular mortality in over 15 studies involving calcium supplementation versus placebo. They noted an increased risk of myocardial infarction in those randomized to calcium supplements with a hazard ratio of 1.31 (1.02-1.67, 95% CI) that rose to 1.85 (1.28-2.67, 95% CI) in patients already taking more than 805 mg of dietary calcium daily.[51] The Institute of Medicine recently adjusted their recommended allowance of calcium to 1000 mg daily for adults older than 19 years and to 1200 mg for women over age 50 years.[53] As noted earlier, we generally recommend that women take the appropriate amount of calcium in the form of food with limited supplement intake, except in cases of severe osteoporosis with insufficient dietary intake.

Previously, hypercalciuric patients were divided into a number of groups including those with excessive renal calcium excretion ("renal leak") and those who absorbed excessive amounts of calcium via the gastrointestinal tract ("absorptive hypercalciuria"). However, it is apparent that hypercalciuric patients generally do not have a transport defect limited to a single site; they appear to have a systemic dysregulation of calcium transport at the major calcium transporting sites, the intestine, kidney, and bone. In both hypercalciuric rats and in humans placed on a low-calcium diet, there is a continuous, wide spectrum of calcium excretion. Hypercalciuric patients may appear to have renal leak on one examination and absorptive hypercalciuria on another.[1,2] Some patients excrete more calcium than they consume, indicating a negative total body calcium balance. This calcium must be derived from the mineral phases of bone, which contain by far the largest repository of calcium in the body.[27] Support for the use of an age- and gender-appropriate amount of dietary calcium was recently provided by a randomized prospective study comparing the rate of stone formation in men assigned a low-calcium diet with those assigned a normal-calcium, low-sodium, and low–animal protein diet.[26] The men assigned the low-calcium diet were twice as likely to have recurrent stones over 5 years compared with those on the normal-calcium, low-sodium, and low–animal protein diet. Urinary calcium oxalate supersaturation also diminished more rapidly in those on the higher-calcium diet and remained lower than that of men on the low-calcium diet for most of the 5-year study. This reduction in supersaturation was the result of a greater fall in urinary oxalate in the men eating the normal-calcium, low-sodium, and low–animal protein diet.[26,54]

Patients prescribed a low-calcium diet can avoid excessive hyperoxaluria when adequately instructed to also consume a low-oxalate diet.[55] Some contend that this approach may benefit patients with excessive intestinal absorption of calcium associated with severe hypercalciuria by allowing calcium restriction without the risk of significant osteopenia. We recommend, however, an age- and gender-appropriate calcium intake, best derived from a diet containing an adequate amount of dairy products. Because stone formation can be reduced with normal calcium intake and there is a risk of bone demineralization with calcium restriction, we consider the low-calcium diet to be obsolete.[26,27,54] Dietary calcium intake exceeding the age and gender recommendations and calcium supplements should be avoided in patients with calcium nephrolithiasis.

Vitamin D Given the great degree of vitamin D deficiency and insufficiency in Northern latitudes, vitamin D supplementation is very common.[56] Patients and physicians often express concern that this might exacerbate nephrolithiasis, given the role of vitamin D in mineral metabolism. In fact, studies have shown no association between vitamin D supplementation or serum 25-hydroxyvitamin D levels and calcium excretion, nor an increased rate of stone formation in hypercalciuric patients on vitamin D supplementation. It is reasonable to treat vitamin D deficiency (25-hydroxyvitamin D levels below 20 ng/ml) with either cholecalciferol or ergocalciferol with no fear of worsening hypercalciuria or increasing stone formation.[57]

SPECIFIC TYPES OF STONES

Calcium Stones

Calcium-containing kidney stones constitute approximately 70% of all stones formed. Most calcium stones are composed of calcium oxalate, either alone or in combination with calcium phosphate or uric acid. A small percentage of stones are composed entirely of calcium phosphate.[1] Most calcium stones do not exceed 1 to 2 cm in width, although surgical intervention is often required for stones greater than 5 mm.

Calcium-based stones most often develop as a result of excessive excretion of calcium (hypercalciuria). Other causes of calcium stones are excessive excretion of oxalate (hyperoxaluria) and uric acid (hyperuricosuria), insufficient citrate excretion (hypocitraturia), renal tubular acidosis, certain medications, and congenital abnormalities of the genitourinary tract (Fig. 59-6). Specific therapy for patients with calcium stones depends on the underlying metabolic abnormalities detected on evaluation. Nonspecific or general therapy as outlined earlier should always be instituted; however, more definitive treatment is often required to significantly decrease the rate of recurrent stone formation.

Hypercalciuria

Etiology Hypercalciuria for which a causative metabolic abnormality cannot be determined is called *idiopathic hypercalciuria.* Affected patients typically have excessive intestinal calcium absorption and may also have decreased renal tubular calcium reabsorption and increased bone resorption. The cause of this systemic disorder in calcium transport has, in hypercalciuric stone–forming rats and in humans, been linked to an excessive number of receptors for vitamin D.[58-60] Metabolic disorders leading to an elevation in serum calcium, parathyroid hormone, or $1,25(OH)_2D$ (1,25-dihydroxyvitamin D) also may result in hypercalciuria.

Treatment For hypercalciuria the usual first-line therapy is a thiazide diuretic, which acts to reduce urinary calcium. In the United States, chlorthalidone 25 to 50 mg is the drug of choice, as it requires only once daily administration. Indapamide 1.25 to 2.5 mg daily does not tend to raise serum lipids as much as other thiazides and may be preferred for patients with cardiac risk factors or elevated serum lipids. On commencing these medications, patients should be instructed to increase their dietary potassium intake, and a serum potassium level should be checked 7 to 10 days later. If the level of potassium is low, oral potassium supplementation should be initiated. Potassium citrate is preferred over potassium chloride because citrate forms complexes with urinary calcium, further lowering supersaturation. However, most patients find potassium citrate

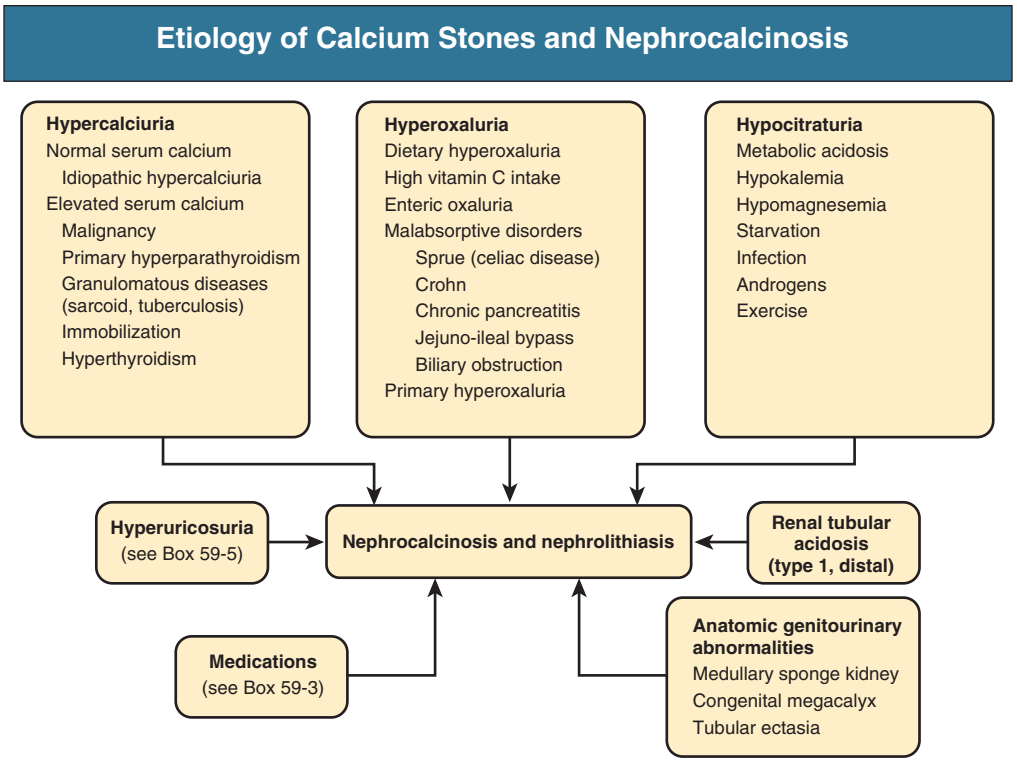

Figure 59-6 **Etiology of calcium stones and nephrocalcinosis.**

liquid preparations unpalatable. A wax matrix tablet of potassium citrate is well tolerated and is available in some countries. In general, patients are able to maintain a normal serum potassium level with potassium citrate 20 to 40 mmol daily. The serum potassium and bicarbonate levels should be rechecked 7 to 10 days later for further dosage adjustment. Because citrate is a base, potassium citrate may excessively raise the serum bicarbonate level or urinary pH, and a change to potassium chloride may be required.

The 24-hour urine calcium, sodium, and citrate should be rechecked after several weeks. If the calcium excretion remains elevated, the thiazide dose should be increased. However, if the sodium excretion also remains high, patients should be encouraged to limit their sodium intake further because they will not have an adequate response to the diuretic on a high-sodium diet. If the serum potassium remains low despite supplementation or the calcium excretion remains high despite increased thiazide dosing, addition of a potassium-sparing diuretic may be required to increase serum potassium. Triamterene should not be used for treatment of hypokalemia because it can precipitate into stones. Amiloride (starting dose 5 mg daily) is a better option to treat thiazide-induced hypokalemia.[1,2]

Dietary Recommendations See the discussion of general treatment.

Hyperoxaluria

Etiology Elevated urinary oxalate results from excessive dietary intake (dietary oxaluria), gastrointestinal disorders that can lead to malabsorption (enteric oxaluria), or an inherited enzyme deficiency that results in excessive metabolism of oxalate (primary hyperoxaluria) (see Fig. 59-6).[61]

Dietary excess of oxalate generally does not raise urinary oxalate above 60 mg/24 h (0.54 mmol/24 h). Enteric oxaluria may occur when malabsorption results in excessive colonic absorption of oxalate, as a result of sprue (celiac disease), Crohn disease, chronic pancreatitis, or short bowel syndrome or after bariatric surgery. The anion exchange transporter Slc26a6 appears responsible for intestinal oxalate secretion, and mice with targeted inactivation of this transporter have hyperoxaluria.[62] It is not yet known whether patients with enteric hyperoxaluria have mutations in Slc26a6. Urinary oxalate is generally more than 60 and can exceed 100 mg/24 h (0.54 and 0.9 mmol/24 h).[63] In primary hyperoxaluria, the tremendous oxalate production results in widespread calcium oxalate deposition throughout the body at an early age. This infiltration of calcium oxalate into organs can result in cardiomyopathy, bone marrow suppression, and renal failure. Urinary oxalate values may range from 80 to 300 mg/24 h (0.72 to 2.70 mmol/24 h).

There are three types of primary hyperoxaluria with unique enzymatic defects in the liver glyoxylate pathway.[64] In type 1, the defective enzyme is alanine–glyoxylate aminotransferase, encoded by the gene *AGXT* on chromosome 2; this accounts for approximately 80% of cases. Type 2 tends to be a milder disorder and is caused by mutations in the *GRHPR* gene on chromosome 9, which results in failure of glyoxylate reduction to glycolate; this accounts for approximately 10% of the cases. Type 3 is a result of mutations in the gene that encodes the mitochondrial 4-hydroxy-2-oxoglutarate aldolase enzyme, which catalyzes the cleavage of 4-hydroxy-2-oxoglutarate to pyruvate and glyoxylate and accounts for about half of the remaining cases.[65]

Treatment of Dietary and Enteric Hyperoxaluria Treatment of dietary oxaluria consists of dietary oxalate restriction. Patients should be given a list of foods that have high oxalate content to avoid or eat in moderation (see Box 59-4). Calcium carbonate 1 to 1.5 g may be added at each meal and snack to bind intestinal oxalate and prevent its absorption.

Specific therapy for the malabsorptive disorder, such as a gluten-free diet for patients with sprue, is the first line of treatment for enteric hyperoxaluria. More generalized therapy for steatorrhea, such as a low-fat diet, cholestyramine, and administration of medium-chain triglycerides, may reduce fat malabsorption as well

as oxalate absorption and subsequent excretion. The low-oxalate diet and mealtime calcium carbonate prescribed for patients with dietary oxaluria is also helpful for these patients. The diarrhea associated with these disorders may result in low urine volumes, hypokalemia, hypocitraturia, and hypomagnesuria. Patients should therefore be advised to increase their fluid intake and to take potassium citrate (in this case, the liquid, although unpalatable, is better absorbed than the tablets) as well as a magnesium supplement. Magnesium also serves as a urinary stone inhibitor and can be given as magnesium gluconate 0.5 to 1 g every 8 hours or as magnesium oxide 400 mg every 12 hours.

Treatment of Primary Hyperoxaluria Primary hyperoxaluria type 1 (PH1) is a severe disorder that can be cured only with liver transplantation to replace the defective hepatic enzyme. Pyridoxine (vitamin B_6 in doses ranging from 2.5 to 15 mg/kg/24 h) may reduce oxalate production in patients with PH1. Efforts should be made to render the calcium and oxalate more soluble in the urine by raising the urinary pH (to at least 6.5) and giving supplemental citrate and magnesium. Potassium citrate and magnesium supplementation can be prescribed as noted earlier. Orthophosphate is also an effective inhibitor of urinary calcium oxalate precipitation and can be safely administered in patients with a glomerular filtration rate (GFR) exceeding 50 ml/min. Because oxalate is poorly excreted in CKD and is not removed well by dialysis, renal transplantation serves not only to improve renal function, but also to improve oxalate excretion and diminish systemic oxalosis.[14,66]

Oxalobacter formigenes primarily uses oxalate for cellular metabolism.[67,68] Calcium oxalate stone formers who are colonized with *O. formigenes* have lower urine oxalate levels than those who are not colonized.[67] A small human therapeutic trial involving administration of *O. formigenes* resulted in a modest decrease in urinary oxalate in some patients.[68] Further studies with larger numbers of patients and an end point of reduction of recurrent stone formation will be necessary before this novel approach becomes accepted therapy.

Hypocitraturia

Citrate inhibits stone formation. A number of conditions reduce urinary citrate excretion, predisposing to stone formation. Excessive protein intake, hypokalemia, metabolic acidosis, exercise, hypomagnesemia, infections, androgens, starvation, and acetazolamide have all been implicated in decreased urinary citrate excretion. Therapy involves treatment of the underlying condition and potassium citrate supplementation. The potassium salt is preferred to sodium citrate because sodium promotes renal calcium excretion. Potassium citrate 15 to 25 mmol two or three times daily is required, and tablets are considered by most patients to be more palatable than the liquid preparation. In patients with renal impairment, serum potassium should be monitored carefully, and dose reduction may be needed if hyperkalemia develops.[14,69]

Distal Renal Tubular Acidosis

Patients with distal (type 1) renal tubular acidosis have impaired distal tubular excretion of hydrogen ions with a non–anion gap metabolic acidosis and alkaline urine (see Chapter 12). The acidosis causes calcium and phosphate to be released from bone with an ensuing increase in renal excretion of these ions. The acidosis also leads to an increase in citrate reabsorption by the proximal tubule. The end result is a high urinary pH, hypocitraturia (urinary citrate generally <100 mg/24 h [0.53 mmol/24 h]), and increased renal excretion of calcium and phosphate, all of which increase the propensity for calcium phosphate precipitation. Nephrocalcinosis in this setting is not uncommon because of calcium precipitating in the alkaline tubule fluid. The metabolic acidosis and hypocitraturia should be treated with a combination of sodium citrate (or bicarbonate) and potassium citrate (or bicarbonate). Often large amounts, 1 to 2 mmol/kg daily in two or three divided doses, are required to neutralize the acidosis.[1] Citrate is generally preferred to bicarbonate by patients because it does not produce carbon dioxide on contact with stomach acid with resultant gastrointestinal bloating. However, citrate is generally more expensive than bicarbonate.

Hyperuricosuria

Calcium oxalate crystals often nucleate around other crystal types such as uric acid. Hyperuricosuria contributes to nephrolithiasis in 10% to 15% of calcium stones. Patients with hyperuricosuric calcium oxalate nephrolithiasis have hyperuricosuria with normal urinary calcium and oxalate, but often a higher urinary pH (>5.5) than patients with pure uric acid stones. Therapy for hyperuricosuria consists of increased fluid intake and reduced dietary purine intake. If uric acid excretion remains elevated, allopurinol should be initiated at 100 to 300 mg daily.[1]

Uric Acid Stones

Epidemiology

The prevalence of uric acid stones depends greatly on geographic location. In the United States, uric acid stones constitute 5% to 10% of all stones formed, whereas in Mediterranean and Middle Eastern countries uric acid stones may constitute as much as 75% of stones. The stones are radiolucent and therefore poorly visible on plain radiographs. They are detectable on ultrasound and CT, and as filling defects on IVU (Fig. 59-7).

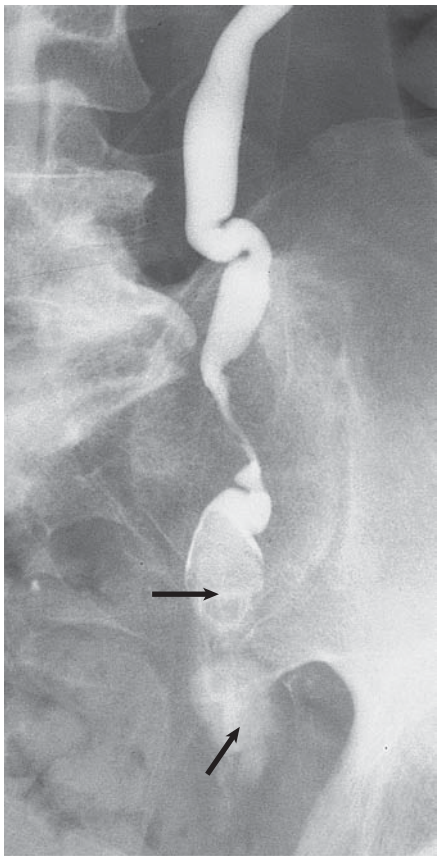

Figure 59-7 Radiolucent urate calculi. Antegrade pyelogram showing multiple radiolucent uric acid stones *(arrows)* obstructing the lower ureter.

Etiology and Pathogenesis

Causes of hyperuricosuria include excessive dietary purine or protein intake, disorders associated with cellular breakdown (tumor lysis syndrome, myeloproliferative disorders, hemolytic anemia), gout, uricosuric medications, certain inborn errors of metabolism, and possibly excessive fructose intake.

Three major factors influence uric acid stone formation: low urine pH, low urine volume, and elevated urinary uric acid levels (Box 59-5). Of the three, low urine pH is the principal metabolic disorder found in patients with uric acid nephrolithiasis. Uric acid is poorly soluble at pH below 5.5. Solubility increases with urine alkalinity such that at urine pH 6.5, urine can contain over six times the quantity of uric acid present at pH 5.3, without exceeding supersaturation. The rising incidence of obesity and insulin resistance in the United States has led to a parallel increase in uric acid lithiasis. The urinary acidosis is likely a result of impaired ammoniagenesis, which results in excessive excretion of unbuffered acid and a very low urine pH.[7,11,70,71]

Treatment

Treatment of uric acid stones involves increasing urine pH and volume as well as decreasing uric acid excretion. Alkaline urine not only can prevent uric acid stone formation, but may also result in stone dissolution. To raise urine pH, potassium citrate is recommended. While sodium bicarbonate alkalinizes the urine and enhances uric acid solubility, the added sodium increases sodium urate formation, which serves as a nidus for calcium oxalate precipitation. Potassium citrate 40 to 50 mmol/day in divided doses is given, increasing the dose as necessary to achieve a urine pH of 6.5 to 7. Patients should monitor pH with urine dipsticks at various times of the day and adjust the dosage accordingly. If urine pH remains low despite potassium citrate exceeding 100 mmol daily, or if that dose results in hyperkalemia, acetazolamide may be added. This carbonic anhydrase inhibitor produces an alkaline urine similar to that seen in renal tubular acidosis. Patients should be cautioned not to exceed urine pH 7 because this may result in calcium phosphate precipitation.

A low-purine and low–animal protein diet is also useful in raising urinary pH and decreasing uric acid excretion (see Box 59-4). If uric acid excretion remains high despite dietary intervention, as in patients with disorders of cellular catabolism, allopurinol should be prescribed, 100 mg increasing to 300 mg daily as needed to keep urinary uric acid excretion below 750 mg/24 h (4.5 mmol/24 h). See Box 59-4 for high-purine foods to avoid.[72]

Factors Associated with Uric Acid Stone Formation

Low Urine pH (≤5.5)
- High–animal protein diet
- Diarrhea
- Insulin resistance (high body mass index, metabolic syndrome, type 2 diabetes)

Low Urine Volume
- Inadequate fluid intake
- Excessive extrarenal fluid losses
  - Diarrhea
  - Insensible losses (e.g., perspiration)

Hyperuricosuria
- Excessive dietary purine intake
- Hyperuricemia
  - Gout
  - Intracellular-to-extracellular uric acid shift
    - Myeloproliferative disorders
    - Tumor lysis syndrome
- Inborn errors of metabolism
  - Lesch-Nyhan syndrome
  - Glucose-6-phosphatase deficiency

Medications
- See Box 59-3.

Box 59-5 Factors associated with uric acid stone formation.

Struvite Stones

Struvite stones are also referred to as "infection stones" or "triple phosphate stones." The stones grow rapidly to a large size, can reduce renal function in the affected kidney, and are difficult to eradicate. Because of the significant morbidity in patients with struvite stones, they have also been termed "stone cancer." Most staghorn calculi, large stones that penetrate more than one renal calyx, are composed of struvite. Their formation requires the presence of urease-producing bacteria in the urine (Box 59-6).[73]

Etiology and Pathogenesis

Struvite stones are composed of magnesium ammonium phosphate and calcium carbonate apatite. They form when urease production by certain urinary bacteria breaks down urea to ammonium (NH_4^+) and a carboxyl (OH^-) group. The urine becomes quite alkaline; urinary phosphate becomes insoluble and forms a solid phase with magnesium, calcium, and the ammonium. Women are more prone to struvite nephrolithiasis than men because of an increased propensity for UTI. Others predisposed to developing struvite stones through infections or urinary stasis include patients with indwelling urinary catheters, neurogenic bladders, genitourinary tract anomalies, and spinal cord lesions. An alkaline urine (pH 7), urine culture of urease-producing bacteria, and large stones suggest the diagnosis of struvite nephrolithiasis.[73]

A number of gram-negative and gram-positive bacteria have been implicated in urease production and consequent struvite formation, with the most common being *Proteus* species (see Box 59-6). *Escherichia coli,* which is frequently present in urine cultures, is not a urease producer. If there is a strong suspicion for struvite stones but no organism is detected in the urine, a specific culture request for

Factors Associated with Struvite Stone Formation

- Urease-producing bacteria
  - *Proteus*
  - *Haemophilus*
  - *Yersinia species*
  - *Staphylococcus epidermidis*
  - *Pseudomonas*
  - *Klebsiella*
  - *Serratia*
  - *Citrobacter*
  - *Ureaplasma*
- Elevated urinary pH

Box 59-6 Factors associated with struvite stone formation. *Escherichia coli* is not a urease producer.

Ureaplasma urealyticum should be considered, because it does not grow on routine culture media.

Treatment

Struvite stones require aggressive medical and surgical management. Antibiotic therapy is important to reduce further stone growth and for stone prevention. Bacteria will remain in the stone interstices, however, and stones will continue to grow unless chronic antibiotic suppression is maintained or the calculi are completely eradicated. Given the need for complete stone removal to effect a cure, early urologic intervention is advised. Stones smaller than 2 cm may respond well to extracorporeal shock-wave lithotripsy (ESWL); however, larger stones will likely require percutaneous nephrolithotomy (PCNL), often in combination with ESWL (see Chapter 61). Any stone fragments retrieved should be cultured, and culture-specific antibiotics continued. Once the urine is sterile, usually approximately 2 weeks after initiation of therapy, the dose is halved. Monthly urine cultures should be performed, and if they remain sterile for 3 consecutive months, antibiotics may be discontinued, although surveillance urine cultures should continue monthly for a full year.[74]

Adjunct medical therapies include urease inhibitors and chemolysis. The most commonly used urease inhibitor is acetohydroxamic acid. By inhibiting urease, these agents retard stone growth and prevent new stone formation. Unfortunately, they have numerous side effects that limit their use, although adverse effects resolve on discontinuation of the drug. In addition, they require adequate renal clearance to be effective and therefore are not useful in patients with CKD (estimated GFR <60 ml/min).[73] Chemolysis involves irrigation of the kidney via a nephrostomy tube or the ureter with a solution designed to dissolve the stones. The most common solution is 10% hemiacidrin, which contains carbonic acid, citric acid, D-gluconic acid, and magnesium at pH 3.9. Lavage chemolysis is controversial because it has previously been associated with a high mortality rate, but it is now considered safe with appropriate monitoring for UTI, assessment of obstruction to flow by intrapelvic pressure measurement, and serum magnesium levels. Although not a treatment of choice for large stones, it may be useful when surgical techniques have been effective but have left residual stone fragments.

Cystine Stones

Cystinuria is an autosomal disorder in which there is a tubular defect in dibasic amino acid transport, resulting in increased cystine, ornithine, lysine, and arginine excretion (see Chapter 50). The pattern of inheritance may be autosomal recessive or autosomal dominant with incomplete penetrance. The stone disease is usually clinically manifest by the second and third decades of life. Because of the high sulfur content of the cystine molecule, the stones are apparent on plain radiographs (see Fig. 59-4, *A*) and will often present as staghorn calculi or multiple bilateral stones.

Cystine is poorly soluble, only approximately 300 mg/l (1.25 mmol/l) at a neutral pH. Normal cystine excretion of approximately 30 to 50 mg (0.12 to 0.21 mmol) per day is readily soluble in the usual daily urine output of approximately 1 l. However, homozygote cystinurics often excrete 250 to 1000 mg (1.04 to 4.20 mmol) of cystine per day, with heterozygotes excreting an intermediate amount. Treatment is directed at decreasing the urinary cystine concentration below the limits of solubility. Because the dietary precursor of cystine, methionine, is an essential amino acid, it is impractical to significantly reduce intake. Increasing urine volume so that cystine remains below the limits of solubility sometimes requires 4 l of urine per day. A low-sodium diet has been reported to reduce urine cystine excretion, although the mechanism by which this occurs is not clear.[75] Increasing urine pH above 7.5 will increase cystine solubility, but this is difficult to achieve on a long-term basis. D-Penicillamine (starting dose 250 mg daily, maximum dose 2 g daily) or tiopronin (800 mg/day in three divided doses) will both bind cystine and reduce urinary supersaturation; however, side effects may limit their use. The angiotensin-converting enzyme inhibitor captopril may be effective by forming a thiol-cysteine disulfide bond that is more soluble than cystine.[76]

Stones Associated with Melamine Exposure

By late 2008, more than 50,000 Chinese children younger than 3 years had been reported to have kidney stones associated with contaminated milk products. Powdered milk and infant formulas were noted to contain melamine, a nitrogenous substance synthesized from urea that increases the apparent protein content of the product.[12] Risk factors for nephrolithiasis after melamine exposure may include volume depletion, small body size, uricosuria, and low urine pH.

Although affected children often were presented with dysuria and hematuria, many children who were subsequently screened were asymptomatic despite kidney stones identified on ultrasound.[12] On urinalysis some children exhibited fan-shaped crystals. The kidney stones formed were radiolucent and fragile. Many were composed of a combination of uric acid with melamine and were amenable to dissolution by hydration and alkalinization. In animal studies of melamine exposure, the distal tubular crystal deposition may lead to tubulointerstitial inflammation and fibrosis. Whether a similar process may occur in humans is unknown.[12]

NEPHROCALCINOSIS

Nephrocalcinosis refers to augmented calcium content within the kidney.[15,77] This disorder may be symmetric or, in anatomic disorders such as medullary sponge kidney, may involve only a single kidney.

Etiology and Pathogenesis

Medullary Nephrocalcinosis

Medullary nephrocalcinosis in which the calcification tends to occur in the area of the renal pyramids accounts for the majority of cases of nephrocalcinosis. It is typically associated with elevated urinary calcium, phosphate, and oxalate, or it can occur with alkaline urine (Box 59-7). Any disorder that can lead to hypercalcemia and/or hypercalciuria may be implicated. Instead of stone formation, smaller parenchymal calcifications deposit in the medulla, which are usually bilateral and relatively symmetric (Fig. 59-8). Some metabolic disorders, particularly oxalosis caused by primary hyperoxaluria, can result in both medullary and cortical nephrocalcinosis[77] (Fig. 59-9).

In adults, the most common causes of medullary nephrocalcinosis are primary hyperparathyroidism, distal renal tubular acidosis, and medullary sponge kidney (see Chapter 47), as well as medications including acetazolamide, amphotericin, and triamterene (see Box 59-3).

Whereas a similar range of disorders can be seen in children, the most common associations are with furosemide therapy and the hereditary disorders associated with hypercalciuria.[15,22] Furosemide, when used in premature neonates and older infants with congestive heart failure, can result in nephrocalcinosis with or without hypercalciuria. The lesions often resolve with discontinuation of therapy. A normal calcium-creatinine ratio at the time of diagnosis of nephrocalcinosis (approximately 0.40 [mg/mg] in premature infants) appears to be a good predictor of resolution.

Causes of Nephrocalcinosis

Medullary

Disturbed Calcium Metabolism

- Hyperparathyroidism
- Sarcoidosis
- Milk-alkali syndrome
- Rapidly progressive osteoporosis
- Idiopathic hypercalciuria

Other Tubular Disease

- Distal (type 1) renal tubular acidosis
- Oxalosis*
- Dent disease (X-linked hypercalciuric nephrolithiasis)
- X-linked hypophosphatemic rickets
- Bartter syndrome
- Hypomagnesemia-hypercalciuria syndrome

Anatomic Disease

- Medullary sponge kidney
- Papillary necrosis

Medications

- Acetazolamide
- Amphotericin
- Triamterene

Cortical

- Cortical necrosis
- Transplant rejection
- Chronic glomerulonephritis
- Trauma
- Tuberculosis
- Oxalosis*

Box 59-7 Causes of nephrocalcinosis. *Oxalosis typically causes both cortical and medullary nephrocalcinosis.

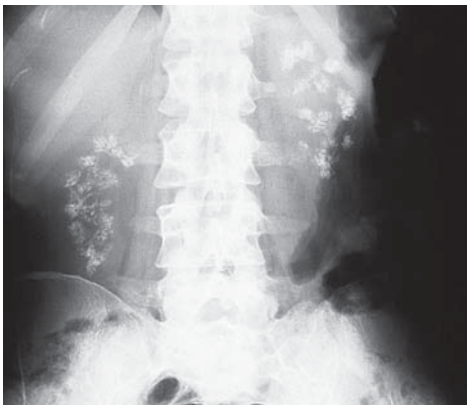

Figure 59-8 Medullary nephrocalcinosis. Plain radiograph showing bilateral metastatic medullary nephrocalcinosis in a patient with distal renal tubular acidosis.

Figure 59-9 Nephrocalcinosis. Dense cortical and medullary calcification in the shrunken kidneys of a patient with oxalosis and longstanding renal failure.

There are many uncommon hereditary disorders associated with nephrocalcinosis including X-linked hypercalciuric nephrolithiasis, X-linked hypophosphatemic rickets, hypomagnesemia-hypercalciuria syndrome, and Bartter syndrome.

X-linked hypercalciuric nephrolithiasis is also termed Dent disease in the United Kingdom, low-molecular-weight proteinuria with hypercalciuria and nephrocalcinosis in Japan, and X-linked recessive hypophosphatemic rickets in Italy.[78] A number of mutations affecting the CLCN5 gene on the X chromosome have been identified that lead to inactivation of CLC-5 voltage-gated chloride channels. The result is a clinical syndrome typically affecting young boys and usually including hypercalciuria, nephrocalcinosis, nephrolithiasis, and hematuria, as well as low-molecular-weight proteinuria, glycosuria, aminoaciduria, hypophosphatemia, renal failure, and rickets.[78]

In X-linked hypophosphatemic rickets, the recommended treatment, with phosphate repletion and vitamin D, may itself result in hypercalcemia, hypercalciuria, and nephrocalcinosis. Thus only enough phosphate and vitamin D should be prescribed to allow bone growth and prevent symptomatic hypophosphatemia.

Another cause of medullary nephrocalcinosis in children is primary hypomagnesemia-hypercalciuria syndrome.[14,15,79] This rare autosomal recessive condition results from defective production of the cellular tight-junction protein paracellin-1. This claudin family protein is necessary for adequate calcium and magnesium reabsorption in the thick ascending limb (TAL) of the loop of Henle. Children typically present with symptoms of UTI (often with nephrolithiasis), polyuria, tetanic seizures (caused by hypomagnesemia), and muscle cramps and weakness. Hypercalciuria, hypermagnesuria, and a urinary concentrating defect also occur. Patients often have renal impairment and may require renal replacement therapy by the third decade of life. Sensorineural hearing disorders and ocular impairment may accompany the renal manifestations in a subset of patients. These inherited tubular disorders are discussed further in Chapter 50.

Cortical Nephrocalcinosis

Cortical nephrocalcinosis is usually the result of dystrophic calcification, which follows parenchymal tissue destruction rather than the precipitation of excessive urinary constituents. It is secondary to infarction, neoplasm, and infection. It is typically asymmetric and is usually localized to the renal cortex (Fig. 59-10). Causes of cortical nephrocalcinosis include transplant rejection, cortical necrosis, tuberculosis, ethylene glycol toxicity, and chronic glomerulonephritis.

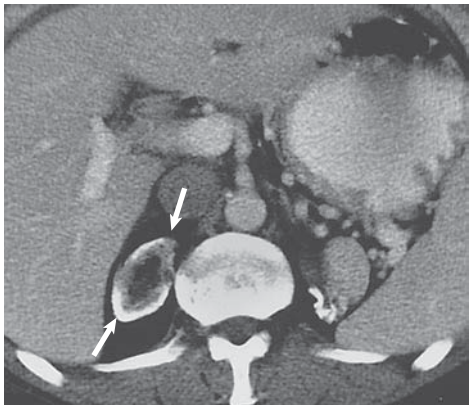

Figure 59-10 Cortical nephrocalcinosis. Noncontrast computed tomography (CT) showing cortical nephrocalcinosis *(arrows)* in the right kidney after cortical necrosis.

Clinical Manifestations

Patients who do not have nephrolithiasis associated with nephrocalcinosis are often asymptomatic. Ultrasound and CT scanning are sensitive diagnostic tests for both cortical and medullary nephrocalcinosis, demonstrating the parenchymal calcifications before they can be visualized on plain radiographs. The extent of calcification correlates poorly with renal function.

Treatment

Similarly to nephrolithiasis, treatment of nephrocalcinosis relies on therapy for the underlying disease, as well as measures to reduce hypercalcemia, hyperphosphatemia, and oxalosis, if possible. The goal of treatment is usually to prevent further deposits, because therapy cannot eradicate existing calcium deposits.

CHAPTER 60

Urinary Tract Obstruction

Jeremy Hughes

DEFINITIONS

Obstructive uropathy refers to the structural or functional changes in the urinary tract that impede normal urine flow. *Obstructive nephropathy* refers to the renal disease caused by impaired flow of urine or tubular fluid. *Hydronephrosis* refers to dilation of the urinary tract. *Hydronephrosis* is not synonymous with *obstructive uropathy* because the former can occur without functional obstruction to the urinary tract and can be absent in established obstruction. Obstructive uropathy and nephropathy frequently coexist, and their management requires close collaboration between nephrologists and urologists. Some surgical aspects of obstruction to the urinary tract are discussed in Chapter 61.

Obstructive uropathy is classified according to the site, degree, and duration of the obstruction. Acute or chronic obstruction can occur anywhere in the urinary tract and includes intrarenal causes (casts, crystals) and extrarenal causes. Acute or chronic obstruction is further subdivided into upper urinary tract obstruction (usually unilateral obstruction occurring above the vesicoureteral junction) and lower urinary tract obstruction (usually bilateral obstruction located below the vesicoureteral junction). Complete obstruction of the urinary tract is termed *high grade,* whereas partial or incomplete obstruction is termed *low grade.*

Unilateral obstruction in a patient with two normal kidneys will not result in significant renal impairment because the contralateral kidney compensates. However, bilateral obstruction or the obstruction of a single functioning kidney will result in renal failure. In acute urinary tract obstruction, changes are mainly functional, whereas structural damage to the kidney results from more chronic obstruction. The kidney with acute functional changes may recover after the effective release of the obstruction, but structural changes may be permanent and lead to chronic renal impairment. Urinary tract obstruction remains a major cause of renal impairment worldwide in children and adults.

ETIOLOGY AND PATHOGENESIS

The causes of obstructive uropathy affecting the upper and lower urinary tracts are summarized in Table 60-1 and Box 60-1.

Congenital Urinary Tract Obstruction

Congenital urinary tract obstruction occurs most frequently in males, most commonly as a result of either posterior urethral valves or pelviureteral junction (PUJ) obstruction. If obstruction occurs early during development, the kidney fails to develop and becomes dysplastic. If the obstruction is bilateral, there is a high mortality rate as a result of severe renal failure. If the obstruction occurs later in gestation and is low grade or unilateral, hydronephrosis and nephron loss will still occur, but renal function may be sufficient to allow survival, and such patients may not present until later in childhood. Pelviureteral junction obstruction, if it is mild, may not present until adulthood and in some patients may be an incidental finding (Fig. 60-1). However, with increased use and improved sensitivity of antenatal scanning, congenital abnormalities of the urinary tract are now frequently identified early, allowing prompt postnatal (and in some cases antenatal) intervention to relieve the obstruction and hence to preserve renal function. Congenital causes of obstruction are discussed further in Chapter 52.

Acquired Urinary Tract Obstruction

Acquired urinary tract obstruction may affect either the upper or lower urinary tract and can result from either intrinsic or extrinsic causes. Intrinsic causes of obstruction may be intraluminal or intramural.

Intrinsic Obstruction

Intraluminal Obstruction Intraluminal obstruction may result from tubular intrarenal obstruction, such as the deposition of uric acid crystals in the tubular lumen after treatment for hematologic malignancies (tumor lysis syndrome). It may also occur with the precipitation of Bence Jones protein in myeloma and with the precipitation or crystal formation of a number of drugs, including sulfonamides, acyclovir, methotrexate, and indinavir. Uncommonly, patients with an underlying glomerulonephritis such as IgA nephropathy may develop severe glomerular hematuria with tubular obstruction from erythrocytes and acute renal dysfunction that typically resolves with time.

Extrarenal intraluminal obstruction in young adults is most commonly caused by renal calculi (see Chapter 59). Calcium oxalate stones are the most common and typically cause intermittent acute unilateral urinary tract obstruction but rarely result in marked chronic renal impairment. Less common causes of urinary lithiasis, such as struvite stones, uric acid stones, and cystinuria are often bilateral and hence more likely to cause long-term renal impairment. Renal calculi lodge more commonly in the calyx, PUJ, or vesicoureteral junction and at the level of the pelvic brim. Surgical management of stones is discussed in Chapter 61. Intraluminal obstruction can also result from a sloughed papilla after papillary necrosis, or blood clots after macroscopic hematuria (clot colic). Papillary necrosis may occur in diabetes mellitus, sickle cell trait or disease, analgesic nephropathy, renal amyloidosis, and acute pyelonephritis. Clot colic can occur with bleeding from renal tumors or arteriovenous malformations, after renal trauma, and in patients with polycystic kidney disease.

Intramural Obstruction Intramural obstruction can result from either functional or anatomic changes. Functional disorders include adynamic ureteral segments (usually at the junction of the ureter with the pelvis or bladder) and neurologic disorders. The latter may result in a contracted (hypertonic) bladder or a flaccid (atonic)

Causes of Upper Urinary Tract Obstruction

Intrinsic Causes	Extrinsic Causes
Intraluminal Intratubular deposition of crystals (uric acid, drugs) *Stones* Papillary tissue Blood clots Fungal ball	**Reproductive system** Cervix: *carcinoma* Uterus: *pregnancy, tumors,* prolapse, endometriosis, pelvic inflammatory disease Ovary: tumor, cysts Prostate: *carcinoma*
Intramural Functional: pelviureteral or vesicoureteral junction dysfunction Anatomic: tumors (benign or malignant) Infections, granulomas, strictures	**Vascular system** Aneurysms: aorta, iliac vessels Aberrant arteries: pelviureteral junction Venous: ovarian veins, retrocaval ureter **Gastrointestinal tract** Crohn disease Pancreatitis Appendicitis Diverticulitis Tumors **Retroperitoneal space** Lymph nodes Fibrosis: idiopathic, drugs, inflammatory or IgG4-related disease Tumors: primary or metastatic Hematomas Radiation therapy Surgical disruption or ureteral ligation

Table 60-1 Causes of upper urinary tract obstruction. The most common causes are in italics.

Causes of Lower Urinary Tract Obstruction

Urethral anatomic causes

Urethral strictures: trauma, *postinstrumentation*, infections such as gonococcal urethritis, nongonococcal urethritis, tuberculosis

Posterior urethral valves

Stones

Blood clots

Periurethral abscess

Phimosis

Paraphimosis

Meatal stenosis

Urethral functional causes

Anticholinergic drugs, antidepressants, levodopa

Prostate

Benign prostatic hypertrophy

Prostatic carcinoma

Bladder anatomic causes

Bladder cancer

Schistosomiasis (*Schistosoma haematobium* infection)

Bladder calculi

Bladder trauma, pelvic fracture

Bladder functional causes

Neurogenic bladder: spinal cord defects or trauma, diabetes, multiple sclerosis, Parkinson disease, cerebrovascular accidents

Box 60-1 Causes of lower urinary tract obstruction. The most common causes are in italics.

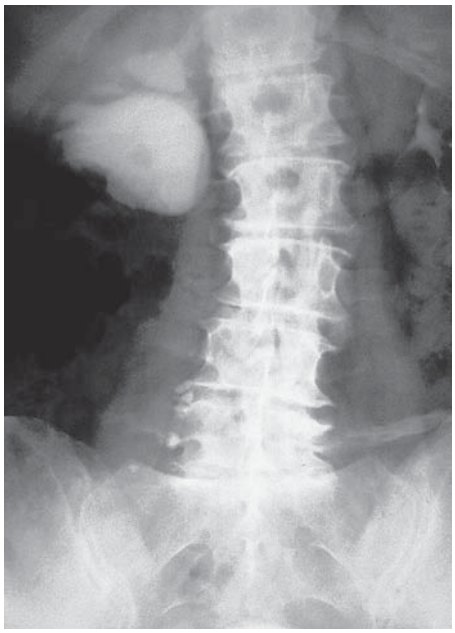

Figure 60-1 Intravenous urogram demonstrating pelviureteral junction obstruction. The study was performed in a previously asymptomatic adult to investigate nonspecific right loin pain. There is unilateral (right side) dilation of the pelvicalyceal system. The ureter has not been visualized.

bladder, depending on whether the lesion affects upper or lower motor neurons, and may lead to impaired bladder emptying with vesicoureteral reflux. Bladder dysfunction is very common in patients with multiple sclerosis and after spinal cord injury and is also seen in diabetes mellitus, in Parkinson disease, and after cerebrovascular accidents. Some drugs (anticholinergics, levodopa) can alter neuromuscular activity of the bladder and result in functional obstruction, especially if there is preexisting bladder outflow obstruction (e.g., prostatic hypertrophy).

Anatomic causes of intramural obstruction of the upper urinary tract include transitional cell carcinoma of the renal pelvis and ureter and ureteral strictures secondary to radiotherapy or retroperitoneal surgery. Rarely, obstruction may result from ureteral valve malfunction, polyps, or strictures after therapy for tuberculosis. Intramural obstruction of the lower urinary tract can result from urethral strictures, which are usually secondary to chronic instrumentation or previous urethritis, or malignant and benign tumors of the bladder. Infection with *Schistosoma haematobium* when the ova lodge in the distal ureter and bladder is a common cause of obstructive uropathy worldwide; up to 50% of chronically infected patients develop ureteral strictures and fibrosis, with contraction of the bladder.

Extrinsic Obstruction

The most common cause of extrinsic compression in women is pressure from a gravid uterus on the pelvic rim; the right ureter is more commonly affected. It is usually asymptomatic, and the changes resolve rapidly after delivery. Rarely, bilateral obstruction and acute kidney injury (AKI) may occur. Ureteral dilation may frequently be seen in pregnancy as a result of hormonal effects (especially progesterone) on smooth muscle, but this does not indicate functional obstruction (see Chapter 43, Fig. 43-1). Carcinoma of the cervix may also cause extrinsic obstruction secondary to direct extension of the tumor to involve the urinary tract. Other pelvic pathologic processes that can cause ureteral compression include benign and malignant uterine and ovarian masses, abscesses, endometriosis, and pelvic inflammatory disease. Compression of the ureters outside the bladder may also occur with uterine prolapse. Rarely, inadvertent

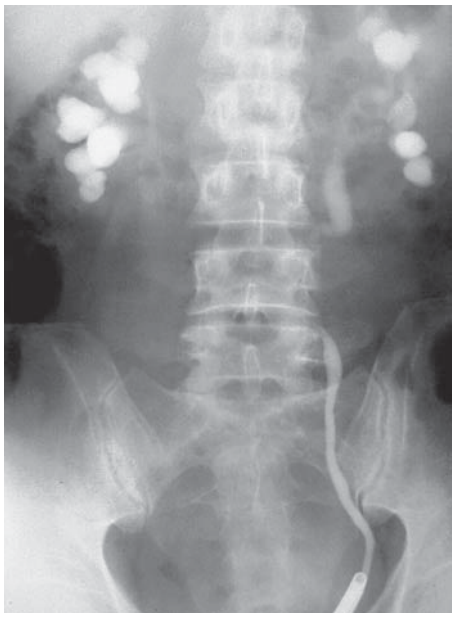

Figure 60-2 Retrograde pyelogram showing idiopathic retroperitoneal fibrosis. Dilation of the pelvicalyceal system is clearly demonstrated. The ureters, however, are not dilated, and the left ureter can be seen displaced medially as a result of being encased in thick fibrous tissue.

ureteric ligation may occur during surgical procedures, particularly those related to obstetrics and gynecology. Unilateral ligation may go undetected, but AKI will result from bilateral ligation.

In men, the most common cause of extrinsic obstruction of the lower urinary tract is benign prostatic hypertrophy. Carcinoma of the prostate can also result in obstruction either from direct tumor extension to the bladder outlet or ureters or from metastatic spread.

Retroperitoneal pathology may also result in extrinsic obstruction of the ureters, as can metastases or extension of tumors from the cervix, prostate, bladder, colon, ovary, and uterus. Primary tumors of the retroperitoneum, such as lymphomas and sarcomas, can commonly cause obstruction. Obstruction can also result from inflammatory conditions affecting the retroperitoneum, such as Crohn disease and large bowel diverticulitis. In Crohn disease the obstruction is usually right sided as a result of ileocecal disease. Less common pathologic processes include retroperitoneal fibrosis, in which thick fibrous tissue extends out from the aorta to encase the ureters and draw them medially (Fig. 60-2). Retroperitoneal fibrosis may be idiopathic but can result from inflammatory aortic aneurysms, certain drugs (e.g., β-blockers, bromocriptine, and methysergide), previous irradiation, trauma or surgery, and granulomatous disease (e.g., tuberculosis, sarcoidosis). Retroperitoneal fibrosis is also associated with IgG4-related disease, which typically presents with autoimmune pancreatitis, and elevated serum IgG4 levels suggests this diagnosis.[1] IgG4-related disease is also suggested in retroperitoneal biopsy material by an IgG4 positive plasma cell infiltrate, fibrosis with a whorled cartwheel pattern, and an obliterative venous phlebitis.[2] Ureteral compression may also be a result of vascular abnormalities, including aneurysmal dilation of the aorta or iliac vessels, aberrant vessels, and anatomic variations in the location of the ureter (retrocaval ureter).

PATHOPHYSIOLOGY

Obstruction of the renal tract causes profound functional and structural changes of the kidney. Initially, changes are predominantly functional and potentially reversible, but with time, chronic and irreversible structural changes occur. Our understanding of the consequences of urinary tract obstruction stems mainly from the study of animal models.[3] Although many studies have focused on the effects of complete ureteral obstruction in rodents, investigators have also examined models of chronic complete, partial, or reversible obstruction in adult and neonatal animals.[3] Available experimental data show little species-to-species variation in the response to acute obstruction, suggesting that similar changes are likely to occur in humans. The complex effects of urinary tract obstruction on the kidney affect both glomerular hemodynamics and tubular function.

Changes in Glomerular Function

Glomerular filtration rate (GFR) declines progressively after the onset of complete ureteral obstruction.[4] Glomerular filtration is determined by the mean hydraulic pressure gradient between the glomerular capillary lumen and Bowman space, the renal plasma flow, the ultrafiltration coefficient of the glomerular capillary wall, and the mean oncotic pressure difference across the glomerular wall. Obstruction can affect all of these, and the effects vary with the duration of the obstruction, the hydration state, and presence or absence of a contralateral functioning kidney.

After complete ureteral obstruction, there is an initial rise in proximal tubular pressure. At the same time, afferent arteriolar dilation occurs as a result of the generation of vasodilatory prostaglandins. Glomerular capillary hydraulic pressure increases, but this does not offset the rise in tubular pressure, and there is a net decrease in the hydraulic pressure gradient across glomerular capillaries, resulting in an 80% decline in GFR.[4]

About 2 to 5 hours after obstruction, renal blood flow begins to decline, whereas intratubular pressure continues to increase. Within 5 hours, proximal tubular pressure begins to decline toward control values. From this time, the main determinant of the decrease in GFR is the fall in intraglomerular capillary pressure as a result of an increase in resistance of afferent arterioles. This results in a progressive fall in renal plasma flow, which reaches 30% to 50% of control values by 24 hours. Preferential constriction of the preglomerular blood vessels lowers both plasma flow and glomerular capillary pressure, resulting in a greater decrement in GFR than in plasma flow and a fall in filtration fraction. A falling filtration fraction also results from diversion of blood to nonfiltering areas of the kidney or a reduction in the ultrafiltration coefficient.[4] The relative changes in ureteral pressure, renal plasma flow, and GFR are summarized in Figure 60-3.

The intrarenal vasoconstriction results from the generation of angiotensin II and thromboxane A_2, the release of vasopressin (antidiuretic hormone), and decreased nitric oxide production. Intrarenal angiotensin II generation occurs secondary to an increase in renin release either through reduced delivery of sodium and chloride to the distal nephron (macula densa mechanism) or through a reduction in transmural pressure at the baroreceptor as a consequence of the prostaglandin-dependent dilation of the afferent arteriole. Generation of thromboxane A_2 occurs in both glomeruli and infiltrating interstitial cells. Angiotensin II and thromboxane A_2 may also reduce the ultrafiltration coefficient. The central role of these two vasoconstrictors has been demonstrated by studies in rats, in which pretreatment with angiotensin-converting enzyme inhibitors and thromboxane synthase inhibitors virtually normalized renal function after the relief of short-term ureteral obstruction.[5]

An interstitial leukocyte infiltrate, predominantly macrophages, develops in response to chemoattractants such as monocyte chemoattractant protein 1 and osteopontin expressed by tubular cells.

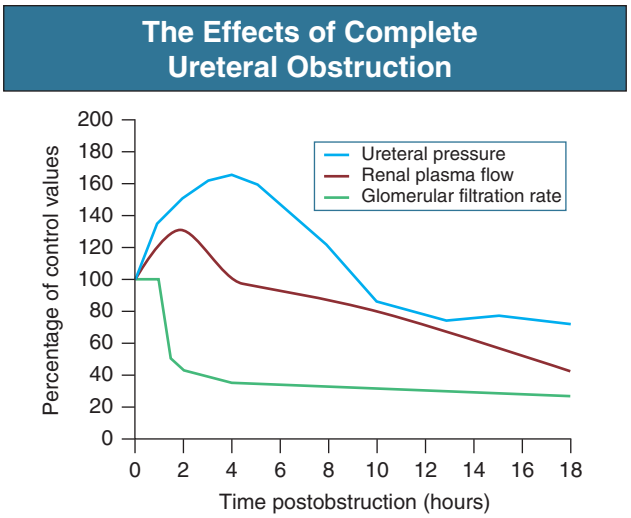

Figure 60-3 The effects of complete ureteral obstruction. The relative changes in ureteral pressure, renal plasma flow, and glomerular filtration rate are shown using data from experimental studies of unilateral ureteral obstruction in rats.

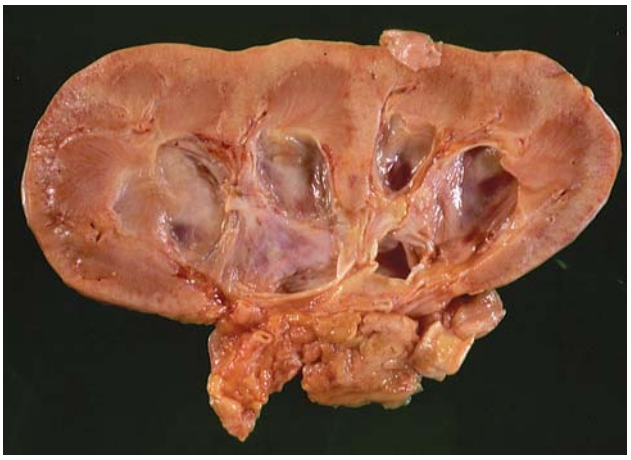

Figure 60-4 Autopsy specimen of a kidney showing the early effects of ureteral obstruction. The kidney is enlarged and edematous with pelvicalyceal dilation. There is good preservation of the renal parenchyma.

This infiltrate plays a key role in the acute functional changes after ureteral obstruction[6] and the pathogenesis of the late structural changes that occur after obstruction as macrophage depletion limits experimental interstitial fibrosis.[7]

The extent to which glomerular function recovers after the release of ureteral obstruction depends on the duration of the obstruction. Whole kidney GFR may return to normal after short-term obstruction (days), whereas recovery may be incomplete after prolonged obstruction. Evidence from studies in rats suggests that even with shorter periods of obstruction (72 hours), there may be a permanent loss of nephrons, and whole kidney GFR returns to normal only at the expense of hyperfiltration (increase in single nephron GFR) in the remaining functional nephrons.[8]

Changes in Tubular Function

Abnormalities in tubular function are common in urinary tract obstruction and manifest as altered renal handling of electrolytes and changes in the regulation of water excretion.[9] The degree and nature of the tubular defects after obstruction depend in part on whether the obstruction is bilateral or unilateral. These differences could result from the dissimilar hemodynamic responses, different intrinsic changes within the nephron, differences in extrinsic factors (e.g., volume expansion and accumulation of natriuretic substances in bilateral obstruction) between the two states, or a combination of all three.

After ureteral obstruction, the ability to concentrate the urine is markedly impaired, with maximum values of 350 to 400 mOsm/kg reported in the rat. Causative factors include a loss of medullary tonicity, an overall decrease in GFR in deep nephrons, and a reduced expression of sodium transporters.[10] Also, the collecting duct is unresponsive to vasopressin because of a reduction in the expression of renal aquaporins that results from both cyclooxygenase-2 activity[11] and angiotensin II.[12]

Rats exhibit reduced expression of multiple acid-base transporters after ureteral obstruction,[13] and patients with urinary tract obstruction often exhibit urinary acidification defects. These defects may be detected only by exogenous acid loading, but hyperchloremic acidosis caused by impaired distal acid secretion, hyporeninemic hypoaldosteronism (type IV renal tubular acidosis), and a combination of these findings have been described. This acidifying defect results from a marked increase in bicarbonate excretion or from a distal acidification defect, possibly as a result of abnormalities of the H^+-ATPase activity of intercalated cells of the collecting duct after ureteral obstruction.

Obstruction alters renal potassium handling. In the presence of a normal functioning contralateral kidney, potassium excretion is reduced after relief of obstruction, either in proportion to or perhaps even exceeding the fall in GFR (i.e., fractional excretion of potassium is unaltered or slightly reduced). There is a defect in the distal potassium secretory mechanism after unilateral obstruction that may be secondary to reduced responsiveness of that nephron segment to aldosterone. By contrast, after release of bilateral ureteral obstruction, there is a marked increase in both net and fractional potassium excretion. The major mechanism by which potassium losses occur in this setting is an increased delivery of sodium to the distal tubule, resulting in an accelerated sodium-potassium exchange.

Recovery of tubular function after release of obstruction is slow and may remain abnormal even after whole-kidney GFR has returned to normal. In rats, acidification and potassium-handling abnormalities persist for at least 14 days and urinary concentrating ability is abnormal for up to 60 days after the release of 24 hours of unilateral ureteral obstruction. These observations are consistent with persistent alterations in distal tubular and collecting duct function or a loss in functioning juxtaglomerular nephrons after the release of the obstruction.

Histopathologic Changes

The morphologic alterations in renal architecture are similar irrespective of the cause of the obstruction. Initially, renal enlargement and edema occur with pelvicalyceal dilation (Fig. 60-4). Tubular dilation that predominantly affects the collecting duct and distal tubular segments develops microscopically, although cellular flattening and atrophy of proximal tubular cells can also occur. Glomerular structures are usually preserved initially, although Bowman space may be dilated and some periglomerular fibrosis may ultimately develop.

Inadequately treated obstruction eventually causes irreversible structural changes to the renal tract. The renal pelvis becomes widely dilated, with the renal papillae either flattened or hollowed out. The cortex and medulla become grossly thinned, such that the kidney

becomes a thin rim of renal tissue surrounding a large saccular pelvis (Fig. 60-5). Histologic examination demonstrates tubulointerstitial fibrosis and obliteration of nephrons. Tubular proliferation and apoptosis, interstitial myofibroblast accumulation, increased extracellular matrix deposition, and tubular atrophy occur. Ischemia as a result of the decreased renal blood flow contributes to the parenchymal damage after obstruction. In both genetic and interventional studies, an important pathologic role for angiotensin II and transforming growth factor β (TGF-β) has been established.[14,15]

Figure 60-5 Chronic ureteral obstruction. Surgical specimen of a kidney showing gross dilation of the pelvicalyceal system and the reduction of the renal cortex to a thin fibrotic rim of tissue. There would have been no prospect for any significant functional recovery in this kidney after the relief of the obstruction.

Infiltrating macrophages play a pivotal role in the chronic tissue injury and fibrosis that result from prolonged ureteral obstruction (Fig. 60-6).[7,16] Interstitial macrophages release profibrogenic factors such as TGF-β and galectin-3 that promote progressive fibrosis. Local angiotensin II generation may also stimulate tubular cell production of TGF-β. Treatments shown to ameliorate chronic interstitial damage in experimental obstructive uropathy include angiotensin receptor blockers, pentoxifylline, simvastatin, and growth factors (such as bone morphogenetic protein 7, hepatocyte growth factor, and epidermal growth factor); beneficial effects include a reduction in tubulointerstitial inflammation and fibrosis and tubular cell apoptosis.[3] However, it is pertinent that differences have been noted in the responses of adult and neonatal rodents to experimental therapeutic interventions and it is unclear whether such differences might occur in humans.

EPIDEMIOLOGY

Obstructive uropathy is a common entity and can occur at all ages. The prevalence of hydronephrosis at autopsy is 3.5% to 3.8%, with about equal distribution between males and females, although this underestimates the true incidence because these figures exclude transient obstruction. The frequency and cause of obstruction vary

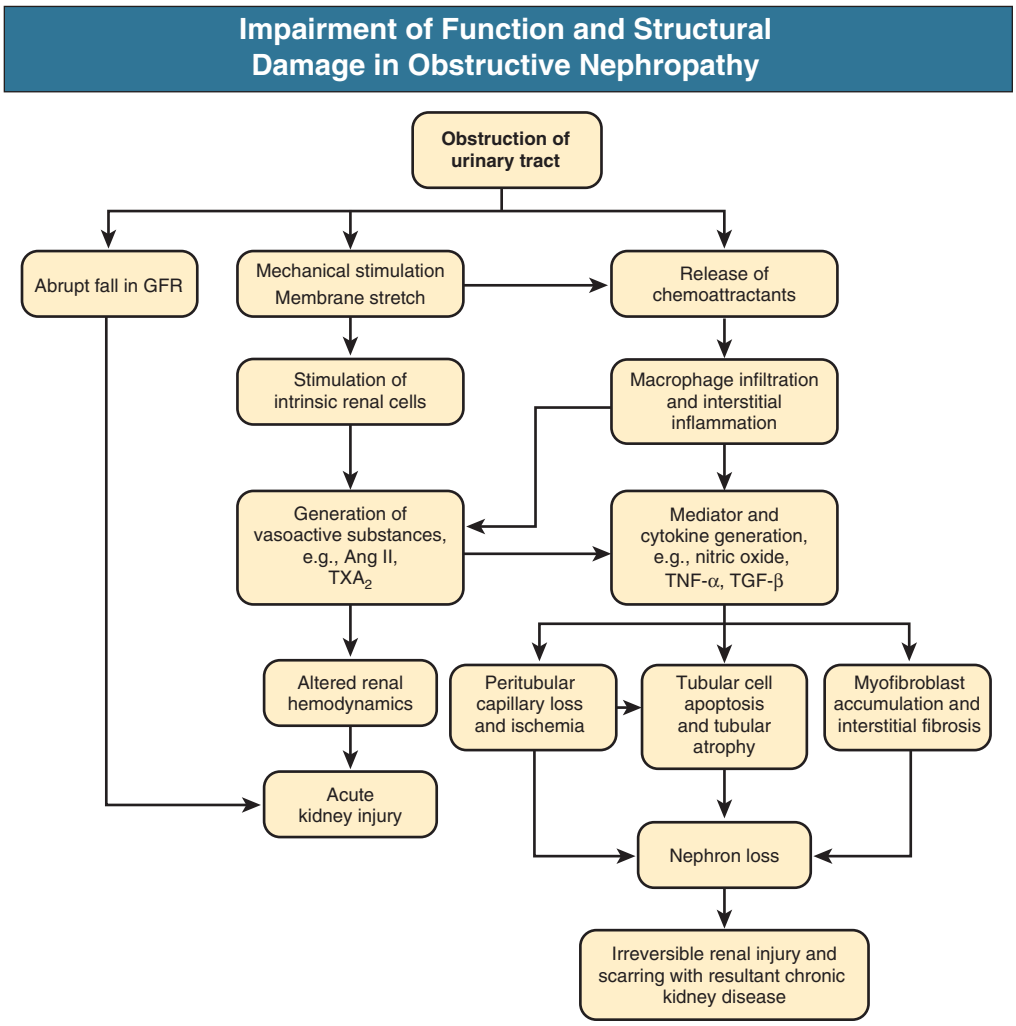

Figure 60-6 Events leading to acute impairment of renal function and chronic structural damage in obstructive nephropathy. *Ang II,* Angiotensin II; *GFR,* glomerular filtration rate; *TGF-β,* transforming growth factor β; *TNF-α,* tumor necrosis factor α; *TXA_2,* thromboxane A_2.

in both sexes with age. Antenatal ultrasound has significantly increased the detection rate of lower urinary tract obstruction in the fetus.[17] In children younger than 10 years, obstruction is more common in boys; congenital urinary tract anomalies, such as urethral valves and pelviureteral obstruction, account for most cases. In North America, obstructive uropathy remains the most common cause of end-stage renal disease (ESRD) in pediatric patients registered for renal transplantation, accounting for 16% of cases. In addition, congenital obstructive uropathy accounts for 0.7% of all patients (median age, 31 years) maintained with renal replacement therapy, demonstrating the continued impact of this disease into adult life.[18] In young adults (younger than 20 years), the frequency of urinary tract obstruction is similar in males and females. Beyond 20 years of age, obstruction becomes more common in females, mainly as a result of pregnancy and gynecologic malignant neoplasms. The peak incidence of renal calculi occurs in the second and third decades of life with a threefold increased incidence in men. After the age of 60 years, obstructive uropathy occurs more frequently in men secondary to benign prostatic hypertrophy and prostatic carcinoma. About 80% of men older than 60 years have some symptoms of bladder outflow obstruction, and up to 10% have hydronephrosis. In Europe, acquired urinary tract obstruction accounts for 3% to 5% of the cases of ESRD in patients older than 65 years, with most resulting from prostatic disease.[19] In the United States, the number of patients receiving renal replacement therapy as a result of acquired obstruction continues to increase, accounting for 1.4% of prevalent patients, although the rise is not as rapid as with other causes of ESRD.[18]

CLINICAL MANIFESTATIONS

Obstruction of the urinary tract can present with a wide range of clinical symptoms, depending on the site, degree, and duration of obstruction. The clinical manifestations of upper and lower urinary tract obstruction differ. Symptoms can be caused by mechanical obstruction of the urinary tract (usually pain) or can result from the complex alterations in glomerular and tubular function that may occur in obstructive nephropathy. The latter commonly present as alterations in urine volume and as renal failure, which can be acute or chronic. For example, patients with complete obstruction present with anuria and AKI, whereas those with partial obstruction may present with polyuria and polydipsia as a result of acquired vasopressin resistance. Alternatively, there may be a fluctuating urine output, alternating from oliguria to polyuria. However, obstructive uropathy and hence obstructive nephropathy can occur without symptoms and with minimal clinical manifestations; therefore obstruction of the urinary tract must be considered in the differential diagnosis of any patient with renal impairment.

Pain

Pain is a frequent complaint in patients with obstructive uropathy, particularly in those with ureteral calculi. The pain is believed to result from stretching of the collecting system or the renal capsule. Its severity correlates with the degree of distention and not with the degree of dilation of the urinary tract. On occasion the location of the pain helps determine the site of obstruction. With upper ureteral or pelvic obstruction, flank pain and tenderness typically occur, whereas lower ureteral obstruction causes pain that radiates to the groin, the ipsilateral testicle, or the labia. Acute high-grade ureteral obstruction may be accompanied by a steady and severe crescendo flank pain radiating to the labia, the testicles, or the groin ("classic" renal colic). The acute attack may last less than half an hour or as long as a day. By comparison, patients with chronic slowly progressive obstruction may have no pain or minimal pain during the course of their disease. In such patients, any pain that does occur is rarely colicky in nature. In PUJ obstruction, pain may occur only after fluid loading to promote a high urine flow rate.

Lower Urinary Tract Symptoms

Obstructive lesions of the bladder neck or bladder disease may cause a decrease in the force or caliber of the urine stream, intermittency, postmicturition dribbling, hesitancy, or nocturia. Urgency, frequency, and urinary incontinence can result from incomplete bladder emptying. Such symptoms commonly result from prostatic hypertrophy and are frequently referred to as *prostatism,* but they are not pathognomonic for this condition.

Urinary Tract Infections

Urinary stasis resulting from obstruction predisposes to urinary tract infections, and patients may develop cystitis with dysuria and frequency or pyelonephritis with loin pain and systemic symptoms. Infection occurs more often in patients with lower urinary tract obstruction than in those with upper urinary tract obstruction.

Urinary tract infection in men or young children of either sex, recurrent or persistent infections in women, infections with unusual organisms such as *Pseudomonas* species, and a single attack of acute pyelonephritis require further investigation to exclude obstruction. Also, the presence of obstruction makes effective eradication of the infection difficult. Infections of the urinary tract with a urease-producing organism such as *Proteus mirabilis* predispose to stone formation. These organisms generate ammonia, which results in urine alkalinization and favors the development of magnesium ammonium phosphate (struvite) stones. Struvite calculi can fill the entire renal pelvis to form a staghorn calculus that eventually leads to loss of the kidney if it is untreated. Thus, stone formation and papillary necrosis can also be consequences of urinary tract obstruction as well as causes of obstruction.

Hematuria

Calculi may cause trauma to the urinary tract uroepithelium and result in either macroscopic or microscopic hematuria. Any neoplastic lesion that obstructs the urinary tract, especially uroepithelial malignancies, may bleed, resulting in macroscopic hematuria. Urinary tract bleeding may also result in obstruction, giving rise to clot colic when it is in the ureter or clot retention when it is in the bladder.

Changes in Urine Output

Complete bilateral obstruction or unilateral obstruction of a single functioning kidney such as a renal transplant will result in anuria. However, when the lesion results in partial obstruction, urine output may be normal or increased (polyuria). A pattern of alternating oliguria and polyuria or the presence of anuria strongly suggests obstructive uropathy.

Abnormal Physical Findings

Physical examination findings can be completely normal. Some patients with upper urinary tract obstruction may have flank tenderness. Longstanding obstructive uropathy may result in an enlarged palpable kidney in children. Lower urinary tract obstruction causes

a distended, palpable, and occasionally painful bladder. A rectal examination and, in women, a pelvic examination should be performed because they may reveal a local malignant neoplasm or prostatic enlargement.

Acute or chronic hydronephrosis, either unilateral or bilateral, may cause hypertension as a result of impaired sodium excretion with expansion of extracellular fluid volume or from the abnormal release of renin. On occasion, in patients with partial urinary tract obstruction, hypotension occurs as a result of polyuria and volume depletion.

Abnormal Laboratory Findings

Urinalysis may show hematuria, bacteriuria, pyuria, crystalluria, and low-grade proteinuria, depending on the cause of obstruction. However, urinalysis findings may be completely negative despite advanced obstructive nephropathy. In the acute phase of obstruction, urinary electrolyte values are similar to those seen in a "pre-renal" state, with a low urinary sodium (<20 mmol/l), a low fractional excretion of sodium (<1%), and a high urinary osmolality (>500 mOsm/kg). However, with more prolonged obstruction, a decreased ability to concentrate the urine and an inability to reabsorb sodium and other solutes occur. These changes are particularly marked after the release of chronic obstruction and give rise to the syndrome commonly referred to as *postobstructive diuresis*.

Increases in serum urea and creatinine are the most significant laboratory abnormalities in patients with obstructive uropathy. Electrolyte abnormalities may also occur, including a hyperchloremic hyperkalemic (type 4) metabolic acidosis or hypernatremia as a result of acquired nephrogenic diabetes insipidus. The development of obstruction in patients with underlying chronic kidney disease may accelerate the rate of progression. ESRD may occasionally be caused by chronic obstructive uropathy that had been asymptomatic.

Obstruction in Neonates or Infants

With the advent of routine antenatal scanning, the diagnosis of hydronephrosis and genitourinary abnormalities is now frequently made antenatally; however, unsuspected obstructive uropathy may present in the postnatal period with failure to thrive, voiding difficulties, fever, hematuria, or symptoms of renal failure. Oligohydramnios at the time of delivery should raise the suspicion of obstructive uropathy, as should the presence of congenital anomalies of the external genitalia. Nonurologic anomalies such as ear deformities, a single umbilical artery, imperforate anus, or a rectourethral or rectovaginal fistula should prompt investigation for urinary tract obstruction. Any infant with neurologic abnormalities may have a neurogenic bladder with associated obstructive uropathy.

DIAGNOSIS

Prompt diagnosis of urinary tract obstruction is essential to allow treatment to limit any long-term adverse consequences. Symptoms such as "renal colic" may suggest the diagnosis and prompt appropriate investigation. However, urinary tract obstruction should be actively considered in any patient with unexplained acute or chronic kidney impairment. The diagnostic approach has to be tailored to the clinical presentation (Fig. 60-7), but a careful history and thorough physical examination are mandatory in all patients.

Urinalysis may provide valuable diagnostic information. Hematuria suggests that the obstructing lesion is a calculus, sloughed papilla, or tumor. Bacteriuria suggests urinary stasis, especially in men or in pregnant women, but it may also be a complication of chronic obstruction. The presence of crystals in the urine sediment (cystine or uric acid) may be an indication of the type of stone causing the ureteral obstruction or the intrarenal obstruction resulting in AKI. Laboratory studies should include an assessment of renal function (serum creatinine and urea) and the measurement of serum electrolytes.

Imaging

Because the sites, causes, and consequences of obstruction to the renal tract are so variable, no single imaging investigation can diagnose renal tract obstruction with certainty. No single imaging investigation should be relied on to definitively exclude obstruction, especially if the clinical suspicion of obstruction is high. Therefore, the approach to the patient with suspected obstruction may require the complementary use of a number of different imaging techniques.

Ultrasound is the most widely used imaging modality, with computed tomography (CT) scanning and magnetic resonance (MR) urography becoming increasingly useful in accurately diagnosing both the site and cause of obstruction. Although less commonly used, older imaging techniques, such as intravenous urography (IVU), can be used effectively to evaluate patients with obstructive uropathy. The role of imaging techniques is shown in Figure 60-7. Imaging is also discussed in Chapter 5.

Ultrasound

Ultrasound can define renal size and demonstrate calyceal dilation[20] but depends on the expertise of the operator (Fig. 60-8). Although it is sensitive for detection of hydronephrosis, ultrasound will often not detect its cause. Pathologic change within the ureter is difficult to demonstrate, and tiny stones will not generate acoustic shadows. However, unilateral hydronephrosis suggests obstruction of the upper urinary tract by stones, blood clots, or tumors. Bilateral hydronephrosis is more likely to result from a pelvic problem obstructing both ureters or obstruction of the bladder outlet, in which case the bladder will also be enlarged. Ultrasound may be combined with radiographic examination of the kidneys, ureters, and bladder (often known as KUB) to ensure that ureteral stones or small renal stones are not overlooked.

Ultrasound produces false-negative results in cases of nondilated obstructive uropathy.[20] Immediately after acute obstruction (within 24 hours), the relatively noncompliant collecting system may not have dilated, so ultrasound examination findings may be normal. Furthermore, if urine flow is low, as in severe dehydration or renal failure, there may be little dilation of the urinary tract. Dilation may also be absent in slowly progressive obstruction when the ureters are encased by fibrous tissue (as in retroperitoneal fibrosis) or by tumor, and in some renal transplants in which there is dense surrounding scar tissue. The acoustic shadow of a staghorn calculus can also mask dilation of the upper urinary tract. The sensitivity of ultrasound for diagnosis of obstruction can be improved by measuring the resistive index with color Doppler sonography. A resistive index above 0.7 reflects the increased vascular resistance present in obstruction and effectively discriminates between obstructed and nonobstructed kidneys.[20] Such ultrasound techniques are particularly useful when it is especially important to minimize radiation exposure, for example, in pregnant women and children, and in the follow-up of patients requiring repeated imaging, such as after extracorporeal shock wave lithotripsy.

Even in experienced hands, ultrasound may have a significant false-positive rate, especially if minimal criteria are adopted to

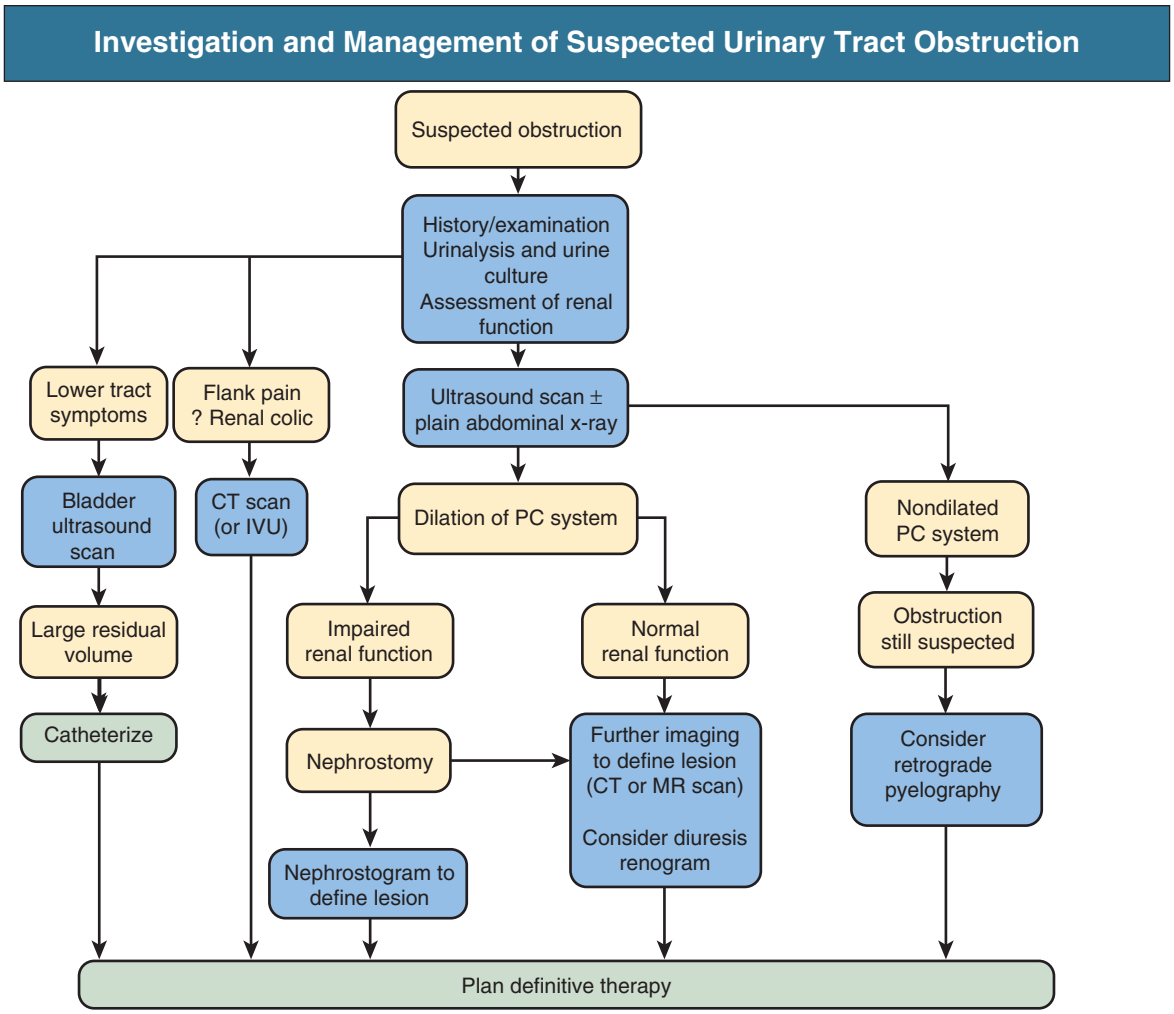

Figure 60-7 Investigation and management of suspected urinary tract obstruction. A full history should be taken and a thorough examination performed, together with urinalysis, urine microscopy and culture, and measurement of renal function and serum electrolytes. Ultrasound is a useful first-line investigation for any patient with suspected urinary tract obstruction. Computed tomography *(CT)* is now the preferred imaging technique when renal calculi are suspected. Either CT or magnetic resonance *(MR)* urography can accurately diagnose both the site and cause of obstruction in most cases. If there is renal impairment, a nephrostomy allows the effective relief of the obstruction and time for renal function to recover while definitive therapy is planned. *IVU,* Intravenous urography; *PC,* pelvicalyceal.

diagnose obstruction. In addition, the echogenicity produced by multiple renal cysts may be mistaken for hydronephrosis.

Ultrasound scanning can be used to assess bladder emptying and should be undertaken in patients with lower urinary tract symptoms. A large postmicturition residual volume suggests bladder outflow obstruction, which should prompt further urologic investigation and treatment.

The investigation of neonates with hydronephrosis diagnosed antenatally depends on the grade of hydronephrosis identified. Neonates with grade 1 or 2 hydronephrosis (no calyceal dilation) undergo ultrasound scanning; neonates with grade 3 or 4 hydronephrosis (indicating increasingly severe pelvicalyceal dilation) require both ultrasound scanning and voiding cystourethrography.[21] This combination can distinguish megaureter resulting from obstruction or reflux and enable the diagnosis of posterior urethral valves and ureteropelvic junction obstruction.

Plain Abdominal Radiography

A plain abdominal radiograph (or KUB) allows an assessment of kidney size and contour and frequently demonstrates renal calculi because about 90% of calculi are radiopaque.

Intravenous Urography

IVU was formerly the first-choice investigation for suspected upper urinary tract obstruction. In patients with normal renal function, it can usually define both the site and the cause of the obstruction. However, the excretion of contrast material may be poor or delayed in patients with low GFR because of a decreased filtered load of the contrast agent, which is potentially nephrotoxic. IVU is no longer a first-line investigation to diagnose urinary tract obstruction, especially in patients with impaired renal function.

Computed Tomography

Non–contrast-enhanced spiral CT scanning is used increasingly as the primary imaging modality for the evaluation of patients with acute flank pain.[22] Stones are easily detected because of their high density, and CT can provide an accurate and rapid diagnosis of an obstructing ureteral calculus with a stone being found more commonly in men.[23] In addition, it provides useful information about the site and nature of the obstructing lesion, especially when this is extrinsic to the urinary tract (Fig. 60-9; see also Chapter 61, Fig. 61-1). CT demonstrates retroperitoneal disease, such as para-aortic and paracaval lymphadenopathy; retroperitoneal fibrosis is evident

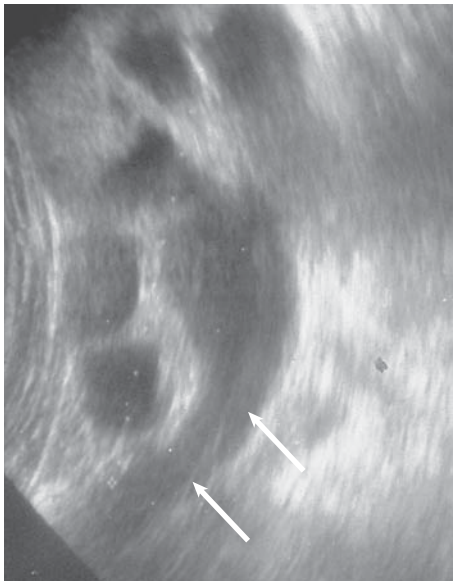

Figure 60-8 Renal ultrasound scan of a patient with obstruction of the urinary tract causing hydronephrosis. The kidney is hydronephrotic with dilation of the pelvicalyceal system; dilation of the upper ureter is also clearly seen *(arrows)*.

Figure 60-9 Computed tomography scan of the abdomen showing a grossly hydronephrotic kidney on the left (*arrows* mark dilated renal pelvis). Dilated loops of small bowel are seen in the right hypochondrium. Sequential sections demonstrated that the ureter was dilated along its length and that there was a pelvic mass, which was responsible for both bowel and left ureteral obstruction. The mass was subsequently shown to be arising from a carcinoma of the colon.

as increased attenuation within the retroperitoneal fat, with encasement of one or both ureters. Hematomas, primary ureteral tumors, and polyps are also detectable. The diagnostic potential of CT is enhanced by the administration of contrast material, but this may limit its use in patients with renal impairment. In addition, it involves considerable exposure to ionizing radiation.

Magnetic Resonance Urography

Magnetic resonance urography (combined with KUB) can enable the diagnosis of ureteral obstruction caused by renal calculi with accuracy similar to that of spiral CT scanning but without exposure to contrast medium or ionizing radiation. The technique has less observer variability and is more accurate than CT in detecting indirect evidence of obstruction, such as perirenal fluid. MR urography can rapidly and accurately depict the morphologic features of dilated urinary tracts and provide information about the degree and level of obstruction (Fig. 60-10).[24] MR urography is a particularly attractive imaging modality for the evaluation of hydronephrosis in children because it provides both anatomic and functional data and can indicate whether the hydronephrosis is compensated (symmetric changes of signal intensity of the nephrogram) or decompensated.[25] Signs of decompensation (acute on chronic obstruction) include edema of the renal parenchyma, a delayed and increasingly dense nephrogram, a delayed calyceal transit time, and a more than 4% difference in the calculated differential renal function. MR urography is likely to be increasingly used in the future.

Figure 60-10 Magnetic resonance urography showing obstructive uropathy. T2-weighted MR image showing a proximal right-sided ureteral obstruction with an associated mild hydronephrosis *(arrow)*. The obstruction was secondary to a ureteric calculus.

Retrograde Pyelography

Retrograde pyelography (Fig. 60-11; see also Fig. 60-2) may be particularly useful to identify both the site and the cause of the obstruction. It is also helpful when nondilated urinary tract obstruction is suspected or when there is a history of allergic reactions to contrast material. Urinary tract infection that may become overwhelming if obstruction is present is a contraindication to retrograde pyelography.

Diuresis Renography

A diuresis renogram using technetium Tc 99m mercaptoacetyltriglycine (^{99m}Tc-MAG3), combined with intravenous furosemide administered 20 to 30 minutes after injection of the isotope (diuretic isotopic renography), can be used to distinguish between simple dilation of the collecting system and true obstruction.[26] Normally there is a rapid washout of the isotope from the kidney, and persistence of the isotope suggests a degree of obstruction (Fig. 60-12). Poor renal function significantly limits the usefulness of renography

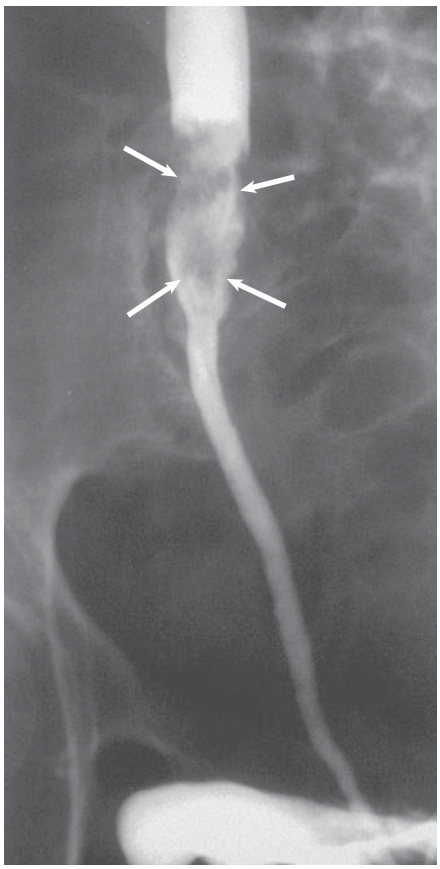

Figure 60-11 Ureteral obstruction by a tumor. A retrograde pyelogram shows the tumor is within and obstructing the ureter *(arrows)*. Above the tumor there is dilation of the ureter, but below it the ureter is of a normal caliber.

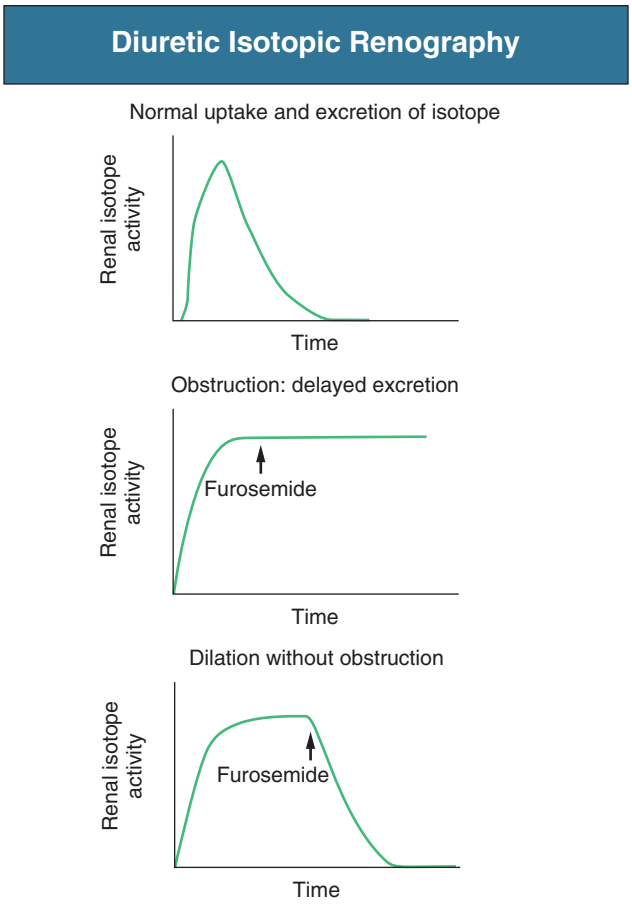

Figure 60-12 Diuretic isotopic renography. Idealized tracings for normal, obstructed, and dilated kidneys without obstruction of the upper urinary tract. In obstruction, there is delayed excretion of ^{99m}Tc-MAG3 despite administration of furosemide. When there is dilation of the upper urinary tract without obstruction, the isotope is retained but is rapidly excreted after the administration of furosemide.

because the diuretic response to furosemide may be absent. Diuresis renography may also be used for follow-up of patients who have undergone surgical procedures to relieve obstruction, such as a pyeloplasty.

Pressure-Flow Studies

A pressure-flow study (Whitaker test) involves puncture of the collecting system with a fine-gauge needle to perfuse fluid (at 10 ml/min) with concurrent measurement of the differential pressure between the bladder and the collecting system: a pressure greater than 20 cm H_2O indicates obstruction. Although this test is rarely required, it can be informative.[27]

Other Evaluations

Lower urinary tract obstruction may be evaluated by cystoscopy, which allows a visual inspection of the entire urethra and the bladder. Urodynamic studies (see Chapter 52, Fig. 52-15) can assess bladder outlet obstruction, measure the residual urine volume after voiding, and detect functional bladder abnormalities.

DIFFERENTIAL DIAGNOSIS

Diagnostic uncertainty arises with nonobstructive dilation of the upper urinary tract, which may be seen with vesicoureteral reflux, diuretic administration, diabetes insipidus, congenital megacalyces, chronic pyelonephritis, and postobstructive atrophy. Diuresis renography or retrograde pyelography may be required to exclude obstruction.

NATURAL HISTORY

Obstructive uropathy is potentially curable but will result in progressive irreversible loss of nephrons and renal scarring if it is left untreated (Fig. 60-13). ESRD will result if both kidneys are affected or if there is only a solitary kidney. Outcome data for obstructive uropathy are limited, but the exact prognosis will depend on the pathologic process responsible for the obstruction, the duration of the obstruction, and the presence or absence of urosepsis. Relief of short-term obstruction (<1 to 2 weeks) usually results in an adequate return of renal function. With chronic progressive obstruction (>12 weeks), there is often irreversible and severe renal damage, and renal functional recovery may be limited even after relief of the obstruction. A single-center study identified 104 patients who presented with obstructive nephropathy.[28] The mean GFR at presentation and at 3, 12, and 36 months was 9 ml/min, 28, 29, and 30 ml/min (patients on dialysis excluded), demonstrating significant but nonprogressive renal impairment after relief of obstruction. It is likely that the prognosis for renal functional recovery is better the earlier the obstruction is diagnosed and relieved.

TREATMENT

General Considerations

Treatment is dictated by the location of the obstruction, the underlying cause, and the degree of any renal impairment. If renal impairment is present, the treatment of obstruction requires close collaboration between nephrologists and urologists to reduce the risks associated with the metabolic and electrolyte consequences of renal failure and to optimize the chances for long-term recovery of renal function. For example, complete bilateral ureteral obstruction presenting as AKI is a medical emergency and requires rapid intervention to salvage renal function. Prompt intervention to relieve the obstruction should result in a rapid improvement in renal function. Dialysis should rarely be required in patients with AKI secondary to obstruction except to make the patient fit for intervention, for example, by improving life-threatening hyperkalemia or severe fluid overload. The rapid relief of obstruction will limit permanent renal damage, but renal function may not recover immediately if acute tubular necrosis has resulted from obstruction or any accompanying sepsis.

Some surgical aspects of the management of obstructive uropathy are discussed in Chapter 61. The site of obstruction frequently determines the approach. If the obstruction is distal to the bladder, a urethral catheter or, if this cannot be passed, a suprapubic cystostomy will effectively decompress the kidneys. Placement of nephrostomy tubes or cystoscopy and passage of a retrograde ureteral catheter will relieve upper urinary tract obstruction. Percutaneous nephrostomy (PCN) is generally the appropriate emergency treatment for upper urinary tract obstruction, especially in the setting of AKI. PCN can be achieved with local anesthetic and should allow rapid recovery of renal function in most patients (>70%), avoiding the need for dialysis. After relief of the obstruction by a nephrostomy, the exact site and nature of the obstructing lesion can be determined by an antegrade study infusing radiographic contrast material into the nephrostomy tube (nephrostogram), and time can be taken to plan definitive therapy (Fig. 60-14). Major complications of nephrostomy insertion (abscess, infection, and hematoma) occur in less than 5% of patients. If both kidneys are obstructed, the nephrostomy should initially be placed in the kidney with the most preserved renal parenchyma, although bilateral nephrostomies may be required to maximize the potential for the recovery of renal function. If infection occurs above a ureteral obstruction (pyonephrosis), drainage of the kidney by PCN can play an important therapeutic role together with appropriate antibiotics.

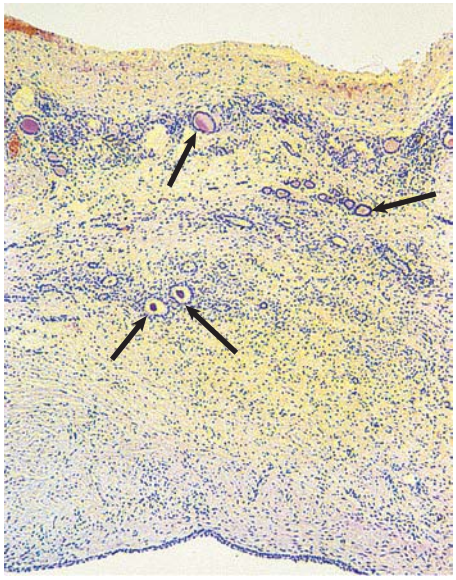

Figure 60-13 Pathology of chronic ureteral obstruction. This is a section of the rim of renal tissue from the kidney shown in Figure 60-5. The renal capsule is at the top, the urinary space at the bottom. The cortex is considerably thinned, and only a few atrophic tubules remain *(arrows)* within an interstitium comprising dense fibrous tissue and a mononuclear cell infiltrate *(blue-staining nuclei)*. No glomeruli can be seen. This demonstrates why there would be no prospect for any significant functional recovery in this kidney even after the relief of the obstruction.

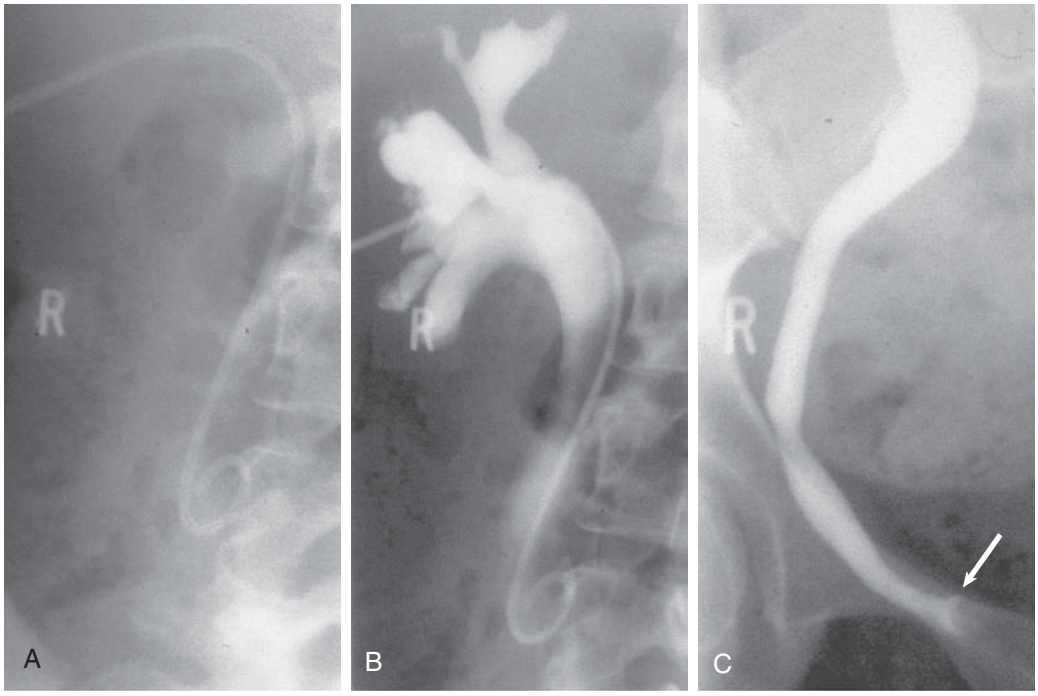

Figure 60-14 Nephrostogram. A nephrostomy has been placed percutaneously into the dilated collecting system of the kidney under ultrasound control **(A).** After infusion of contrast material down the nephrostomy, the dilated pelvicalyceal system and upper ureter **(B)** and the lower ureter **(C)** are outlined. The ureter is dilated along its length but tapers abruptly at the vesicoureteral junction *(arrow)*. In this patient the obstruction was caused by a radiolucent stone.

A nephrostomy can be used to gauge the potential for functional recovery in patients with chronic obstruction. Failure of renal recovery after several weeks of nephrostomy drainage strongly suggests irreversible structural damage and therefore no likely benefit from undertaking a more definitive surgical correction of the obstructing lesion. Long-term nephrostomy is increasingly used as a definitive therapy for patients who are unsuitable for major surgical intervention and those with incurable malignant disease (see Chapter 59 for further discussion).

Ureteral obstruction requiring intervention occurs in up to 3% of renal transplant recipients.[29] It can be treated by nephrostomy and ureteral stenting, percutaneous incision or balloon dilation of the stricture, or open surgical repair (see Chapter 103).

Specific Therapies

Calculi are the most common cause of ureteral obstruction, and their treatment includes relief of pain, elimination of obstruction, and treatment of infection (see Chapters 59 and 61). Ureteral obstruction by papillary tissue, blood clots, or a fungus ball is treated by procedures similar to those used for calculi. When obstruction is caused by neoplastic, inflammatory, or neurologic disease, there is unlikely to be spontaneous remission of the obstruction, and some form of urinary diversion, such as an ileal conduit, should be considered. Some obstructing neoplastic lesions, such as lymphadenopathy from lymphoma, may respond to chemotherapy. Management of malignant urinary tract obstruction is discussed further in Chapter 61.

In idiopathic retroperitoneal fibrosis, ureterolysis (in which the ureters are surgically freed from their fibrous encasement) may be beneficial, especially if combined with corticosteroid therapy to prevent recurrence. A recent retrospective study demonstrated the effectiveness of ureteric stent insertion and corticosteroids in idiopathic retroperitoneal fibrosis[30]; retroperitoneal fibrosis complicating IgG4 disease may also respond to corticosteroid treatment.[2]

Functionally significant PUJ obstruction should be corrected surgically by either an open (Anderson-Hynes) pyeloplasty or a laparoscopic approach. The laparoscopic approach results in significantly less morbidity and has good long-term outcomes that are comparable to those of the open procedure.[31] Balloon dilation of the abnormal segment of the ureter is also possible, but the recurrence rate is high. Studies have suggested the usefulness of urine proteomics to identify neonates with ureteropelvic junction obstruction who require surgical intervention,[32] although a subsequent small study indicated that this approach was less specific and sensitive in older children.[33]

Benign prostatic hypertrophy is the most common cause of lower urinary tract obstruction in men and may be mild and nonprogressive. A patient with minimal symptoms, no infection, and a normal upper urinary tract can continue with assessment until he and his physician agree that further treatment is desirable. Medical therapy with either α-adrenergic blockers (e.g., tamsulosin) or 5α-reductase inhibitors (e.g., finasteride) may be used in patients with moderate symptoms.[34] α-Blockers relax the smooth muscle of the bladder neck and prostate and decrease urethral pressure and outflow obstruction. 5α-Reductase inhibitors inhibit the conversion of testosterone to the active metabolite dihydrotestosterone and reduce prostatic hypertrophy. Combination therapy with these agents may be synergistic. Surgical intervention with transurethral resection of the prostate is generally required for failed medical treatment, debilitating symptoms, urinary retention, recurrent infection, or evidence of renal parenchymal damage. Holmium laser enucleation of the prostate is a less invasive alternative to transurethral resection of the prostate with good short-term and long-term outcomes.[35]

Urethral strictures in men can be treated by dilation or direct-vision internal urethrotomy. The incidence of bladder neck and urethral obstruction in women is low and treatment rarely required. Suprapubic cystostomy may be necessary for bladder drainage in patients unable to void after injury to the urethra or in those who have an impassable urethral stricture.

When obstruction results from neuropathic bladder function, urodynamic studies (see Chapter 52, Fig. 52-15) are essential to determine therapy. The goals of therapy are to establish the bladder as a urine storage organ without causing renal parenchymal injury and to provide a mechanism for bladder emptying that is acceptable to the patient. Patients may have either a flaccid atonic or an unstable hypertonic bladder. Ureteral reflux and parenchymal damage may develop in both cases, although it is more common in patients with a hypertonic bladder. Asking the patient to void at regular intervals may achieve satisfactory emptying of the bladder. Patients with an atonic bladder and significant residual urine retention associated with recurrent urosepsis need to undertake clean intermittent self-catheterization. The aim should be to catheterize four or five times per day to ensure that the amount of urine drained from the bladder on each occasion is less than 400 ml. External sphincterotomy has also been used in men with an atonic bladder and may relieve outlet obstruction and promote bladder emptying, but it may cause urinary incontinence and the need to wear an external collection device. In patients with a hypertonic bladder, improvement in the storage function of the bladder may be obtained with anticholinergic agents. Occasionally, chronic clean intermittent self-catheterization is necessary.

Whenever possible, chronic indwelling catheters should be avoided in patients with a neurogenic bladder because they may lead to the formation of bladder stones, urosepsis, and urethral erosion, and they predispose to squamous cell carcinoma of the bladder. Patients who have had chronic indwelling catheters for more than 5 years should have annual cystoscopic examinations. If deterioration in renal function occurs despite conservative measures or there is intractable incontinence or a small contracted bladder, an upper urinary tract diversion procedure such as an ileal conduit may be required.

Management of Postobstructive Diuresis

Marked polyuria (postobstructive diuresis) is frequently seen after the release of bilateral obstruction or obstruction of a single functioning kidney. Indeed, a diuresis of greater than 7 liters per day is associated with a good functional outcome.[36] Release of unilateral obstruction rarely results in a postobstructive diuresis[37] despite the presence of tubular dysfunction and a concentrating defect. This is because of intrinsic differences in the tubular response to unilateral and bilateral obstruction and, more important, the salt and water retention and renal impairment that occurred in bilateral obstruction (not evident in unilateral obstruction because of the contralateral normal kidney). The resultant increase in natriuretic factors (including atrial natriuretic peptide) and substances able to promote an osmotic diuresis such as urea[38] promote an appropriate postobstructive diuresis to excrete water and electrolytes that were retained during the period of obstruction. However, the postobstructive diuresis may also be inappropriate as a result of tubular dysfunction, and, if not managed correctly, this may result in severe volume depletion and electrolyte imbalance with continued renal dysfunction. Intravenous and oral fluid replacement is usually required, with careful and regular assessment of the fluid balance and serum

electrolytes to tailor the fluid replacement regimen appropriately. Once the patient is deemed euvolemic, urine losses plus an allowance for insensible losses should be replaced. Urine volume should be measured regularly (hourly) to facilitate fluid administration, and serum electrolytes should be measured at least daily and as frequently as every 6 hours when there is a massive diuresis. Daily weighing of the patient is also helpful. Replacement fluid regimens should include sodium chloride, a source of bicarbonate and potassium. Calcium, phosphate, and magnesium replacement may also be necessary.

If fluid administration is overzealous, the kidney will not recover its concentrating ability, and a continued "driven" diuresis will result. It may then be necessary to decrease fluid replacement to levels below those of the urine output and observe the patient carefully for signs of volume depletion.

Future Prospects

Understanding the pathophysiologic changes that follow ureteral obstruction has allowed the development of rational interventional therapies to hasten the recovery of renal function and limit permanent renal damage. Although the best treatment option in humans remains the prompt and effective relief of the obstruction, the development and implementation of improved imaging modalities that provide more sophisticated anatomic and functional information (including intrarenal oxygen content[39]) as well as future advances in urine proteomics will undoubtedly refine patient management and increase the data available for making key clinical decisions such as whether and when surgical intervention is required.

CHAPTER 61

Urologic Issues for the Nephrologist

Sunjay Jain, James E. Dyer, Evangelos G. Gkougkousis, and J. Kilian Mellon

Close interaction between nephrologists and urologists is crucial to the optimal management of a number of common clinical problems. A proper understanding of urologic strategies helps the nephrologist ensure that patients with these problems are given clear information and are optimally managed. Areas in which such coordinated work is most important are discussed in this chapter. They include the management of stone disease, the surgical approach to urinary tract obstruction, the investigation of hematuria, and the management of urinary tract malignant neoplasms.

SURGICAL MANAGEMENT OF STONE DISEASE

The management of urinary tract stones has been irrevocably changed by the introduction of extracorporeal shock wave lithotripsy (ESWL), percutaneous nephrolithotomy (PCNL), and ureteroscopy.

Such advances have rendered open stone surgery an increasingly rare management option that is now second- or third-line treatment when indicated. Table 61-1 details the use of different treatment modalities over time since the introduction of newer techniques.[1] As familiarity with available techniques and technology develops, standardized treatment strategies will undoubtedly evolve. At present, however, there remains controversy over the optimal treatment for a variety of stone patients, the specifics of which are beyond the scope of this text.

Advances in Imaging for Urinary Tract Stones

In recent years, unenhanced computed tomography (CT) scanning of the abdomen and pelvis has replaced intravenous urography (IVU) as the standard imaging modality for stone diagnosis (Fig. 61-1). CT offers increased sensitivity compared with IVU (99% vs. 70%) without the need for the intravenous administration of contrast material. An additional advantage is the ability of CT to demonstrate radiolucent stones (mainly uric acid and xanthine stones) and to detect concomitant lesions and/or alternative diagnoses. CT does require an increased radiation dose, but this is lessening with modern machines. Comparative doses are 0.42 mSv for plain radiography of the kidneys, ureters, and bladder (KUB); 2.5 mSv for IVU; and 4 mSv for non–contrast-enhanced CT.

Treatment of Urinary Tract Stones

Spontaneous stone passage can be expected in up to 80% of patients with a stone size smaller than 4 mm. Conversely, for stones with a diameter of more than 7 mm, the chance of spontaneous stone passage is very low. The location is also important; up to 70% of distal ureteral stones pass spontaneously, in contrast to only 45% of midureteral and 25% of proximal ureteral stones. Intervention is strongly recommended when there is persistent pain (for more than 72 hours) despite adequate analgesia, persistent obstruction with risk of impaired renal function (e.g., with preexisting renal impairment or in a single kidney), bilateral obstruction, or associated urinary tract sepsis.

In the absence of an acute indication for surgical management, medical expulsive therapy (tamsulosin 400 μg once daily, nifedipine 30 mg once daily), which relaxes the distal ureter and increases the likelihood of stone passage, is now commonplace in many centers. There is a growing body of evidence to support the use of medical expulsive therapy in ureteral stone disease. However, there is inconsistency in reported studies (with respect to stone size and location), and as yet outcomes of well-conducted randomized controlled trials (RCTs) are still awaited.

Another conservative treatment option is chemolysis, as several stone types are in principle amenable to dissolution by oral medications or by direct instillation of chemical solutions. However, in most patients this form of treatment is either impractical or clinically ineffective. The major exception is patients with uric acid stones, which can readily be dissolved by alkalization of the urine, usually with oral potassium citrate. (Commercially available preparations typically include potassium citrate 30% and citric acid monohydrate 5% to be diluted in water for a dose of 10 ml three times daily.)

Acute Surgical Intervention

The main goal of acute surgical intervention is to relieve obstruction. If the patient is considered well enough for general anesthesia, ureteroscopic stone destruction can be attempted in most cases. Alternatively, a double-J stent (a ureteral stent with two coiled ends) can be inserted, which will relieve obstruction until definitive treatment is performed (Fig. 61-2). However, in the setting of uncontrolled urinary tract infection, percutaneous nephrostomy (PCN) is the preferred option because it can be performed with local anesthesia and is less likely than endoscopic surgery to cause septicemia (Fig. 61-3). Rarely, an open procedure to remove a stone or a grossly infected kidney may be necessary.

Elective Surgical Intervention

Extracorporeal Shock Wave Lithotripsy

During ESWL, acoustic shock wave energy is delivered to a stone under fluoroscopic or ultrasound guidance. Treatment sessions typically last about 30 minutes, during which 1500 to 2500 shock waves are delivered. Sessions are performed on an outpatient basis with the patient under analgesia or intravenous sedation and can be repeated at intervals of 10 to 14 days. Stones up to 20 mm in size can be treated effectively, and stone-free rates of 60% to 98% have been reported. However, ESWL is operator dependent, and outcome is influenced by the size, composition, and location of the stone and the type of

Changing Use of Techniques for Stone Removal			
	1984	1990	1999
Location (%)

A, Preoperative plain radiograph showing stones in the left renal pelvis. **B,** After ESWL, note the disappearance of the pelvic stone, the string of stone fragments throughout the length of the ureter, and the double-J ureteral stent placed to facilitate their passage.

lithotripter used. Cystine and calcium oxalate monohydrate stones are especially resistant. Targeting of the stone may be impossible in the presence of obesity and skeletal deformities (increased skin-to-stone distance), and ESWL is contraindicated in patients with aortic or renal artery aneurysm, uncontrolled urinary tract infection, or coagulation disorders and in pregnant women.

A double-J ureteral stent is sometimes placed endoscopically before ESWL treatment to prevent stone fragments from obstructing the distal ureter (*Steinstrasse,* literally "stone street"; Fig. 61-4). Other

Indications for Percutaneous Nephrolithotomy		
Composition*	Struvite stones	Complete removal necessary to eliminate infection and minimize stone recurrence
	Calcium oxalate monohydrate stones	Difficult to pulverize by ESWL
	Cystine stones	Difficult to pulverize by ESWL
Stone position	Lower pole stones	Fragments less easily evacuated from dependent lower pole calyces, especially if collecting system dilated
Anatomic abnormalities	PUJ obstruction Calyceal diverticula	Prevent passage of fragments after ESWL
Patient characteristics	Morbid obesity Ureteral obstruction	Stone cannot be placed in focal point of ESWL machine

Table 61-2 Indications for percutaneous nephrolithotomy. ESWL is the first choice for stone intervention, except in those circumstances that may favor PCNL. *ESWL,* Extracorporeal shock wave lithotripsy; *PCNL,* percutaneous nephrolithotomy; *PUJ,* pelviureteral junction. *Stone composition can be defined with certainty only by direct stone analysis, but advances in imaging may ultimately provide a means to accurately assess stone composition *in situ* before treatment, thus allowing the urologist to select the treatment most likely to be successful.

acute complications of ESWL include hemorrhage or hematoma, infection, and injury to adjacent organs. The risk for the later development of hypertension or renal impairment after ESWL remains controversial.

Extracorporeal shock wave lithotripsy is the first-line treatment for more than 75% of stone patients. Table 61-2 shows circumstances in which ESWL is less effective and PCNL becomes the preferred approach or a combination of the two modalities is used. For lower pole stones in particular, ESWL may not provide optimal clearance because of problems with the drainage of residual fragments. An RCT has shown that for lower pole stones larger than 10 mm, PCNL has much better clearance rates than ESWL (92% vs. 23%).[2]

Percutaneous Nephrolithotomy

During PCNL, a tract is created between the skin and the collecting system of the kidney and used as a working channel to remove stones. Preoperatively, IVU or CT, sometimes with three-dimensional reconstruction, is used to accurately localize calculi and neighboring organs (e.g., spleen, liver, large bowel, pleura, or lungs) and to plan access. The most frequently used access site is the dorsal calyx of the lower pole, and stone fragmentation is undertaken by ultrasound, pneumatic, or laser devices. The PCNL technique is modified for special circumstances, usually by altering the site of puncture (e.g., directly into a calyceal diverticulum) or, if there are ureteral stones, by using a higher-placed puncture to permit antegrade ureteroscopy. The percutaneous puncture may be facilitated by the preliminary placement of a retrograde ureteral catheter to dilate and to opacify the collecting system, which is then punctured under fluoroscopy. After completion of PCNL, a self-retaining balloon nephrostomy tube is used to tamponade the tract and to provide further access if needed. Hemorrhage can complicate PCNL (from renal or, rarely, intercostal arteries) and can usually be treated conservatively or by selective angiographic embolization. Other complications include sepsis; fluid overload (similar to transurethral resection syndrome); injury to spleen, pleura, or colon; and extravasation. PCNL usually results in minimal parenchymal injury, averaging only 0.15% of the total renal cortex.[3]

Indications for PCNL are shown in Table 61-2. These continue to evolve and are being challenged by developments in ureteroscopic techniques, which are allowing more upper ureteral and renal pelvic stones to be dealt with by a retrograde approach.

Open Stone Surgery

Although it is performed increasingly rarely, open surgery still has a place in the treatment of stone disease. It is reported that approximately 2% of stone patients are treated with open surgery, mainly when anatomic factors preclude the use of minimally invasive methods or when these techniques have failed. Other indications include complex stone burden and the presence of intrarenal anatomic abnormalities (e.g., pelviureteral junction obstruction). During surgery the renal pelvis as well as the parenchyma can be opened along avascular planes, and clamping of the renal vessels and hypothermia of the kidney may be needed. In selected patients a laparoscopic approach can be used for the treatment of stone disease.

Ureteroscopy

Recent advances in the design of endoscopes for ureteronephroscopy have rendered the entire urinary tract accessible to endoscopic examination and manipulation. Ureteroscopes may be semirigid or flexible, the latter allowing access to the renal pelvis and calyces. Stone fragmentation is achieved ideally by laser but also by ultrasound or pneumatic devices (lithoclast). Laser use is equally effective for all types of stones and has the additional advantages of a flexible fiber (allowing intrarenal stone fragmentation), low tissue penetration, and minimal stone displacement during use. Success rates for laser fragmentation of ureteral stones are high, in the region of 80%. Figure 61-5 highlights the increasing use of ureteroscopy in stone disease and also the increasing proportion of procedures in which a laser rather than ultrasound or a lithoclast is used to achieve stone fragmentation.

In the case of lower pole renal stones, although flexible ureteroscopes can access the lower pole to facilitate treatment, the stone-free rate in comparative studies is similar to that of ESWL.[4,5] Furthermore, patient preference is often ESWL in the first instance. As a result, it is common for patients to undergo ESWL before flexible ureteroscopy and lasertripsy. In the event of failed stone clearance after ureteroscopy, PCNL is commonly used next and is likely to remain an essential treatment for lower pole stones. Complications of ureteroscopy, particularly with use of graspers and baskets, include ureteral avulsion, perforation, extravasation, mucosal damage, hematuria, infection, and stricture. Advances in laser technology now enable stones to be reduced to dust-like particles, reducing the need for graspers and baskets and hence reducing complications.

Management of Staghorn Calculus

A staghorn calculus should usually be managed by intervention because reports of conservative therapy show a high rate of eventual nephrectomy (up to 50%) and an increase in associated morbidity (mainly renal failure) and mortality (up to 28%). Surgical options are ESWL monotherapy, complete endoscopic stone removal, and a combined approach with use of PCNL for debulking followed by ESWL. The advantage of the combined approach is the reduced need for additional renal access and secondary endourologic procedures.

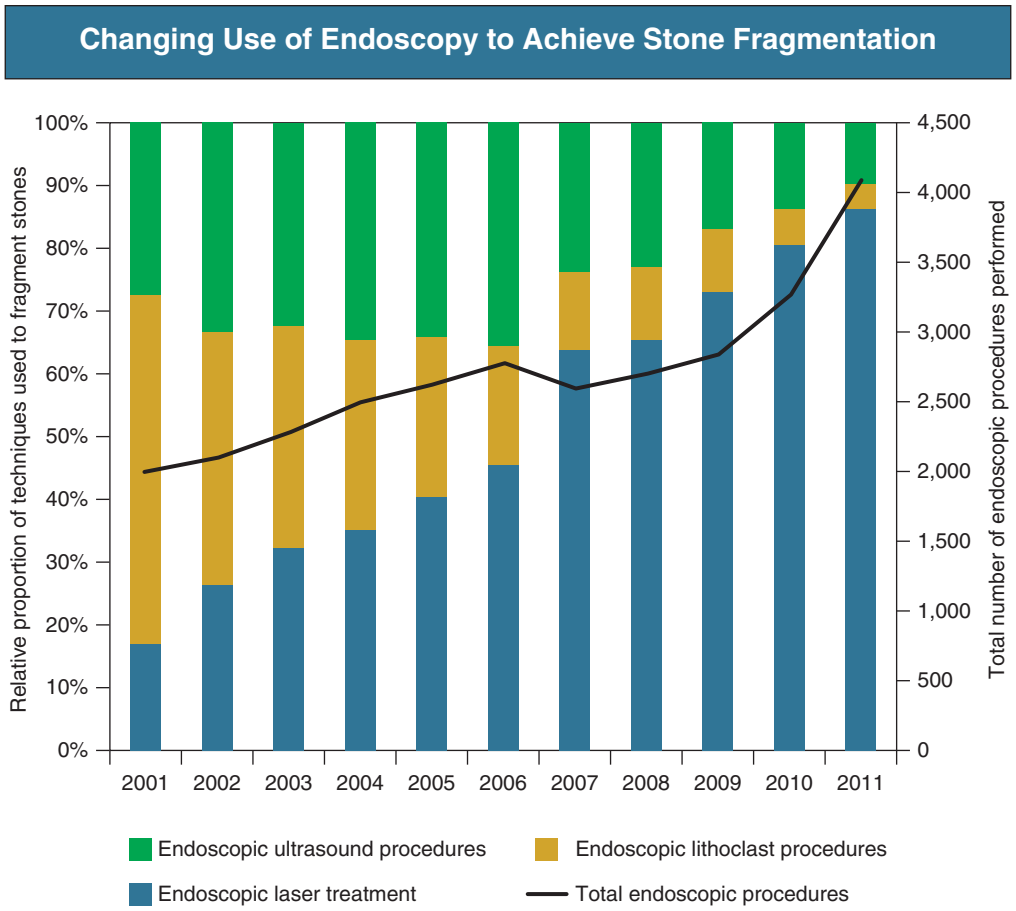

Figure 61-5 Changing use of endoscopy to achieve stone fragmentation. Chart showing the increasing use of endoscopy in stone surgery in addition to the increasing proportion of cases using lasers to achieve stone fragmentation. *(Data from UK Hospital Episode Statistics dataset.* http://www.hscic.gov.uk/hes. *Accessed June 9, 2012.)*

The choice of treatment depends on many factors, including the age and renal function of the patient. ESWL will not usually render the patient entirely stone free (the ideal goal of treatment), especially in the treatment of large staghorn stones; nevertheless, it can be considered successful when less than 40% of a staghorn calculus persisting as fragments is achieved. Rarely, open surgical removal of the stone may be indicated.

Stones in Transplanted Kidneys

The management of stone disease in a transplanted kidney is challenging because of the solitary kidney, the anatomic location within the pelvis, and the difficulty with retrograde access to the ureter and kidney. Early active intervention is indicated; prophylactic stenting, ureteroscopy, and PCNL are preferred to ESWL because stone targeting may not be possible. Open surgery may be needed in selected cases.

MANAGEMENT OF URINARY TRACT OBSTRUCTION

The causes of upper tract obstruction are listed in Chapter 60, Table 60-1, and a summary of the management of obstruction is given in Chapter 60, including Figure 60-7. Upper tract obstruction caused by malignant disease can be a result of direct tumor invasion or external compression by metastatic lymph node involvement or, rarely, true metastasis to the ureter. Some 70% of tumors causing ureteral obstruction are genitourinary (cervical, bladder, prostate) in origin; breast and gastrointestinal carcinomas and lymphoma constitute the majority of the remainder.[6] The presentation of a patient with obstruction may vary significantly, and hydronephrosis may develop progressively and insidiously and remain unrecognized until the patient develops anuria and uremia. Upper tract obstruction from malignant disease rarely presents with classic acute ureteral colic, which is typically seen with a benign cause such as a stone. Bladder outflow obstruction may be acute and dramatic, or chronic with few or no symptoms. To aid in understanding of the immediate needs and longer-term prognosis of these patients, the acute as well as the definitive management of the most common urologic diseases associated with obstruction and renal impairment are outlined.

Acute Management of Urinary Tract Obstruction

Relief of obstruction is crucial to reverse renal impairment and to preserve remaining renal function. In cases of bladder outflow obstruction, a urethral or suprapubic catheter is indicated; whereas in upper tract obstruction, a double-J ureteral stent is preferable, when possible. The most straightforward approach is endoscopic retrograde placement under fluoroscopy, with PCN reserved for

patients in whom the procedure fails. Bilateral stents should be placed if it is technically possible. However, tumor infiltration can distort trigonal anatomy, making identification of ureteral orifices for double-J stent insertion impossible at the time of cystoscopy. Furthermore, it has been suggested that stents fail to relieve obstruction in 40% to 50% of cases of external ureteral compression. Thus, these patients need to be closely monitored to ensure resolution of the obstruction. A new type of metallic, self-expanding stent, used alone or in conjunction with double-J stents, has had good results in maintaining ureteral patency and avoiding PCN in malignant ureteral obstruction.[6]

A stable patient with obstruction but without major signs of sepsis is a candidate for retrograde stent placement with use of general anesthesia. However, in a patient with sepsis, endoscopic manipulation can lead to bacteremia and rapid deterioration. Furthermore, such patients may not be fit for general anesthesia, in which case the preferred initial approach is PCN, which can then be followed after an interval with antegrade ureteral stenting. The success rate of this combined approach is high (>90%).[8] In patients with bilateral ureteral obstruction, it is not always necessary to insert bilateral PCN tubes. Significant palliation and return to nearly normal renal function can be accomplished by drainage of a single kidney, preferably the unit with the better preserved parenchyma as determined by CT scan or ultrasound. Once they have been placed, PCN tubes or double-J stents need to be replaced every 4 to 6 months. If they are left for a longer time, they become increasingly brittle and encrusted and are liable to fracture or break when they are manipulated. Complications of ureteral stents include migration, obstruction with proteinaceous material, infection, fragmentation, and rarely erosion through the urinary tract.[9] As many as 70% of patients with stents report lower urinary tract symptoms (LUITS), mainly urgency, frequency, and nocturia as well as pain along the urinary tract.

Morbidity after stenting or PCN is similar.[10] The main problem with indwelling stents is the increased risk of recurrent obstruction (11% for stents versus 1% for PCN). PCN may have an increased infection rate, and there may be psychological issues relating to the need for an external drainage bag.

Extra-anatomic stents are an alternative for patients in whom conventional stent insertion has failed or for whom permanent nephrostomy drainage is unacceptable. An extra-anatomic stent is placed by an initial percutaneous puncture and insertion of the upper end of a long (50-cm) double-J stent into the kidney. A subcutaneous tunnel is then created to bring the stent to the level of the iliac crest. Another tunnel is fashioned to bring the lower end of the stent out suprapubically, followed, finally, by suprapubic puncture of a full bladder and insertion of the lower end (Fig. 61-6).[11] Extra-anatomic stents are usually changed at 6-month intervals, and preliminary experience confirms their value in maintaining ureteral patency and avoiding PCN. Because of the effectiveness of minimally invasive methods, open surgery today is rarely indicated in the acute setting.

Pelviureteral Junction Obstruction

Surgical management of pelviureteral junction obstruction is aimed at obliterating the redundant (aperistaltic) portion of the ureter, allowing normalization of drainage from the affected kidney. The need for treatment is heralded by the onset of pain, infection, calculus formation, decline in renal function, or proven impaired excretion on MAG3 renography with impending decline in renal function. The gold standard treatment is now laparoscopic pyeloplasty, although traditional open techniques are still used. Robotic pyeloplasty and endoscopic treatments are also performed in some specialist centers.

Figure 61-6 Extra-anatomic stenting for malignant ureteral obstruction. Plain radiograph showing placement of an extra-anatomic stent for malignant obstruction of the right ureter. The upper end of the double-J stent has been placed in the right renal pelvis *(arrow)*. The stent then runs through a subcutaneous tunnel before the lower end enters the bladder *(arrowhead)*.

Retroperitoneal Fibrosis

Retroperitoneal fibrosis can be treated medically or surgically. A causative factor should be excluded (see Chapter 60). There are reports of favorable outcomes after immunosuppression with high doses of corticosteroids or azathioprine. Alternatively, surgery, consisting of ureterolysis (freeing the ureters from the fibrotic plaques) and omentoplasty (transposition of the ureters into the peritoneal cavity in omental wraps), can have good long-term results.

Malignant Obstruction

For upper tract transitional cell carcinoma, acute obstruction is best treated by internal stenting. PCN is avoided because of the risk of tumor seeding. Upper tract transitional cell carcinoma is an aggressive tumor and necessitates prompt extirpative surgery.

Bladder cancer can lead to hydronephrosis by invading the ureteral orifices and intramural ureter. Radical cystectomy is indicated, although temporary ureteral decompression may normalize renal function if neoadjuvant chemotherapy is planned. In selected cases, bladder preservation strategies combining systemic chemotherapy and radiotherapy can offer long-term control of the disease.

Prostate cancer causes obstruction by occluding the urethra or invading the ureteral orifices. Hormonal treatment can shrink prostatic tissue and malignant deposits and offer long-term remission of symptoms. Limited resection of the prostate may sometimes be indicated.

The decision to offer ureteral decompression for upper tract obstruction caused by cancer is not straightforward and requires input not only from the urologist but also from colleagues in radiation and medical oncology and the palliative care team. There must also be careful discussion of the options with the patient and family.

Percutaneous Nephrostomy for Malignant Obstructive Uropathy		
	Median Survival (wk)	5-yr Survival Rate (%)
Group I: primary untreated malignancy	27	10
Group II: recurrent malignancy with further treatment	20	20
Group III: recurrent malignancy with no further treatment	6.5	None survived longer than 1 yr
Group IV: benign disease as a result of previous treatment	Not stated	64
Overall	26	22

Table 61-3 Percutaneous nephrostomy for malignant obstructive uropathy. Outcome in 77 patients undergoing percutaneous nephrostomy for obstructive uropathy secondary to pelvic malignant disease. *(Data from reference 12.)*

Ureteral decompression is justified when radiotherapy and systemic chemotherapy remain therapeutic options after improvement in renal function but may also be justified for palliation of pain or ongoing renal tract sepsis.

A review of patients undergoing PCN for obstructive uropathy secondary to pelvic malignant disease identified a group of patients with very poor survival in whom ureteral decompression is usually not justified (Table 61-3).[12] Patients with gastric or pancreatic cancer survive a median of only 1.4 months after ureteral decompression, calling into question the benefit of such a procedure in this setting.[13] In another report, the average survival of patients with advanced malignant neoplasms undergoing endourologic diversion was only 5 months, half of which time was spent in the hospital.[14]

Benign Ureteral Strictures

These can be secondary to stone disease, iatrogenic, or caused by various benign diseases. The treatment of choice is endoscopic balloon dilation or ureterotomy. Open surgical repair or major reconstructive surgery may be needed in cases of recurrent strictures.

Bladder Outflow Obstruction

Bladder outflow obstruction in men is most frequently caused by either benign or malignant prostatic enlargement. Common presentations of both conditions include the onset of LUITS and acute (painful) or chronic (painless) retention of urine.

Chronic retention can be considered as the maintenance of voiding with incomplete bladder emptying. It is further classified into low- and high-pressure chronic retention. Low-pressure chronic retention occurs in the absence of upper tract compromise, whereas high-pressure chronic retention is associated with hydronephrosis and kidney injury.

In acute retention, low-pressure chronic retention, and LUITS caused by bladder outflow obstruction, medical therapy in the form of 5α-reductase inhibitors (finasteride, dutasteride) or α-adrenergic receptor blockers (tamsulosin, alfuzosin) is an accepted first-line treatment before surgery is offered.[15] Given the risk of worsening renal failure if medical therapy fails, it is not a safe management option in high-pressure chronic retention. Surgical management is reserved for patients who either derive no benefit from or are not willing to pursue medical therapy, those with acute and low-pressure chronic retention, and those with high-pressure chronic retention. Before surgery, evaluation of likelihood of success is essential. Patients with very high postvoid residual volumes of urine (more than 1 liter) are less likely to benefit from surgery because of the chronicity of their symptoms and consequent detrusor muscle weakness. These patients will be treated best with intermittent clean self-catheterization or a permanent urethral or suprapubic catheter.

The number of surgical management options available for bladder outflow obstruction is continually increasing. Although transurethral resection of the prostate (TURP) remains the gold standard procedure, the advancement of laser technology is likely to change this in the future. Holmium laser enucleation of the prostate (HoLEP) and vaporization of prostatic tissue (Green light laser) are being performed in specialist centers with favorable results with respect to reduced patient stay and postoperative catheterization. The widespread use of this technology is dependent on the results of ongoing comparative studies. A recently published 7-year follow-up study comparing TURP with HoLEP reported no significant difference in quality of life, maximum urinary flow, incontinence, or erectile dysfunction, with a reduced need for reoperation in the HoLEP arm of the study.[16]

Neurologic Diseases of the Lower Urinary Tract

Diseases of the central or peripheral nervous system can present with bladder underactivity or detrusor-sphincter dyssynergia and lead to bilateral hydroureter and hydronephrosis. Diabetes mellitus can also produce a flaccid denervated bladder through destruction of the peripheral nerves and can cause chronic retention and renal failure. Of diabetics who develop peripheral neuropathy, 75% to 100% will develop some neurogenic lower urinary tract dysfunction. The treatment of choice is generally intermittent clean self-catheterization, with a limited role for surgery.

INVESTIGATION OF HEMATURIA

Macroscopic, visible hematuria (macrohematuria) is perhaps the most important symptom in urologic practice, and quite apart from being alarming to the patient, it can be the first presenting sign of an underlying malignant condition of the urinary tract (most often a transitional cell tumor of the bladder). Studies show that 15% to 22% of patients with visible hematuria have an underlying genitourinary tract malignant neoplasm.

Patients with macrohematuria must be distinguished from those who have been found to have dipstick hematuria or microscopic hematuria, in whom the risk of malignant change is significantly lower (2% to 11%).

The outcome of full evaluation of a large group of patients (with both macrohematuria and microhematuria) attending a hematuria clinic is shown in Table 61-4.[17] In addition to a small but important group of patients in whom malignant disease was identified, there was a significant pickup rate of parenchymal renal disease (about 10%) presenting with both macrohematuria and microhematuria. It is also important to note the sizable proportion of patients in whom a definitive diagnosis could not be reached.

Evaluation of Macroscopic Hematuria

All adults with a single episode of macrohematuria require full urologic evaluation, including renal imaging and cystoscopy. The only

Outcome of Evaluation in a Hematuria Clinic			
Diagnoses Found	**All**	**Microscopic Hematuria**	**Macroscopic Hematuria**
No diagnosis	61	69	53
Renal cancer	0.6	0.3	0.9
Upper tract transitional cell carcinoma	0.1	0.1	0.1
Bladder cancer	12	5	19
Prostate cancer	0.4	0.2	0.6
Stone disease	4	4	3
Urinary tract infection	13	13	13
Renal parenchymal disease	10	9	10
Likelihood of Finding Malignancy			
		Microscopic Hematuria	**Macroscopic Hematuria**
Male, age >40 yr		8	24
Male, age <40 yr		2	7
Female, age >40 yr		5	19
Female, age <40 yr		0	0

Table 61-4 Outcome of evaluation in a hematuria clinic. Percentage of cases investigated, according to age. *(Data from reference 17.)*

exception to this rule occurs when an adult younger than 40 years gives a history characteristic of glomerular hematuria, such as is typically seen in IgA nephropathy, in which dark brown hematuria lasting 24 to 48 hours coincides with intercurrent mucosal infection, usually of the upper respiratory tract. This hematuria may be painless, or there may be bilateral loin ache. These young adults should be referred first for nephrologic assessment.

Evaluation of Microhematuria

Perhaps the greatest degree of overlap in practice between urologists and nephrologists occurs in the initial assessment of patients with microhematuria. Concurrent urinary tract infection will cause microhematuria and should be treated before further evaluation. Furthermore, features such as menstruation, vigorous exercise, viral illness, and trauma can themselves account for microhematuria. In the presence of a transient or treatable underlying cause other than urinary tract infection, repeat urinalysis should be performed 2 days later. In the presence of confirmed urinary tract infection, further urinalysis should be deferred until 6 weeks after treatment. If microhematuria resolves, no further investigation is required.

In 2012 the American Urological Association, after extensive systematic review of the literature, produced their guidance on the assessment and management of asymptomatic microscopic hematuria (AMH).

The definition of AMH for the purposes of these guidelines was the presence of three or more red blood cells per high power field on microscopic examination of one properly collected, noncontaminated urine sample. In addition to the benign causes listed, pyuria and bacteriuria should also be excluded with either dipstick or microscopy.

The most notable departure from previous guidance is the recommendation of urologic investigation after one episode of AMH, rather than waiting for two of three positive samples as previously suggested. There are currently no direct comparative studies identifying diagnostic yields in patients with one or more than one episode

Common Risk Factors for Urinary Tract Malignancy in Patients with Microhematuria
Male gender
Age (>35 years)
Past or current smoking
Occupational or other exposure to chemicals or dyes (benzenes or aromatic amines)
Analgesic abuse
History of gross hematuria
History of urologic disorder or disease
History of irritative voiding symptoms
History of pelvic irradiation
History of chronic urinary tract infection
History of exposure to known carcinogenic agents or chemotherapy such as alkylating agents
History of chronic indwelling foreign body

Box 61-1 Risk factors for malignancy in patients with microhematuria.

of AMH. Indirect comparison, however, reveals a diagnostic yield of urinary tract malignancy of 3.6% and 1.8% in patients with one or more than one episode of AMH, respectively.[18] Dipstick-positive hematuria may still herald significant disease in the absence of red cells on microscopy because red cells may lyse in alkaline or hypotonic urine before reaching the laboratory for analysis.[19] Urine microscopy is discussed further in Chapter 4.

Complete evaluation of microhematuria includes a history and physical examination, laboratory analysis, and radiologic imaging of the upper urinary tract, followed by cystoscopy (Fig. 61-7). In women, urethral and vaginal examinations should be performed to exclude local causes of microscopic hematuria. In uncircumcised men, the foreskin should be retracted to expose the glans penis, if possible. If a phimosis is present, a catheter specimen of urine may be required. Patients with urinary tract infection should be treated appropriately, and urinalysis should be repeated 6 weeks after treatment. If the hematuria resolves with treatment, no additional evaluation is necessary. An estimate of renal function should be obtained (estimated glomerular filtration rate [eGFR], creatinine, or blood urea nitrogen [BUN]) because intrinsic renal disease may have implications for consequent imaging and treatment. The remaining laboratory investigations are guided by specific findings of the history, physical examination, and urinalysis. Multiphase CT urography, which allows evaluation of renal parenchyma and also the collecting system, has been shown to have the highest sensitivity and specificity for imaging the upper tracts. If CT urography is unavailable, then IVU, and ultrasound combined with plain abdominal radiography are alternative imaging strategies. Cystoscopy is now advocated in all patients with AMH who are older than 35 years and those under the age of 35 years with risk factors for urologic malignancy or clinical suspicion of malignancy (Box 61-1). The use of adjuncts to AMH workup such as urine cytology and other urine biomarkers is no longer advocated.

Significant proteinuria (>0.3 g/24 h), red cell casts, predominance of dysmorphic red blood cells in the urine, or renal impairment should prompt referral to a nephrologist and evaluation for parenchymal renal disease. When present, red cell casts are virtually pathognomonic of glomerular bleeding, but they are often absent in low-grade glomerular disease. Accurate determination of red blood cell morphology requires inverted phase contrast microscopy. In general, glomerular bleeding is associated with more than 80%

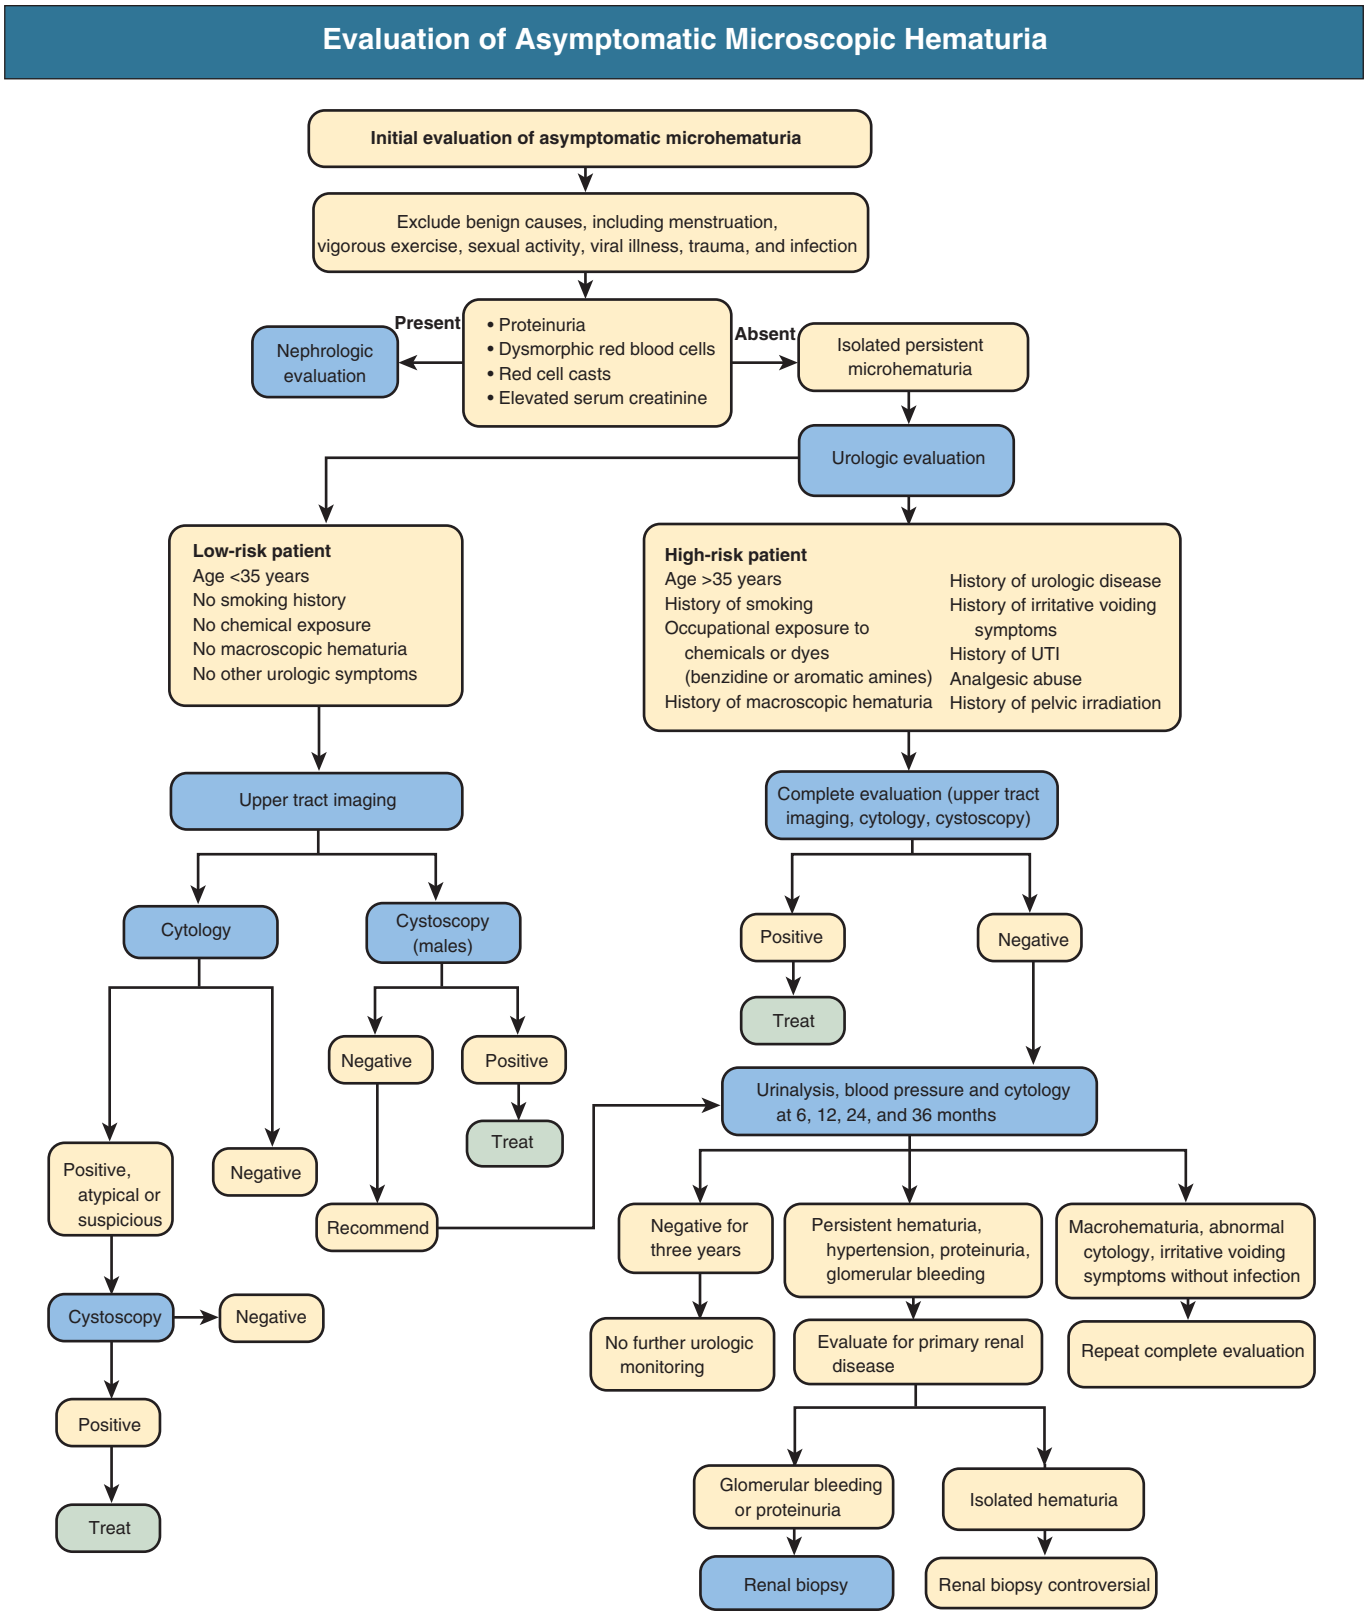

Figure 61-7 Evaluation of asymptomatic microscopic hematuria. *UTI,* Urinary tract infection.

dysmorphic red blood cells, and lower urinary tract bleeding is associated with more than 80% normal red blood cells.[20] This assessment is operator dependent. An alternative is to assess urinary red cell size by Coulter counter analysis because dysmorphic red cells are smaller than normal red cells, but this method is not useful when red cell numbers in the urine are small. Even in the absence of features of glomerular bleeding, many patients with isolated microscopic hematuria have glomerular disease, most commonly IgA nephropathy or thin basement membrane nephropathy.[21] Because there is a low risk of progressive renal disease, renal biopsy in this setting is not usually

recommended. Nevertheless, one study showed that microhematuria unexplained by urologic evaluation carries a twofold risk for eventual development of ESRD,[22] so these patients should be observed for the development of hypertension, renal impairment, or proteinuria.

Cyclophosphamide

Past treatment with cyclophosphamide increases the risk of bladder cancer up to ninefold, probably in a dose- and duration-dependent manner. Tumors have been reported 6 to 13 years after cyclophosphamide exposure and are often high grade. Hematuria is also common after cyclophosphamide in the absence of cancer. If full evaluation does not identify a cause of hematuria, there is no agreed-on surveillance protocol; it is not clear whether routine follow-up by cystoscopy and urine cytology is valuable, although a high index of suspicion should be maintained.

INVESTIGATION AND MANAGEMENT OF A RENAL MASS

The incidence of renal cancer has more than doubled in the last 30 years, and this cancer now accounts for 3% of all cancers. It is the third most common tumor of the urinary tract but is the most lethal. The apparent increased incidence is partly attributed to the widespread use of cross-sectional and sonographic imaging; more than 50% of new cases are incidental findings on CT, ultrasound, or magnetic resonance imaging (MRI).

The primary goal in investigating a renal mass is to exclude malignancy. Ultrasound has been reported to be 79% sensitive for the detection of renal parenchymal masses but does not detect lesions smaller than 5 mm. Until recently, the gold standard method of assessing renal masses was CT scanning with contrast enhancement, with use of no more than 5-mm slices. MRI, especially with T2-weighted images, may be superior to CT in the correct characterization of benign lesions.[23] Choice of imaging techniques and their interpretation are discussed further in Chapter 5.

Any solid mass larger than 3 cm should be regarded as malignant unless the radiologist can be confident that the mass is an angiomyolipoma because there is fat on CT images. A biopsy may be required if there is evidence suggestive of an alternative diagnosis (e.g., lymphoma or metastasis from another site) to guide appropriate management. In a recent study, in cases in which there was diagnostic uncertainty, a biopsy of the mass produced a high diagnostic accuracy rate (91.5%) with a low incidence of bleeding (2.8%) and no evidence of tumor seeding.[24]

The management of mixed cystic and solid masses is more of a problem. Table 61-5 shows the Bosniak classification of cystic renal masses.[25] This classification, based on CT appearances, provides the basis for management according to risk of malignancy. The evaluation of multiple cystic lesions in the kidney is discussed further in Chapter 47.

Tumor size is important; in a large retrospective study of 2935 patients with surgically treated solid renal tumors, 46% of lesions smaller than 1 cm were benign compared with 22% and 10% of tumors 1 to 2 cm and 4 to 5 cm, respectively. Furthermore, only 2.3% of cancers smaller than 1 cm were of high grade, whereas for tumors larger than 7 cm, the percentage was 58%.[26] Surveillance studies of small renal tumors have shown a median growth rate of 0.28 cm per year; about 30% of these lesions will not increase in size.

Traditionally, radical nephrectomy has been considered the gold standard treatment for localized renal cancers; however, partial nephrectomy for small renal masses is becoming increasingly popular. Comparison of these two approaches for lesions both smaller than 4 cm and 4 to 7 cm (T1 and T2 disease, respectively)

Classification and Management of Cystic Renal Masses

Bosniak Class	Features on Imaging	Comment	Management
Class I: simple benign cyst	Round or oval Uniform density <20 HU Unilocular No perceptible wall No contrast enhancement	Majority of asymptomatic cystic lesions	No further intervention required
Class II: benign cyst	One or two nonenhancing septa Calcifications in the wall or septum Hyperdense lesions (50-90 HU, resulting from the presence of blood, protein, or colloid) < 3 cm No contrast enhancement		No further intervention required
Class II F: probable benign cyst	Multiple hairline septa "Perceived" enhancement Nodular calcification Hyperdense lesions >3 cm	"Perceived" enhancement resulting from contrast within capillaries of septa	Surveillance with CT scans every 6-12 months
Class III: indeterminate cystic lesions	One or more of the following: Thick, irregular borders Irregular calcifications Thickened or enhancing septa Multilocular form Uniform wall thickening Small nonenhancing nodules	About 40% are neoplastic Magnetic resonance imaging may improve characterization	Surgical exploration
Class IV: presumed malignant cystic masses	Appear malignant Heterogeneous cysts Shaggy, thickened walls or enhancing nodules	Appearances result from necrosis and liquefaction of a solid tumor or a tumor growing in the wall	Surgical exploration

Table 61-5 Classification and management of cystic renal masses. Approach to renal mass found incidentally by ultrasound or computed tomography (CT) scanning. All patients with symptomatic renal masses should be referred for urologic assessment. Classification after Bosniak. *HU,* Hounsfield units. *(Data from reference 25.)*

has shown equal tumor outcome and a reduction in long-term cardiovascular complications with partial nephrectomy in younger patients.[27] Furthermore, increased early detection of small renal lesions with a possibility of late contralateral tumor development should be considered when surgery is planned. Radical nephrectomy should therefore be reserved for large renal cancers not amenable to partial nephrectomy.

Cryosurgery and radiofrequency ablation via open, laparoscopic, or percutaneous approaches are promising options for the treatment of localized renal cancers. There is currently no consensus on the maximum size of lesions amenable to these techniques, but they are usually reserved for tumors smaller than 4 cm in diameter. Laparoscopic cryotherapy was reported in one series to result in 5-year cancer-specific survival of 100%.[28] Radiofrequency ablation has also resulted in a 5-year recurrence-free survival rate of 93%.[29] Such treatments offer the advantages of nephron-sparing surgery in addition to their potential use in patients with high surgical risk. Disadvantages include absence of histologic confirmation of complete tissue destruction and potential for more difficult salvage surgery in the presence of local recurrence. These techniques to date have been used on a cohort of highly selected patients, and there are no comparative data or ongoing RCTs comparing radical and partial nephrectomy, cryosurgery, and radiofrequency ablation.

Adjunctive Therapy for Renal Cancer

The 5-year survival for patients diagnosed with localized renal cell carcinoma (RCC) is approximately 90%. However, up to one third of patients with RCC present with metastasis, and 5-year survival falls to 60% and 10% in the presence of regional and distant metastasis, respectively. Metastatic RCC (mRCC) is resistant to commonly used chemotherapeutic agents, and cytokine therapy with either interleukin (IL)–2 or interferon-α (IFN-α) was standard treatment for mRCC in the United States and Europe until 2005. Although more effective than traditional chemotherapy, it produced only modest response rates with significant toxicity.[30] Identification of the molecular pathways implicated in the progression from localized RCC to mRCC has led to the development of new targeted therapies directed against vascular endothelial growth factor (VEGF) (sorafenib, sunitinib, bevacizumab, pazopanib) and mammalian target of rapamycin (mTOR) (temsirolimus, everolimus). In Phase III trials these agents caused improvements when compared with cytokine therapy in both median progression-free survival (from 2 to 8 months to 4 to 11 months) and median overall survival (from 8 to 22 months to 11 to 26 months).[31-35] Furthermore, they caused improvements in progression-free survival and overall survival when used as second-line therapy for mRCC. There is not yet an international consensus on which agent or combination of agents is superior, although in the United Kingdom pazopanib is now considered first-line therapy in mRCC.[36] The adverse effects of pazopanib include hypertension, gastrointestinal hemorrhage, and fatigue.

Natural History of Renal Impairment After Surgical Treatment of Renal Cancer

It is well established that normal renal function can be preserved in the long term after donor transplant nephrectomy. However, donors are highly selected to minimize comorbidities and generally are younger than patients treated for renal tumors. After surgery for suspected renal cancer, when the residual renal mass is small, there is significant risk of late sequelae, including proteinuria, glomerulosclerosis, and progressive renal failure. These risks are greater when radical rather than partial nephrectomy is used. A retrospective survey studied 662 patients who underwent surgery for a tumor 4 cm or smaller, with normal preoperative serum creatinine concentration and a normal contralateral kidney on imaging[37]; 26% of patients had postoperative GFR lower than 60 ml/min, and mean GFR was 69 ml/min, significantly lower than reported after donor nephrectomy (92 to 103 ml/min). Postoperatively, the 3-year and 5-year probabilities that GFR remained above 60 ml/min were 80% and 67% after partial nephrectomy and 35% and 23% after radical nephrectomy. The probabilities that GFR remained above 45 ml/min were 95% and 93% after partial nephrectomy and only 64% and 57% for radical nephrectomy at 3 and 5 years postoperatively. Considering the excellent cancer-specific survival (>90%) of patients treated for renal tumors smaller than 4 cm, treatment-induced renal failure may have significant long-term consequences.

In another study, the effect of nephron-sparing surgery on solitary kidneys was assessed in a series of 400 patients.[38] Preoperatively, 56% of the patients had serum creatinine concentrations above 1.5 mg/dl (136 µmol/l). Transient renal failure was observed in 21% of patients postoperatively; hemodialysis was necessary in 3.5%. At a mean follow-up of 44 months, 38% had a greater than 50% increase in serum creatinine, although only 5% of patients progressed to end-stage renal disease (ESRD) requiring renal replacement therapy. Overall, patients with a congenital single kidney tolerated partial nephrectomy better than did patients with acquired solitary kidneys. Other factors affecting long-term renal function were age and the percentage of parenchyma resected but not the use of hypothermia or the duration of renal ischemia during surgery.

Renal Cell Carcinoma in von Hippel–Lindau Disease

von Hippel–Lindau disease (VHL) is a rare autosomal dominant condition with a predisposition to the development of RCC. The genetics, clinical manifestations, and general management of VHL are discussed further in Chapter 47. The incidence of RCC in patients with VHL is about 45%. On histologic examination, the tumors are of the clear cell type, often multifocal and bilateral, and can be solid or cystic. The mean age at diagnosis is 39 years, and there is a 30% to 35% risk for tumor progression, metastasis, and death.

A serial CT study[39] identified multiple lesions (on average, eight per patient) in VHL patients, of which 74% were classified as cysts, 8% as cysts with solid components, and 18% as solid masses. The solid components of cysts and the solid lesions almost always contained RCC. During a mean 2.4-year follow-up (range, 1 to 12 years), most cysts remained the same size (71%) or enlarged (20%), and 9% became smaller. On the contrary, 95% of solid masses increased in size. Although it is generally thought that the cysts are premalignant, the transformation of a simple cyst to a solid lesion was observed in only two patients. VHL patients require multidisciplinary management. Surgical intervention is deferred for tumors smaller than 3 cm because metastasis is rare. In addition, bilateral nephrectomy should be avoided, if possible, because of the substantial morbidity associated with renal replacement therapy. The standard of care for these patients is partial nephrectomy, and a 10-year survival rate of 81% has been reported.

The results of nephron-sparing surgery for VHL appear less satisfactory than for sporadic RCC because of a high risk of local tumor recurrence. Repeated surgery may be needed for new or growing lesions, and for this reason the use of minimally invasive methods is being investigated. Repeated ablation of tumors with radiofrequency and cryotherapy is possible with minimal morbidity; however, the long-term effectiveness of these methods has not yet been established.

SECTION XI

Tubulointerstitial and Vascular Diseases

CHAPTER 62

Acute Interstitial Nephritis

Jerome A. Rossert and Evelyne A. Fischer

DEFINITION

Acute interstitial nephritis (AIN) is an acute, often reversible disease characterized by inflammatory infiltrates within the interstitium. AIN is a rare cause of acute kidney injury (AKI), but it should not be overlooked because it usually requires specific therapeutic interventions.

PATHOGENESIS

Most studies suggest that AIN is an immunologically induced hypersensitivity reaction to an antigen that is classically a drug or an infectious agent. Evidence for a hypersensitivity reaction in drug-induced AIN includes the following: it occurs only in a small percentage of individuals; it is not dose dependent; it is often associated with extrarenal manifestations of hypersensitivity; it recurs after accidental reexposure to the same drug or to a closely related one; and it is sometimes associated with evidence of delayed-type hypersensitivity reaction (renal granulomas). Similarly, AIN secondary to infections can be differentiated from pyelonephritis by the relative absence of neutrophils in the interstitial infiltrates and the failure to isolate the infective agent from the renal parenchyma, again suggesting an immunologic basis to the disease.

Studies of experimental models of AIN have shown that three major categories of antigens can induce AIN.[1] Antigens may be tubular basement membrane (TBM) components (such as the glycoproteins 3M-1 and TIN-Ag/TIN1), secreted tubular proteins (such as Tamm-Horsfall protein), or nonrenal proteins (such as from immune complexes).

Although some types of human AIN may be secondary to an immune reaction directed against a renal antigen, the majority of cases of AIN are probably induced by extrarenal antigens, being produced in particular by drugs or infectious agents. These antigens may be able to induce AIN by a variety of mechanisms. These mechanisms include binding to kidney structures ("planted antigen"); acting as haptens that modify the immunogenicity of native renal proteins; mimicking renal antigens, resulting in a cross-reactive immune reaction; and precipitating within the interstitium as circulating immune complexes.

Studies of experimental models of AIN show that their pathogenesis involves either cell-mediated immunity or antibody-mediated immunity (Fig. 62-1). In humans, most forms of AIN are not associated with antibody deposition, which suggests that cell-mediated immunity plays a major role. This hypothesis is reinforced by the fact that interstitial infiltrates usually contain numerous T cells and that these infiltrates sometimes form granulomas. Nevertheless, deposition of anti-TBM antibodies or of immune complexes can be observed occasionally in renal biopsy specimens, and antibody-mediated immunity may play a role in the pathogenesis of the disease in these cases.

Formation of immune complexes within the interstitium, or interstitial infiltration with T cells, will result in an inflammatory reaction. This reaction is triggered by many events, including activation of the complement cascade by antibodies and release of inflammatory cytokines by T lymphocytes and phagocytes (see Fig. 62-1). Although the interstitial inflammatory reaction may resolve without sequelae, it sometimes induces interstitial fibroblast proliferation and extracellular matrix synthesis, leading to interstitial fibrosis and chronic renal failure. Cytokines such as transforming growth factor β appear to play a key role in the latter process.

EPIDEMIOLOGY

Acute interstitial nephritis is an uncommon cause of AKI and is identified in only about 2% to 3% of all renal biopsy specimens, although this proportion could be increasing.[2] However, it may account for up to 10% to 25% of patients undergoing renal biopsy for unexplained or drug-induced AKI, respectively.[2] Although AIN can occur at any age, it appears to be rare in children.

Before antibiotics were available, AIN was most commonly associated with infections, such as scarlet fever and diphtheria. Currently, AIN is most often induced by drugs, particularly antimicrobial agents, proton pump inhibitors, and nonsteroidal anti-inflammatory drugs (NSAIDs). Drug-induced AIN appears to account for about 75% to 90% of all cases.

DRUG-INDUCED ACUTE INTERSTITIAL NEPHRITIS

Clinical Manifestations

In the 1960s and 1970s, most cases of drug-induced AIN were caused by methicillin, and the clinical manifestations of methicillin-induced AIN were considered the prototypical presentation of AIN. Since then, many other drugs have been implicated in the induction of AIN (Box 62-1), of which antimicrobial agents (in particular, β-lactam antibiotics, sulfonamides, fluoroquinolones, and rifampin) and NSAIDs (especially fenoprofen) as well as cyclooxygenase-2 (COX-2) inhibitors have been most commonly involved. Antiulcer agents, diuretics, phenindione, phenytoin, and allopurinol have also been reported to cause AIN. There are increasing numbers of reports of AIN induced by proton pump inhibitors, with more than 70 reported biopsy-proven cases.[3] Recently, cases of drug-induced AIN have also been reported in human immunodeficiency virus (HIV)–infected patients treated with highly active antiretroviral therapy (HAART)[4] and in cancer patients treated with tyrosine kinase inhibitors.[5] Most other drugs have only rarely been linked with AIN (see Box 62-1). The clinical characteristics of drug-induced AIN are now recognized as much more varied and nonspecific than the spectrum seen in classic methicillin-induced AIN (Fig. 62-2).[2,6,7]

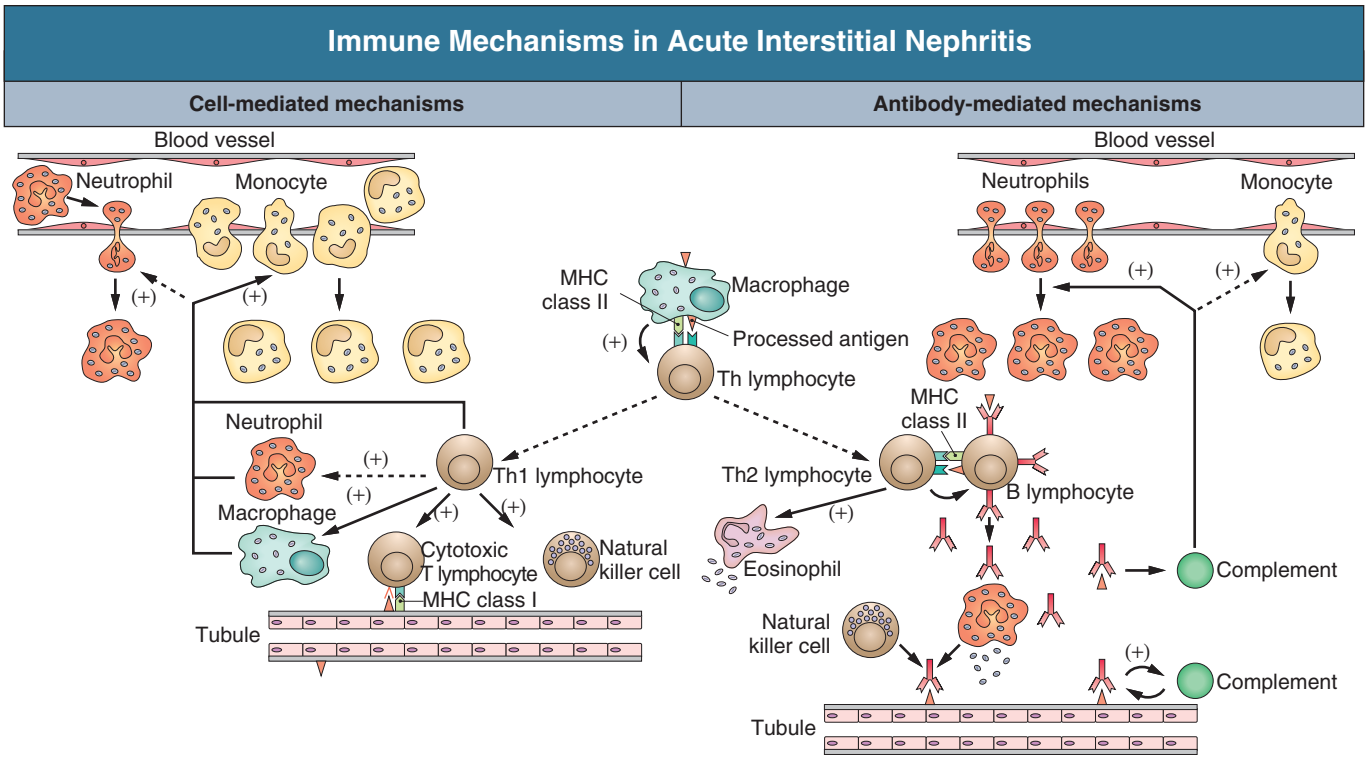

Figure 62-1 Immune mechanisms that can be involved in acute interstitial nephritis. Both cell-mediated and antibody-mediated mechanisms occur. The cell-mediated mechanism is primarily associated with macrophages and T cells. The antibody-mediated mechanism is frequently associated with neutrophil or eosinophil infiltration as well as with local complement activation. *MHC,* Major histocompatibility complex.

Renal Manifestations

Symptoms of AIN usually develop a few days to a few weeks after the inciting drug is started, although cases have occurred months after initial exposure to the drug. The typical presentation is sudden impairment in renal function, associated with mild proteinuria (<1 g/day) and abnormal urinalysis, in a patient with flank pain, normal blood pressure, and no edema. In patients with AIN not caused by methicillin, the clinical presentation is often incomplete (see Fig. 62-2), and AIN should be considered in any patient with unexplained AKI.[2,6,7] The renal dysfunction may be mild or severe; dialysis is required in about one third of patients. Hematuria and pyuria are present in a little more than half of the patients, and although leukocyte casts are common, hematuria is almost never associated with red blood cell casts. Flank pain, reflecting distention of the renal capsule, is observed in about one third of the patients and can be the main complaint on hospital admission. On occasion, patients have a low fractional excretion of sodium.

Standard imaging procedures show kidneys normal in size or slightly enlarged. Ultrasound usually discloses an increased cortical echogenicity (comparable to or higher than that of the liver).

Extrarenal Manifestations

Extrarenal symptoms consistent with a hypersensitivity reaction are occasionally observed, including low-grade fever, maculopapular rash (Fig. 62-3), mild arthralgias, and eosinophilia. If patients with methicillin-induced AIN are not considered, each of these symptoms is present in less than half of the patients (see Fig. 62-2), and all these symptoms are present together in less than 10% of patients.[2,6,7] With some drugs, other manifestations of hypersensitivity, such as hemolysis or hepatitis, can be present. Serum IgE levels may also be elevated.

The association of AKI either with clinical signs suggestive of hypersensitivity or with eosinophilia should lead to consideration of a diagnosis of AIN. However, signs of hypersensitivity can also be observed in patients with AKI not related to AIN, including patients with drug-induced acute tubular necrosis.

Other Specific Drug Associations

The clinical and biologic manifestations of AIN may have some specificity, depending on the drug involved.

As outlined earlier, methicillin-induced AIN is characterized by a high frequency of abnormal urinalysis and extrarenal symptoms and by good preservation of renal function. Renal failure has been reported in only about 50% of patients (see Fig. 62-2).

More than 200 cases of rifampin-induced AKI have been reported. Most have been observed either after readministration of rifampin or several months after intermittent administration of the drug. Renal failure is usually associated with the sudden onset of fever, gastrointestinal symptoms (nausea, vomiting, diarrhea, abdominal pain), and myalgias. It may also be associated with hemolysis, thrombocytopenia, and less frequently hepatitis. Renal biopsy typically discloses tubular injury in addition to interstitial inflammatory infiltrates. Although circulating anti-rifampin antibodies are usually found in these patients, immunofluorescence staining of renal biopsy specimens has been negative in most cases, suggesting that cell-mediated immunity plays a key role in the induction of the nephritis. In a few cases, AIN developed after continuous treatment with rifampin for 1 to 10 weeks. It was almost never associated with extrarenal symptoms or with anti-rifampin antibodies, and renal biopsy specimens showed severe interstitial infiltrates but few tubular lesions.

Phenindione-induced AIN is generally associated with the development of hepatitis, which can be fatal.

Drugs Responsible for Acute Interstitial Nephritis (AIN)

Box 62-1 Drugs responsible for acute interstitial nephritis. Drugs most commonly involved are in bold. *NSAIDs,* Nonsteroidal anti-inflammatory drugs. *Drugs that can cause granulomatous AIN.

Allopurinol-induced AIN appears to occur more often in patients with chronic kidney disease (CKD) and is usually seen in association with rash and liver dysfunction, and sometimes with full manifestations of the Stevens-Johnson syndrome. This severe allergic reaction is primarily observed in patients with the human leukocyte antigen (HLA)–B58 genotype. It has been suggested that the decreased excretion of oxypurinol, a metabolite of allopurinol, might favor the occurrence of AIN. There is also some experimental evidence that in the setting of renal impairment, allopurinol may precipitate as microcrystals or crystals and cause direct nephrotoxicity. Whether this can occur in humans is unknown, but it may provide an additional reason to reduce allopurinol doses in patients with CKD.

Acute interstitial nephritis occurring secondary to NSAIDs is associated with nephrotic syndrome in about three fourths of cases. This usually occurs in patients older than 50 years, and although it has been observed with all NSAIDs, including COX-2–selective

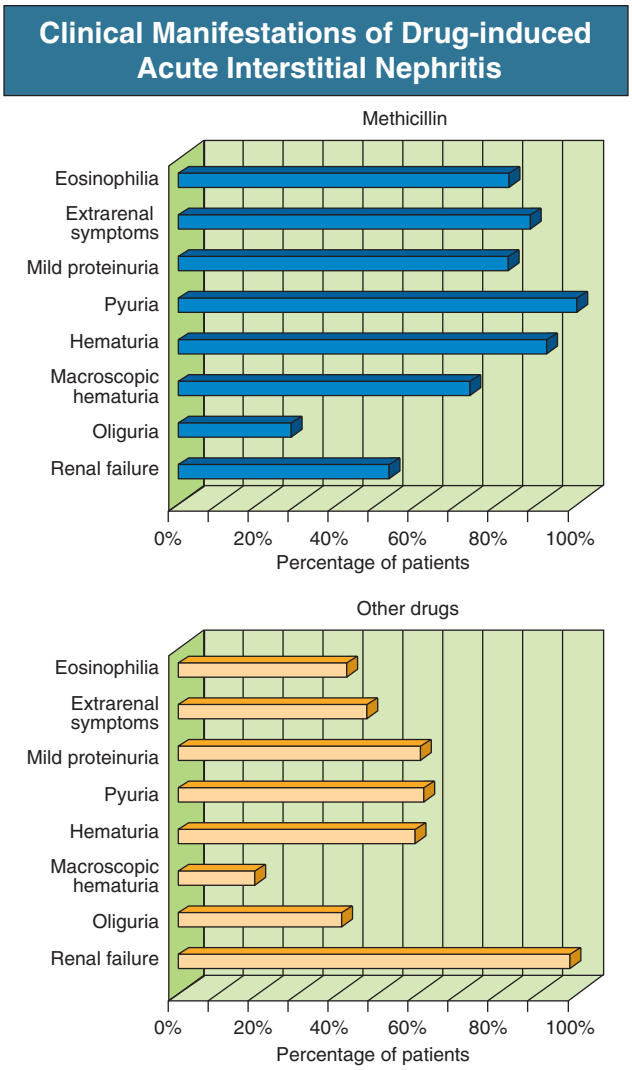

Figure 62-2 Clinical manifestations of drug-induced acute interstitial nephritis (AIN). Data were pooled from different case reports, including 95 patients with methicillin-induced AIN and more than 200 patients with other drug-induced AIN. Patients with AIN associated with a nephrotic syndrome are not included.

Figure 62-3 Maculopapular rash in a patient with drug-induced acute interstitial nephritis (AIN). Such cutaneous lesions occur in about 40% of patients with drug-induced AIN, but they can also be seen in patients with drug-induced acute tubular necrosis.

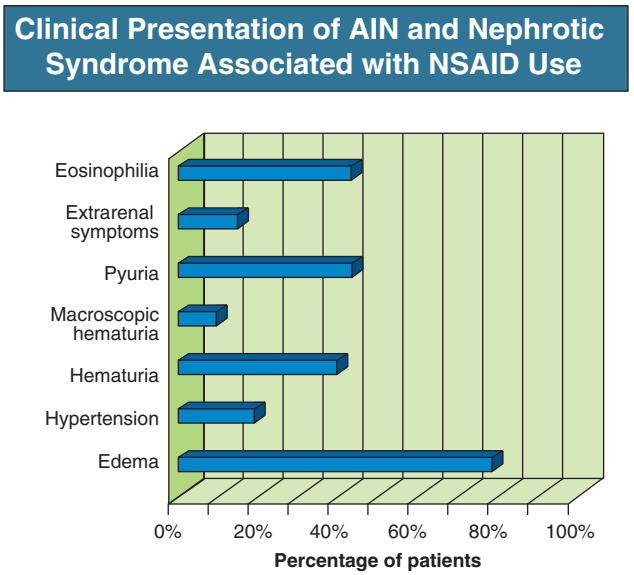

Figure 62-4 Clinical presentation of acute interstitial nephritis (AIN) and nephrotic syndrome associated with nonsteroidal anti-inflammatory drug (NSAID) use. Data were pooled from different case reports from more than 60 patients.

inhibitors, half of the incidents have been reported with fenoprofen. Most occurrences develop after the patient has taken NSAIDs for some months (mean, 6 months), but AIN can occur within days or after more than a year. With the exception of the heavy proteinuria and associated edema, the presentation of these patients is similar to that of patients with other drug-induced AIN (Fig. 62-4). The main difference is that extrarenal symptoms are present in only about 10% of patients. Renal disease caused by NSAIDs must be differentiated from other NSAID-induced nephropathies, including hemodynamically mediated AKI, papillary necrosis, and NSAID-induced membranous nephropathy. Drugs other than NSAIDs can rarely induce AIN associated with a nephrotic syndrome; a few cases have been reported after administration of ampicillin, rifampin, lithium, interferon, phenytoin, pamidronate, and D-penicillamine.

Pathology

The hallmark of AIN is the presence of inflammatory infiltrates within the interstitium (Fig. 62-5). These infiltrative lesions are often patchy, predominating in the deep cortex and in the outer medulla, but they can be diffuse in severe cases. They are composed mostly of T cells and monocytes-macrophages, but plasma cells, eosinophils, and a few neutrophilic granulocytes may also be present. The relative number of $CD4^+$ T cells and $CD8^+$ T cells is variable from one patient to another. In some cases, T lymphocytes infiltrate across the TBM and between tubular cells, mainly in distal tubules, and the resulting lesion is referred to as tubulitis.

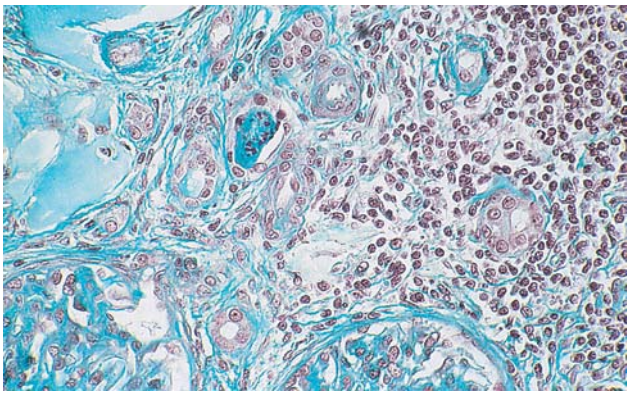

Figure 62-5 Drug-induced acute interstitial nephritis. On light microscopy, the characteristic feature is interstitial infiltration with mononuclear cells, with normal glomeruli. It is usually associated with interstitial edema and tubular lesions. *(Courtesy Dr. B. Mougenot, Paris VI University, Paris.)*

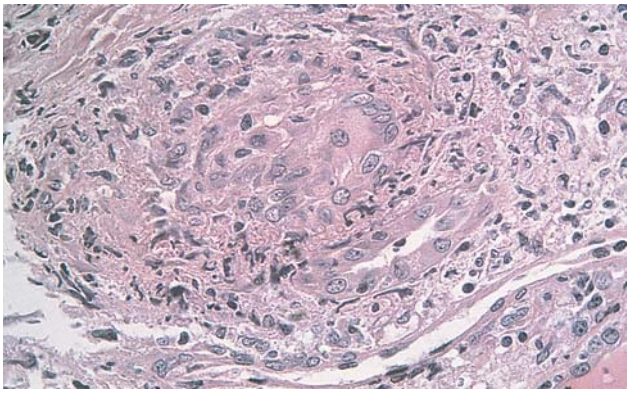

Figure 62-6 Drug-induced granulomatous acute interstitial nephritis. Some drugs can induce the formation of interstitial granulomas, which reflect a delayed-type hypersensitivity reaction. *(Courtesy Dr. B. Mougenot, Paris VI University, Paris.)*

In some cases of drug-induced AIN, renal biopsy shows interstitial granulomas (Fig. 62-6). These granulomas are usually sparse and non-necrotic, with few giant cells, and are associated with nongranulomatous interstitial infiltrates. Granulomas are also found in AIN related to infection (see Table 62-2), sarcoidosis, Sjögren syndrome, and Wegener granulomatosis.

Interstitial infiltrates are always associated with an interstitial edema, which is responsible for separating the tubules (see Fig. 62-5). They can also be associated with focal tubular lesions, which range from mild cellular alterations to extensive necrosis of epithelial cells and are sometimes associated with a disruption of the TBM. These tubular lesions usually predominate where the inflammatory infiltrates are most extensive.

Tubulointerstitial lesions are not associated with vascular or glomerular lesions. Even in AIN associated with a nephrotic syndrome, glomeruli appear normal on light microscopy; glomerular lesions are similar to those seen in minimal change disease (see Chapter 17).

In most patients with AIN, renal biopsy specimens do not show immune deposits, and both immunofluorescence and electron microscopy are negative. Nevertheless, staining of the tubular or capsular basement membrane for IgG or complement may occasionally be seen by immunofluorescence; the staining pattern is either granular or linear (Fig. 62-7). Linear fixation of IgG along the TBM indicates the presence of antibodies directed against membrane antigens or against drug metabolites bound to the TBM, and circulating anti-TBM antibodies have been detected in some cases. These linear deposits are seen mostly in patients taking methicillin, NSAIDs, phenytoin, or allopurinol.

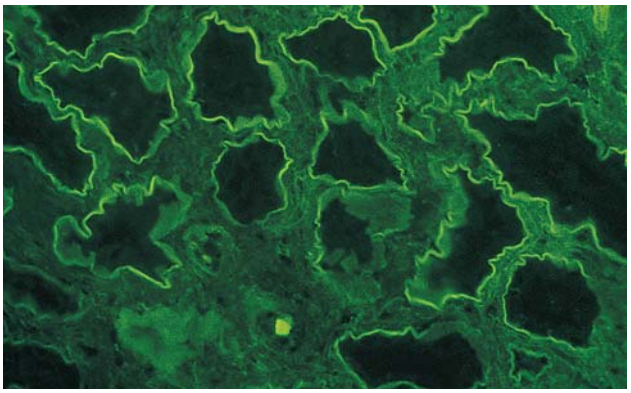

Figure 62-7 Linear deposits of IgG in methicillin-induced acute interstitial nephritis. Deposits along the tubular basement membrane (TBM) are shown on immunofluorescence microscopy. These antibodies recognize either a component of the TBM or a methicillin metabolite (dimethoxyphenylpenicilloyl) bound to the TBM. *(Courtesy Dr. B. Mougenot, Paris VI University, Paris.)*

Diagnosis

The most accurate way to diagnose AIN is by renal biopsy. However, both eosinophiluria and gallium scanning have been suggested as helpful in making the diagnosis.

Eosinophils can be detected in urine with use of either the Wright stain or the Hansel stain, both of which are eosin–methylene blue combinations, but the Hansel stain appears to be much more sensitive.[8,9] The result of this test is usually considered positive if more than 1% of urinary white blood cells are eosinophils. However, although eosinophiluria is frequently used to corroborate the diagnosis of drug-induced AIN, review of four large series shows that this test has rather poor sensitivity (67%) and a low positive predictive value, even when only patients with AKI are considered (50%) (Table 62-1).[8-11] In these series, the specificity of the test was 87%, and eosinophiluria was also observed in patients with acute tubular necrosis, postinfectious or crescentic glomerulonephritis (GN), atheroembolic renal disease, urinary tract infection, urinary schistosomiasis, and even pre-renal AKI. In particular, 28% of patients with urinary tract infection had eosinophiluria. Thus, whereas screening for eosinophiluria is still the commonly used screening test, it lacks sensitivity and specificity, and firm diagnosis requires renal biopsy and/or a clinical response on withdrawal of the drug of concern.

An increased renal uptake of gallium 67 has been reported in AIN.[12] Analysis of available series shows that in 45 patients with AIN, 88% had an abnormal renal scan (maximum after 48 hours), whereas it was normal in 17 of 18 patients with acute tubular necrosis. However, these studies were small and retrospective, and gallium 67 renal scanning is not specific for AIN and may be abnormal in patients with pyelonephritis, cancer, or glomerular diseases. Therefore, we also do not recommend use of gallium scanning as a diagnostic tool.

Because the clinical presentation of AIN may be polymorphic and because noninvasive diagnostic procedures have important limitations, renal biopsy is often essential for the diagnosis of AIN. Several studies have shown that prebiopsy diagnosis may be incorrect in a substantial number of patients.

Eosinophiluria in the Diagnosis of Acute Interstitial Nephritis (AIN)					
	Corwin et al.[8]	Nolan et al.[9]	Corwin et al.[10]	Ruffing et al.[11]	All series n (%)
Patients with AIN (n)	9	11	8	15	43
Eosinophiluria	8	10	5	6	29 (67%)
No eosinophiluria	1	1	3	9	14 (33%)
Patients without AIN (n)	56	81	175	184	496
Eosinophiluria	27	12	15	10	64 (13%)
No eosinophiluria	29	69	160	174	432 (87%)
Patients with Acute Kidney Injury					
Patients with AIN (n)	9	11	8	15	43
Eosinophiluria	8	10	5	6	29 (67%)
No eosinophiluria	1	1	3	9	14 (33%)
Patients without AIN (n)	14	46	84	23	167
Eosinophiluria	6	5	2	6	19 (11%)
No eosinophiluria	8	41	82	17	148 (89%)

Table 62-1 Eosinophiluria in the diagnosis of acute interstitial nephritis. The four large available series were analyzed to assess the value of eosinophiluria (defined by the presence of >1% of eosinophils in urine) for the diagnosis of drug-induced AIN. Only 67% of AIN was associated with eosinophiluria, whereas 13% of non-AIN was associated with eosinophiluria.

Identification of the Causative Drug

Identification of the causative drug is relatively easy when AIN occurs in a patient taking only one drug. However, patients are often taking more than one drug capable of inducing AIN. Two biologic tests have been used, primarily in research laboratories, to help identify the causative drug: the lymphocyte stimulation test and the identification of circulating antidrug antibodies.

Identification of circulating antidrug antibodies has been used mostly for patients thought to have AIN induced by rifampin. Antirifampin antibodies are present in most patients with rifampin-induced AIN; but unfortunately, they have also been detected in patients taking rifampin and having no adverse reaction to the drug, so this test has a limited diagnostic value.

The lymphocyte stimulation test has been used since the 1960s to identify a sensitizing drug. It is based on the measurement of lymphocyte proliferation in the presence of different drugs; a high proliferative index reflects a sensitization of T lymphocytes against the drug. However, this test lacks specificity and we do not recommend using it.

Natural History

Drug-induced AIN was long considered benign, with complete recovery of renal function if the inciting agent was removed. For example, with methicillin-induced AIN, a complete normalization of serum creatinine has been observed in about 90% of uremic patients. Nevertheless, although hematuria, leukocyturia, and extrarenal symptoms usually disappeared within 2 weeks, complete recovery of renal function was often delayed, with an average recovery time of about 1.5 months.

More recent studies show that with drugs other than methicillin, the course of AIN is not always benign and that serum creatinine remains elevated in about 40% to 50% of patients.[6,13] Moreover, as for methicillin, recovery of renal function can be delayed, and an increase in serum creatinine can persist for several weeks. Unfortunately, few prognostic factors are available. The severity of renal failure does not appear to be linked with the prognosis.[6] It has been suggested that the presence on renal biopsy of diffuse neutrophil- or macrophage-rich infiltrates, interstitial granulomas, or tubular atrophy is associated with a poor prognosis, but this has not been consistently found in all series. The best prognostic factors may actually be the duration of AKI and the severity of interstitial fibrosis.

Treatment

In addition to removal of the inciting agent, corticosteroids have been used to treat AIN. Most commonly, patients received an initial daily dose of 1 mg of prednis(ol)one per kilogram, which was then tapered during about 1 month; this oral therapy was sometimes associated with pulses of methylprednisolone. Analysis of series comparing patients who did or did not receive corticosteroids does not allow firm conclusion about the effect of corticosteroid therapy on long-term renal function, all the series being small, uncontrolled, and retrospective. However, some authors advocate an early and systematic use of a short course of corticosteroids.[7,13] In addition, it seems that a brief course of corticosteroids can hasten the recovery of renal function. In different series, corticosteroids rapidly induced a reduction in serum creatinine in patients whose renal function did not improve within about 1 week after discontinuation of the inciting agent. It is interesting to note that in patients with NSAID-induced AIN, corticosteroids do not seem to modify the course of the nephrotic syndrome.

On the basis of anecdotal case reports, some authors have also advocated use of mycophenolate mofetil in patients resistant to corticosteroids.[14]

We recommend administration of a short course of prednis-(ol)one in patients who are dialysis dependent or whose renal function fails to improve rapidly within 1 week after discontinuation of the inciting drug and return to baseline values, provided the diagnosis of AIN has been confirmed by renal biopsy. We initiate the treatment with a dose of prednis(ol)one of 1 mg/kg/day and not higher than 60 mg/day, and after 1 to 2 weeks, we progressively taper the dose so that the total duration of treatment is 4 to 6 weeks.

ACUTE INTERSTITIAL NEPHRITIS SECONDARY TO INFECTIOUS DISEASES

Infections were once the most common cause of AIN, but the frequency of AIN induced by an infection has dramatically decreased

with the widespread use of antibiotics. Nevertheless, the diagnosis of infectious AIN should not be overlooked, and AIN occurring in patients treated with antibiotics should not always be attributed to the drug.

Infectious agents can cause renal parenchymal inflammation by direct infection, resulting in acute pyelonephritis (see Chapter 53). However, many infectious agents may also induce an immunologically mediated AIN in the absence of direct invasion (Table 62-2). In this case, the clinical presentation depends mostly on the underlying infection. On histologic examination, lesions are identical to those described for drug-induced AIN, and they can also occasionally result in granulomas (see Table 62-2). Infection-associated AIN usually resolves with the treatment of the underlying infection, and corticosteroid therapy is not recommended.

An important cause of infection-associated AIN is hantavirus.[15] Hantavirus infections occur worldwide and are responsible for a disease that has been known as hemorrhagic fever with renal syndrome, epidemic hemorrhagic fever, and nephropathia epidemica. Rodents are the main reservoir of the virus, and humans are most probably infected by the airborne route. Extrarenal symptoms usually include fever, headache, lightheadedness, abdominal pain, nausea and vomiting, and thrombocytopenia; the last can be responsible for hemorrhagic complications. AKI is almost always associated with proteinuria, sometimes in the nephrotic range, and with hematuria. When a kidney biopsy is performed, it discloses not only interstitial inflammatory infiltrates, which predominate in the medulla, but also vascular congestion and interstitial bleeding (Fig. 62-8). In about 50% of the patients, immunofluorescence studies show granular immune deposits along the TBM and within glomeruli. Serum creatinine concentration usually starts to decrease after a few days, and a complete recovery of renal function is the rule. Nevertheless, in the more severe cases, recovery can be complicated by the occurrence of hemorrhagic complications or severe shock. The diagnosis is based on serologic test results, which become positive early (within weeks) in the course of the disease.

Tubulointerstitial lesions are common in HIV-positive patients who undergo a renal biopsy for AKI. Interstitial infiltrates are often associated with glomerular lesions, but they can also be isolated. These forms of AIN have been observed in both Caucasian and Black patients, and they might be related not only to drugs and opportunistic infections but also to the HIV infection itself.[16]

ACUTE INTERSTITIAL NEPHRITIS ASSOCIATED WITH SYSTEMIC DISEASES

Sarcoidosis

In sarcoidosis, renal impairment usually occurs as a complication of hypercalciuria and hypercalcemia, but granulomatous AIN associated with sarcoidosis has also been reported (Fig. 62-9).[17,18] The presentation is usually that of AKI, which can be isolated or associated with mild proteinuria and sterile leukocyturia. It is associated with extrarenal symptoms of sarcoidosis in about 90% of patients, most frequently with lymphadenopathy and lung, eye, or liver involvement. Nevertheless, only slightly more than half of the patients have hilar lymphadenopathy or pulmonary interstitial

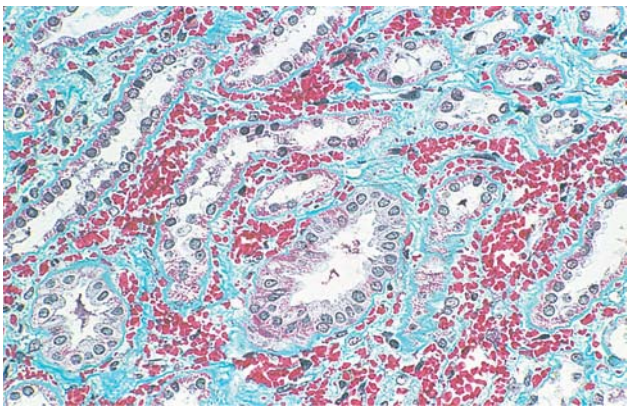

Figure 62-8 Acute interstitial nephritis secondary to hantavirus infection. Vascular congestion and foci of medullary hemorrhage are suggestive of the diagnosis. *(Courtesy Dr. B. Mougenot, Paris VI University, Paris.)*

Staphylococcus species	Measles virus		
Streptococcus species	Polyomavirus		
Yersinia pseudotuberculosis	Rickettsia		

Table 62-2 Infections that can be associated with acute interstitial nephritis. *Infections that can induce granulomatous AIN.

fibrosis at the time of diagnosis.[19] Treatment with high-dose corticosteroids quickly improves renal function, but most patients do not recover completely. The starting dose should be 1 mg of prednis(ol)one per kilogram daily and not higher than 60 mg/day, and corticosteroid therapy should be tapered slowly and not withdrawn before at least 1 year to prevent relapses. Whereas some authors advocate long-term maintenance therapy with low-dose corticosteroids, we usually stop corticosteroids after 2 to 3 years. Because of the risk of late relapse, these patients should be observed for a prolonged time.

Sjögren Syndrome

Clinically significant interstitial nephritis is rare in Sjögren syndrome and usually results in chronic tubular dysfunction.[20] Some patients may present with severe symptomatic hypokalemia with distal renal tubular acidosis. Rarely, Sjögren syndrome presents with AKI as a result of AIN. In these patients, treatment with high-dose corticosteroids may dramatically improve renal function.

Systemic Lupus Erythematosus

About two thirds of renal biopsies performed in patients with systemic lupus show some tubulointerstitial involvement, but significant tubulointerstitial injury in the setting of minimal glomerular abnormalities is rare, with only about 10 cases reported in the literature.[21] In these cases, renal biopsy shows typical features of AIN on light microscopy, and immunofluorescence staining always discloses immune deposits along the TBM, usually with a granular pattern. Renal function improves after high-dose corticosteroids, and additional immunosuppressive drugs are not usually required. However, azathioprine has been used as a corticosteroid-sparing agent.

Other Systemic Diseases

Among patients with cryoglobulinemia and AKI, a few exhibit significant interstitial inflammatory infiltrates associated with granular immune deposits in the interstitium and along the TBM. This AIN is usually associated with characteristic glomerular lesions and rarely lesions of the arterioles, and treatment is the same as for cryoglobulinemia-induced GN (see Chapter 21).

IgG4-related disease is a newly recognized systemic autoimmune disease that predominantly affects males older than 50 years of age. In the kidney, it is most commonly responsible for AIN characterized by the presence of interstitial infiltrates rich in IgG4-positive plasma cells and immune deposits along the TBM.[22] This interstitial nephritis can be associated with a membranous glomerulopathy, with the presence of renal inflammatory masses visible on radiographic studies, or with ureteral obstruction (see also Chapter 60). It usually responds very rapidly to treatment with corticosteroids.

Most renal lesions associated with small-vessel vasculitis consist of both an extracapillary GN and a tubulointerstitial nephritis (see Chapter 25). Nevertheless, a few patients with AIN and minimal glomerular lesions have been described.

ACUTE INTERSTITIAL NEPHRITIS ASSOCIATED WITH MALIGNANT NEOPLASMS

Infiltration of renal parenchyma by malignant cells is common in patients with leukemia or lymphoma. Most of the time, this infiltration is totally asymptomatic or only causes enlarged kidneys, but a few patients with AKI have been described.[23] Chemotherapy or radiotherapy may rapidly improve renal function in these patients, but before these treatments are started, it is important to exclude more common causes of AKI associated with neoplastic diseases (see Chapter 68).

IDIOPATHIC ACUTE INTERSTITIAL NEPHRITIS

More than 50 cases of idiopathic AIN with anterior uveitis have been reported (TINU syndrome).[24] This syndrome is found most commonly in girls of pubertal age but can also occur in pubertal boys and in adults. Initial symptoms may be ocular, with ocular pain and visual impairment, or pseudoviral, with fever, myalgia, and asthenia. AIN is responsible for AKI, ranging from mild to severe, that may or may not be associated with abnormal urinalysis. Renal biopsy shows diffuse interstitial inflammatory infiltrates, almost always without granulomas and without immune deposits. In children, renal prognosis is excellent, and serum creatinine usually returns to baseline values within a few weeks, with or without corticosteroid therapy. In adults, the renal prognosis seems to be less favorable, and corticosteroid therapy might be useful in preventing evolution to chronic renal impairment. Uveitis, which can occur at any time in respect to AIN, is usually responsive to topical corticosteroids, but it may relapse without any recurrence of AIN.

Cases of idiopathic AIN without uveitus have been reported. Immunofluorescence studies of renal biopsy specimens can show linear deposits of IgG along the TBM, granular deposits of IgG along the TBM, or no immune deposits, suggesting that this entity is heterogeneous. The treatment of patients with idiopathic AIN is still controversial. Patients who receive corticosteroids usually show a dramatic improvement of renal function, but others have recovered normal renal function without any treatment.

ACUTE INTERSTITIAL NEPHRITIS IN RENAL TRANSPLANTS

Acute rejection is by far the most common cause of AIN in renal allograft recipients (see Chapter 104). Nevertheless, AIN can also be induced by drugs or infections. Cases of drug-induced AIN have been reported even in the first weeks after transplantation, when immunosuppression is maximal.[25] Among patients with infectious AIN, the frequency of polyomavirus-induced AIN appears to be increasing, and it should be suspected in patients with acute deterioration of renal function and so-called decoy cells in urine (see Chapter 105).[26]

CHAPTER 63

Primary Vesicoureteral Reflux and Reflux Nephropathy

Ranjiv Mathews and Tej K. Mattoo

DEFINITION

Vesicoureteral reflux (VUR) is a congenital or acquired abnormality in which there is retrograde flow of urine from the bladder to the kidneys. This retrograde flow of urine, although normal in some animals, is not normal in humans. VUR may be primary (congenital) and associated with or without associated syndromes, or secondary, such as from increased bladder pressure resulting from obstructive uropathy or neurogenic bladder.

Vesicoureteral reflux may be suggested by fetal ultrasound in pregnancy (in which renal pelvis dilation is observed) or after urinary tract infection (UTI) in childhood. The presence of VUR increases the risk of upper tract UTI, and the two together can cause renal injury leading to scarring of the kidney termed reflux nephropathy (RN). RN may present as hypertension, toxemia of pregnancy, chronic kidney disease (CKD), and even end-stage renal disease (ESRD). Whereas RN involves primary injury to the renal parenchyma, some patients also have proteinuria as a result of secondary focal segmental glomerulosclerosis (FSGS).

Traditional management includes prompt treatment of UTI and long-term antimicrobial prophylaxis until the resolution of VUR. Surgical correction of the VUR may be recommended in those with high-grade VUR who have recurrent UTI in spite of antimicrobial prophylaxis or who are noncompliant with medical management. Debate persists on the superiority of one intervention over the other; most studies have concluded that long-term outcomes are similar.

CLASSIFICATION

Vesicoureteral reflux is classified by radiologic evaluation on voiding cystourethrography (VCU) into five grades as defined by the International Reflux Study in Children (Fig. 63-1 and Table 63-1).[1] Grade I is reflux into the ureter; grade II is reflux into the renal pelvis without any dilation of the calyces; grade III is reflux to the renal pelvis with mild dilation of the renal pelvis; grade IV is reflux to the renal pelvis with greater dilation of the renal pelvis; and grade V is reflux to the renal pelvis with ureteral and pelvic dilation. An example of grade V reflux is shown in Figure 63-2.

Grading of VUR is used to predict the outcomes of children with VUR. Because VUR may resolve spontaneously, grading is used to standardize management strategies as well as to compare clinical outcomes between institutions. Although it is widely used, the classification system is not perfect; differences between grade III and grade IV are not always obvious. The degree of reflux may be modified by how aggressively the bladder is filled during VCU. Ureteral dilation may also be present without calyceal dilation, leading to difficulties with grading.

EPIDEMIOLOGY

Vesicoureteral reflux is often first suggested by dilation of the fetal kidney during ultrasound examination. VUR is suspected when the fetal renal pelvis is more than 5 mm in anteroposterior diameter; a diameter of more than 10 mm is considered to be high-grade VUR. In neonates who had evidence of fetal dilation, as many as 13% to 22% will have VUR on VCU. Indeed, it is estimated that 1% to 2% of healthy children have VUR, with a higher frequency in boys and premature infants.[2] The incidence of renal dysplasia is also greater in male infants with VUR.[3] Most cases of grades I to III VUR will spontaneously resolve within the patient's first year of life, whereas grades IV and V are more likely to persist. Spontaneous resolution of VUR is greater in male infants.

Vesicoureteral reflux is also diagnosed in 30% to 40% of children presenting with UTI, predominantly girls. VUR is both less common and less severe in African American children.[4,5] Only about one third as many African American as Caucasian girls with UTI have VUR, and no significant differences in age or mode of presentation exist between the two races.

Renal scarring is responsible for 5% to 10% of ESRD in pediatric and adult patients.[6,7] In the Chronic Kidney Disease in Children (CKiD) study, in children with an estimated glomerular filtration rate (eGFR) of 30 to 90 ml/min/1.73 m^2, RN was the underlying cause for CKD in 14.8% of the patients.

ETIOLOGY AND PATHOGENESIS

Primary VUR is a congenital anomaly of the ureterovesical junction caused by a preexisting anatomic abnormality with shortening of the intravesical submucosal length of the ureter, leading to an incompetent valve (Fig. 63-3). The formation of the ureteral bud from the mesonephric duct signals the initial development of the metanephric kidney, the final stage of renal development. The ureteral bud interacts with the mesenchyme to give rise to the metanephric kidney. As the mesonephric duct is gradually absorbed into the enlarging urogenital sinus (the precursor of the developing bladder), the location of the ureteral bud plays a role in the eventual location of the ureteral meatus within the bladder. If the ureteral bud reaches the urogenital sinus too early because of the absorption pattern of the mesonephric duct, it is eventually located more laterally and proximally in the bladder. This location is associated with the development of reflux because there is reduction in the intravesical submucosal length of the ureter.

The ureterovesical junction is designed to prevent free reflux of urine from the bladder to the kidney. The ureters pass into the bladder through the detrusor in an oblique path. The distal end of

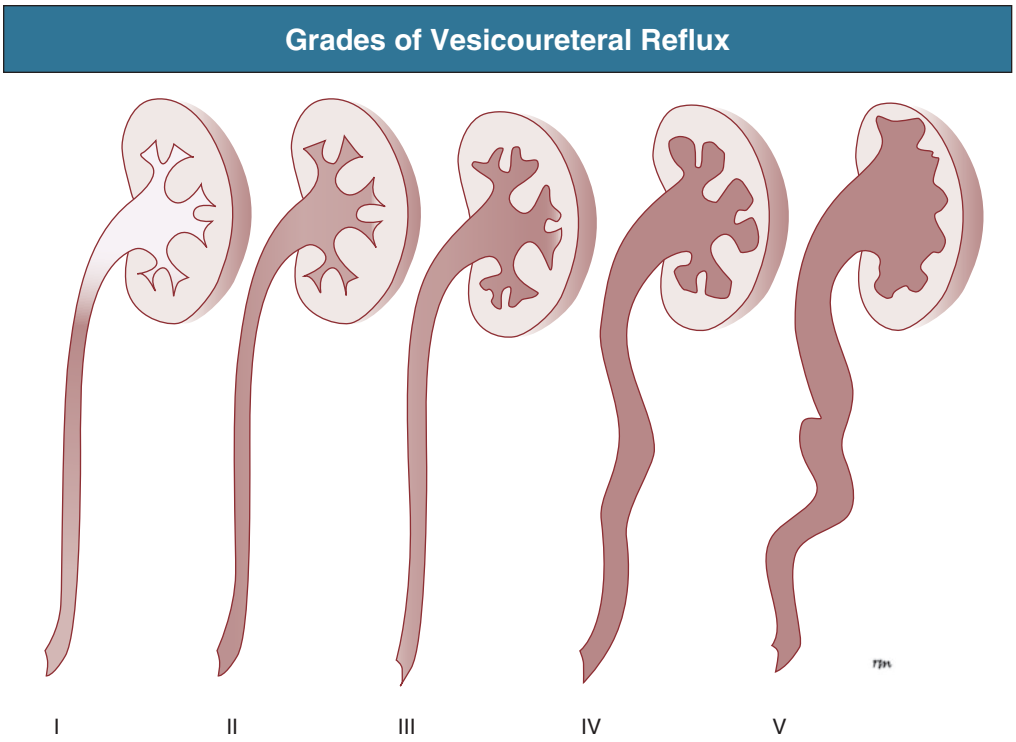

Figure 63-1 Grades of vesicoureteral reflux.

International Reflux Study in Children Classification of Vesicoureteral Reflux (VUR)	
Grade	**Degree of VUR**
I	Ureter only
II	Reflux into ureter, pelvis, and calyces with no dilation and with normal calyceal fornices
III	Mild or moderate dilation and/or tortuosity of the ureter and mild or moderate dilation of the pelvis; no or slight blunting of the fornices
IV	Moderate dilation and/or tortuosity of the ureter, and moderate dilation of the pelvis and calyces; complete obliteration of the pelvis and calyces; complete obliteration of the sharp angles of the fornices but maintenance of the papillary impressions in the majority of the calyces (see Fig. 63-7C)
V	Gross dilation and tortuosity of the ureter, pelvis, and calyces; the papillary impressions are no longer visible in the majority of calyces (see Fig. 63-2)

Table 63-1 Classification of VUR. The International Reflux Study in Children classification.

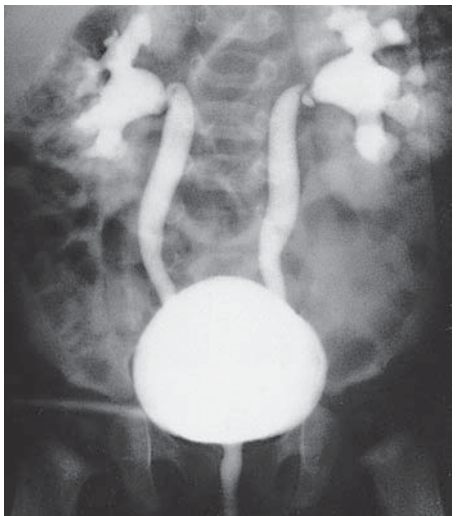

Figure 63-2 Gross vesicoureteral reflux (VUR) and intrarenal reflux. A voiding cystourethrogram shows grade V VUR with intrarenal reflux into several renal lobes in an infant.

the ureter is located submucosally within the bladder. The length of the submucosal ureter is critical in the prevention of VUR. The muscles of the ureter extend into the trigone of the bladder and mesh with the fibers from the opposite ureter. This intermingling of fibers helps anchor the ureters into the trigone of the bladder. The distal submucosal segment is compressed against the muscular bladder wall with bladder filling, acting as an additional mechanism to prevent reflux. Because urine is propelled antegrade down the ureter, the tone of the ureter and the meatus in the bladder also help prevent reflux.

Multiple genes are involved in the development of VUR. *PAX2* (necessary for ureteral budding in mice), glial-derived neurotrophic factor (GDNF), angiotensin II type 2 receptor, and uroplakin 3 (which is a component of tight junctions in uroepithelial cells) have been implicated in the development of VUR in mice; however, their role in human VUR remains controversial.[8,9] Neither autonomic innervation nor histology of the ureterovesical junction is different between patients with VUR and controls.[10]

Reflux Nephropathy

Reflux nephropathy is thought to result from one of two processes (Table 63-2).[51] Prenatal renal injury has been postulated to be secondary to the "water-hammer" effect of high-grade reflux and occurs in the absence of infection. This typically causes renal dysplasia. This form of renal scarring, which is also called congenital RN, is more

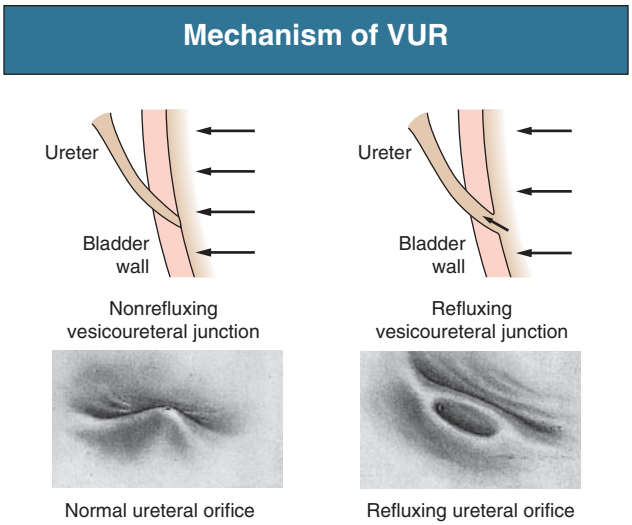

Figure 63-3 Pathogenesis of vesicoureteral reflux. Competent *(left)* and incompetent *(right)* vesicoureteral junctions and ureteral orifices.

Types of Renal Damage Associated with Vesicoureteral Reflux (VUR)

	Congenital	Acquired
Time of occurrence	Often prenatal	Postnatal, sometimes in adulthood
Previous urinary infection	Not usually	Usually
Gender	Usually boys	Usually girls (particularly after infancy)
Grade of VUR	Usually grades IV and V	Grades IV and V less common
Renal scarring	Often present	Present in minority of cases*
Associated bladder dysfunction	Hypercontractile bladder common	Less commonly, high-capacity bladder with incomplete voiding

Table 63-2 Types of renal damage associated with VUR. *Depends on unilateral versus bilateral involvement, and the severity of renal involvement. *(Adapted from reference 51, with permission.)*

commonly noted in infants with high-grade VUR, and there is a greater predominance of males in this cohort. The second mechanism for development of renal injury is the combination of VUR and repeated UTI, which is also called acquired RN. In these children, who are more commonly female, the combination of upper tract infection and reflux leads to renal inflammation and permanent scarring.

In both conditions, the damage to the kidney is likely to be greatest in children younger than 2 years, particularly in those with severe VUR.[11] Renal injury is more common in this age group because of delay in diagnosis of UTI as a result of the nonspecific clinical presentation, the difficulties in obtaining urine specimens, and the higher prevalence and severity of VUR in infants.

Reflux nephropathy is diagnosed by using technetium Tc 99m dimercaptosuccinic acid (DMSA) renal scanning as defects in the renal outline.[12] These defects can be seen in the absence of febrile UTIs. As noted previously, high-grade prenatal reflux can lead to renal injury in the absence of infection. Unfortunately, renal scarring secondary to UTI is indistinguishable by DMSA renal scan from that

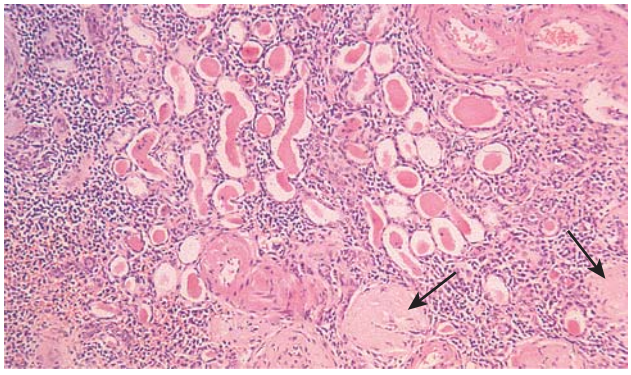

Figure 63-4 Histologic changes in reflux nephropathy. Sclerosed glomeruli *(arrows),* chronic inflammatory cell infiltration, and atrophic tubules with eosinophilic casts are present. (Hematoxylin-eosin; original magnification ×40.)

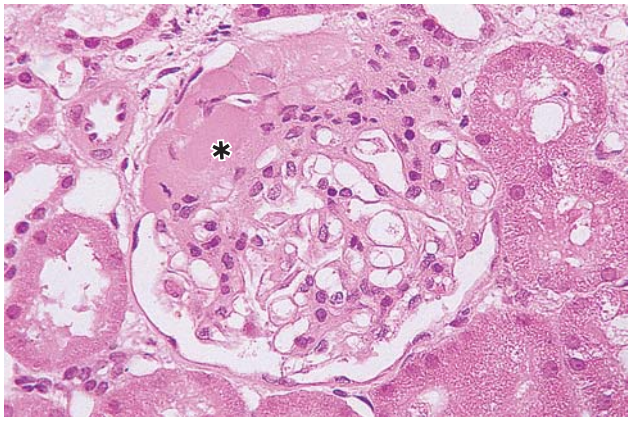

Figure 63-5 Focal segmental glomerulosclerosis (*) in reflux nephropathy. Light microscopy of a glomerulus from a patient with reflux nephropathy shows FSGS. (Hematoxylin-eosin; original magnification ×400.)

caused by prenatal renal dysplasia. In addition, renal injury can be noted after febrile UTI in the absence of identified VUR.

Finally, renal scarring as shown by technetium Tc 99m DMSA scan correlates more closely with the severity of VUR than with a history of UTI.[13]

PATHOLOGY

The process of renal scarring may take several years; in one study, the mean time from discovery of VUR to the appearance of a renal scar was 6.1 years.[14] Grossly, the injury favors the renal poles and is associated with clubbed calyces with medullary and cortical damage. The injury results from the local inflammatory response that may persist with chronic inflammation, tubular injury, local fibroblast activation, and interstitial collagen deposition (Fig. 63-4).[15] The loss of nephrons is associated with hyperfiltration and hypertension that result in proteinuria and progressive loss of renal function. This can also lead to the development of FSGS (Fig. 63-5).

CLINICAL MANIFESTATIONS

Presentation with Vesicoureteral Reflux

Patients with primary VUR may present in a variety of ways (Box 63-1). The three most common presentations are during follow-up

Clinical Presentations of Vesicoureteral Reflux (VUR)

- Complicated urinary infection—usually acute pyelonephritis in infants and children
- Asymptomatic
  - Detected by fetal ultrasound
  - Detected in the workup of members of an affected family
  - Detected in pregnant women with urinary tract infection
  - Detected during workup of kidney stones in children
  - Detected during assessment of other urologic congenital abnormalities

Box 63-1 Clinical presentations of VUR.

Prevalence of Vesicoureteral Reflux (VUR) in Patients with Urinary Tract Infection, According to Age

Age	Percentage with VUR
2-3 days	57
3-6 days	51
2-6 months	60
7-12 months	35
1-4 years	50
5-9 years	35
10-14 years	14
14 years	10
Adult	5

Table 63-3 Prevalence of VUR in patients with urinary tract infection, according to age. *(From reference 25.)*

for antenatal hydronephrosis, after a diagnosis of UTI, and on screening of a sibling of a patient with VUR.

Reflux Identified Secondary to Antenatal Hydronephrosis

Diagnosis of VUR may be suspected in utero with unilateral or bilateral hydronephrosis and confirmed at birth with VCU. There is a higher incidence of male infants diagnosed with VUR after identification of antenatal hydronephrosis.[16] Spontaneous resolution of the VUR occurs more commonly in boys with lower grades and unilateral reflux; infection rates are also lower in this cohort.[17] Female infants are more likely to have lower grades of VUR and are also less likely to develop renal damage compared with newborn boys. Reflux in newborn boys may be a result of elevated bladder pressures secondary to dyssynergia of the urethral sphincter, which improves with time with secondary resolution of even higher grades of VUR.[18,19]

Reflux Identified After a Urinary Tract Infection

Vesicoureteral reflux is most commonly found after UTI, particularly in a young child. The prevalence of VUR is higher in younger patients and decreases with age (Table 63-3). In neonates and toddlers, UTI may be manifested as failure to thrive as opposed to typical symptoms of dysuria and frequency. VUR is more common in patients with complicated or upper tract UTI. Because VUR may potentiate the effect of UTI in children, the recommendations for evaluation of

Algorithm for Evaluation of Young Children with Diagnosed UTI

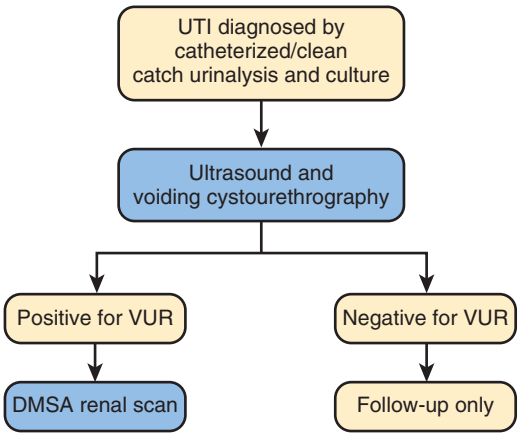

Figure 63-6 Current recommended algorithm for evaluation of young children with diagnosed urinary tract infection (UTI).

UTI have included ultrasound and VCU after resolution of the first UTI in both boys and girls (Fig. 63-6). However, in its most recent recommendations, the National Institute for Health and Care Excellence (NICE) from the United Kingdom and the American Academy of Pediatrics did not support routine voiding cystourethrogram (VCUG) in all children and children 2 to 24 months old, respectively, with first febrile UTI.[20]

Most children diagnosed with VUR after a UTI are younger than 7 years. UTI in these patients may be associated with modifiable host factors, such as voiding dysfunction and constipation. For example, toilet-trained children with VUR identified after a UTI have a 43% incidence of dysfunctional voiding.[21]

Sibling Vesicoureteral Reflux

Approximately one third of siblings of an index patient with VUR also have VUR.[22] There is a slightly higher incidence of VUR in female siblings of female index patients; 75% of children with VUR identified by sibling screening are asymptomatic. The incidence of renal damage is also lower in the siblings diagnosed with reflux compared with the index patient with VUR.[23] For example, UTI with progression of scar was noted in only 5% of siblings with VUR observed for 3 to 7 years, and most of those with grades I and II VUR had resolution.[23] The more "benign" course of sibling reflux compared with reflux identified after a UTI has led many to suggest limitation of those being screened. At this time, most suggest screening of younger siblings (younger than 2 years) of index children with VUR and reserve screening of older siblings for those who present with a UTI or other symptoms.

Reflux Nephropathy

Renal scarring can occur in patients with VUR and can be seen in those with or without proven UTI. This scarring is called reflux nephropathy.[24,25] Young children are particularly at risk of renal scarring. Renal scarring is more common with febrile UTI in children, and in those younger than 5 years, as many as 75% develop acute pyelonephritis and renal scarring. Renal cortical defects (by DMSA scanning) are present in 45% of children with febrile UTI and VUR compared with 24% with UTI without VUR.[25] In a large prospective

Clinical Presentations of Reflux Nephropathy

- Complicated urinary infection—usually acute pyelonephritis in infants and children
- Hypertension: may be accelerated
- During pregnancy: urinary infection, hypertension, preeclampsia
- Proteinuria
- Chronic renal impairment
- Urinary calculi
- Asymptomatic
  - Detected in the workup of members of an affected family
  - Detected by fetal ultrasound
  - Detected during assessment of other urologic congenital abnormalities

Box 63-2 Clinical presentations of reflux nephropathy.

study of a population-based cohort of 1221 children aged 0 to 15 years with symptomatic UTI, primary scarring during initial evaluation was even higher, occurring in 86% of the boys and 30% of the girls. Girls had significantly more recurrences of febrile UTIs and acquired renal scarring than boys.[26]

The clinical manifestations of RN are varied and may include complicated UTI, hypertension, proteinuria, and various manifestations of CKD (Box 63-2).

Hypertension

Hypertension occurs in 10% to 30% of children and young adults with RN,[26,27] and according to one study, hypertension may take 8 years to develop.[14] The exact cause of hypertension resulting from renal scarring is not known, but it is believed to be caused by impaired sodium excretion resulting from the renal injury. Hypertension is relatively uncommon in children with VUR, with an estimated probability of 2%, 6%, and 15% at 10, 15, and 21 years of age, respectively. However, hypertension increases in proportion to the degree of renal injury.[28] Renal scarring (noted by DMSA scans) was reported in 20% of newly diagnosed hypertension in children and adolescents.

Proteinuria

Patients may also present with microalbuminuria, persistent proteinuria, or rarely nephrotic-range proteinuria. The presence of proteinuria may suggest a histologic diagnosis of secondary FSGS, which can be confirmed by renal biopsy if kidney size is normal and diagnosis is uncertain (see Fig. 63-5).[29] Proteinuria is usually modest (0.5 to 4 g/day) and is commonly associated with hypertension and renal dysfunction. CKD progression often occurs gradually over 5 to 10 years.

End-Stage Renal Disease

According to the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) annual report of 2008, 3.5% of the 6491 children on dialysis had RN, which makes it the fourth most common cause of ESRD after FSGS; renal aplasia, hypoplasia, or dysplasia; and obstructive uropathy.[30,31] The number of pediatric patients with RN who present with ESRD as adults is not clear. According to one study of 123 adults with VUR diagnosed in childhood, the eGFR in those with nondilating VUR averaged 75 ml/1.73 m^2 and that in the dilating group was 72 ml/1.73 m^2; four patients (9%) in the nondilating group and 13 (17%) in the dilating group had eGFR below 60 ml/1.73 m^2.[30]

Presentation of Vesicoureteral Reflux in the Mother During Pregnancy

Vesicoureteral reflux may also first be manifested in the mother during pregnancy, when it can be associated with asymptomatic bacteriuria or symptomatic UTI, hypertension, preeclampsia, low-birth-weight babies, or miscarriage. VUR is present in approximately 5% of women with UTI in pregnancy and 4% to 5% of women with preeclampsia. VUR can be distinguished from the normal ureteral dilation that occurs in pregnancy, which preferentially affects the midportion of the ureter, and lack of involvement of the renal parenchyma.

Other Presentations

An increased risk of renal calculi has also been reported in children with VUR. Recurrent infections with urease-splitting organisms can lead to staghorn calculi. VUR or RN may also be discovered in adults after recurrent lower or upper UTI; indeed, about 5% of sexually active women with UTI have VUR.

DIAGNOSIS OF VESICOURETERAL REFLUX AND REFLUX NEPHROPATHY

An algorithm for diagnosis of VUR after the discovery of UTI is shown in Figure 63-6, and an example of the various tests in a child with UTI and VUR is shown in Figure 63-7. A similar approach should be performed in children after treatment of their first UTI.

Renal Ultrasound

Ultrasound is the initial modality for the evaluation of postnatal hydronephrosis and UTI in children. Ultrasound is also used as a screening tool in siblings of children with VUR to determine whether renal dilation suggestive of high-grade reflux is present. Whereas ultrasound can suggest the possibility of high-grade VUR, it has less sensitivity for diagnosis of acute pyelonephritis. In patients with acute pyelonephritis, abnormalities compatible with the diagnosis were reported in 20% to 69% by ultrasound compared with 40% to 92% by DMSA scintigraphy.[32] Nonetheless, ultrasound may be useful in detection of renal abscess and abnormalities of the perinephric space. Renal ultrasound is not diagnostic for VUR and is not a sensitive method for diagnosis of renal scars.

Voiding Cystourethrography

Voiding cystourethrography is the primary diagnostic modality for identification of VUR. It requires catheterization, which can lead to significant distress in both children and parents. The grading of VUR is based on radiographic appearance by VCU (see Fig. 63-1). In children with UTI, VCU should be performed as soon as the child has completed the course of antibiotic therapy. Evaluation with VCU has been suggested after the first febrile infection in children younger than 5 years.

The results of VCU can be affected by size, type, and position of the catheter; rate of bladder filling; height of the column of contrast media; state of hydration of the patient; and volume, temperature, and concentration of the contrast medium.

Nuclear cystography has been used to reduce the radiation exposure for children during follow-up of VUR. Nuclear cystography, although more sensitive, does not permit specific grading of VUR or reveal other anatomic defects, such as ureterocele and diverticulum. Therefore it is typically not the primary study performed

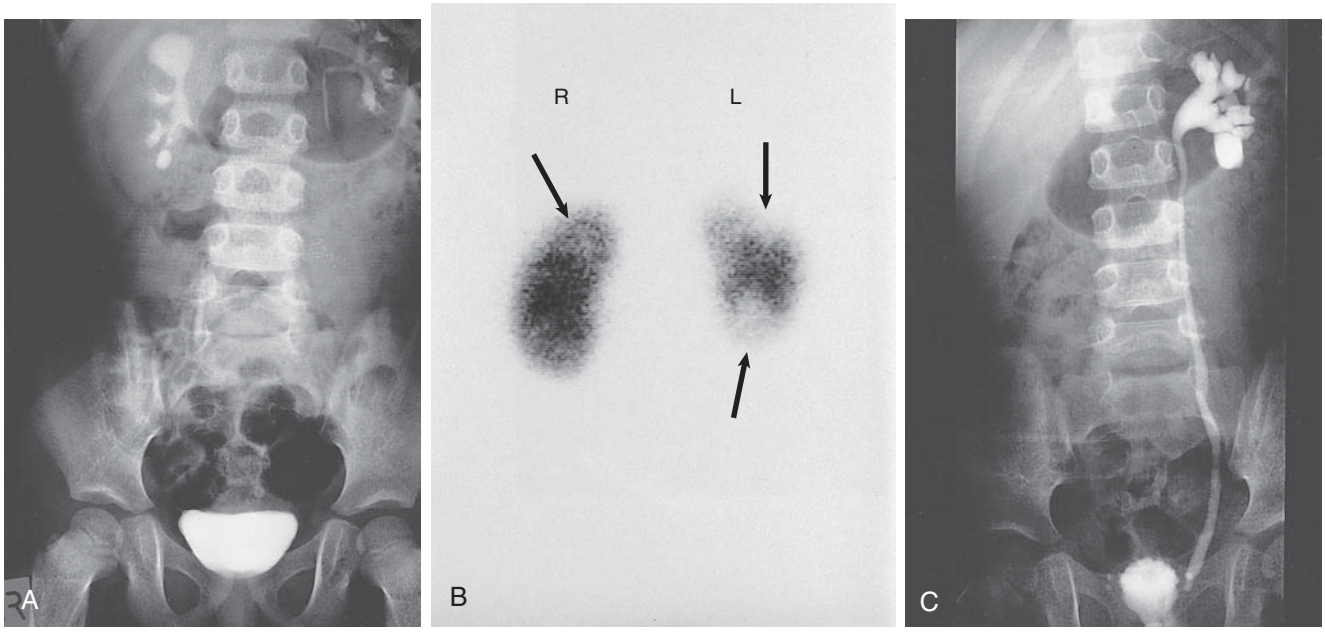

Figure 63-7 Investigation of reflux nephropathy. Investigation of a 3-year-old child with urinary tract infection. **A,** Intravenous urogram showing calyceal diverticulum in the upper pole of the right kidney and renal scarring in the upper pole and, probably, the lower pole of the left kidney. **B,** DMSA scintigraphy (posterior view) demonstrating upper and lower pole scarring *(arrows)* in the left kidney and scarring of the right upper kidney in association with the calyceal diverticulum *(arrowhead).* **C,** Voiding cystourethrogram showing grade IV vesicoureteral reflux on the left.

for identification of VUR, but it is useful in determining improvement or resolution of reflux during follow-up or after surgical correction.

DMSA Renal Scintigraphy

Use of DMSA scintigraphy is currently the accepted gold standard for diagnosis of acute pyelonephritis and renal scarring. Single-photon emission computed tomography (SPECT) DMSA scintigraphy is superior to planar imaging for detection of renal cortical damage.[34,35] The sensitivity of DMSA scintigraphy in experimentally induced acute pyelonephritis in a pig model was reported to be 92% when correlated with histologic findings.[35] By use of standardized criteria for its interpretation, high levels of intraobserver and interobserver agreement were reported.[36]

An abnormal DMSA scan during a febrile UTI allows the identification of children with renal inflammation who are at risk for development of renal scars. For acute pyelonephritis, DMSA scintigraphy can be performed within 2 to 4 weeks after the onset of UTI symptoms. However, routine use of DMSA renal scan after acute pyelonephritis is not encouraged because it does not change the clinical management. For renal scarring, DMSA scintigraphy to identify renal scarring should ideally be performed 6 months after acute infection to allow acute reversible lesions to resolve.[37,38]

Dysplasia secondary to congenital reflux will appear similar to renal scarring after postnatal infections. In the context of a child presenting with VUR, obtaining a baseline DMSA renal scan allows identification of renal dysplasia and scarring, which can then be observed over time.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has recently been used for the diagnosis of renal scars because it discriminates swelling from scarring, both of which would be interpreted by DMSA scintigraphy as renal scarring. MRI may also diagnose other coexisting conditions, such as nephrolithiasis,[38,39] which is not diagnosed by DMSA scintigraphy. Newer imaging methods that show promise in diagnosis of renal scarring include dynamic contrast-enhanced MRI and MRI using a gadolinium-enhanced short-tau inversion-recovery (STIR) sequence. However, routine use of MRI is less practical because of limited availability, especially for infants, need for prolonged sedation, and high cost. Gadolinium is also contraindicated in the presence of significant renal impairment (glomerular filtration rate below 30 ml/min/1.73 m^2).

Proteinuria as a Marker for Reflux Nephropathy

Proteinuria predicts CKD progression due to RN.[40] Persistent microalbuminuria is helpful in diagnosis of glomerular damage at a very early stage.[41] Microalbuminuria increases with increasing severity of VUR and renal scarring.[42] In children with bilateral VUR with renal scarring and normal creatinine clearance, microalbuminuria was detected in 54% of the cases.[43] Microalbuminuria screening offers the possibility of early intervention, such as the use of ACE inhibitors, aimed at retarding CKD progress. Proteinuria, when it is severe, is usually associated with FSGS.

NATURAL HISTORY OF VESICOURETERAL REFLUX AND REFLUX NEPHROPATHY

Primary VUR, especially grades I to III, generally improves with time, and this is attributed to the lengthening of the submucosal segment of the ureter. Spontaneous resolution of VUR is more common with non-Caucasian race, lower grades of reflux, absence of renal damage, and lack of voiding dysfunction. Resolution of VUR occurs more slowly in children with bilateral VUR in most but not all studies. In one study of children younger than 5 years with grades I to III VUR, the resolution rate of left unilateral VUR was better than for right VUR.[44] In another study, the mean time until

spontaneous resolution in Black children was 15 months versus 21 months in Caucasian children.[45] Increasing age at presentation and bilateral VUR decrease the probability of resolution, and bilateral grade IV or grade V VUR has a particularly low potential for spontaneous resolution.[46]

The natural history of VUR in adults has been reported in few studies. In one study of adults (mean age of 24 years) with gross VUR diagnosed in infancy, proteinuria and CKD were present in 3 of the 13 patients with unilateral RN and 2 of the 4 patients with bilateral RN.[47] In another study of 127 adults (mean age of 41 years) with VUR diagnosed during childhood, 35% had unilateral renal scarring, 24% had bilateral renal scarring, 24% had albuminuria, and 11% had hypertension. Of the patients with bilateral renal scars, 83% had reduced GFR.[48] An increased frequency of UTI and abnormal voiding patterns has also been noted in adults with VUR. UTIs may also be increased in frequency in adults who have had surgical management of VUR.

TREATMENT

The management of VUR has been based on the premise that VUR predisposes to the development of recurrent UTI and renal parenchymal injury, but also has the potential for spontaneous resolution. Various treatment strategies have been used with the ultimate objective of preventing renal injury. The two main treatment modalities are long-term antimicrobial prophylaxis and surgical correction. Surgical correction of VUR was common until antimicrobial prophylaxis for childhood UTI was introduced in 1975.[49] Many subsequent studies have reported no significant differences in outcome with medical management of VUR versus surgical treatment in the prevention of renal injury. For example, in the International Reflux Study in Children, which involved 306 patients, no significant difference in outcome was found between medical and surgical management in terms of the development of new renal lesions or the progression of established renal scars.[50] Long-term follow-up of this cohort for a period of 5 years in the European arm of the study also indicated no difference in outcomes.[11]

The 2010 American Urological Association (AUA) guidelines reviewed seven treatment modalities used to manage VUR in children: intermittent antibiotic therapy; bladder training; continuous antibiotic prophylaxis; antibiotic prophylaxis and bladder training; antibiotic prophylaxis, anticholinergics, and bladder training; open surgical repair; and endoscopic repair. The key outcome measures were resolution of VUR, risk of pyelonephritis and scarring, and complications of medical versus surgical management. The study panel's recommendations are shown in Table 63-4. Antibiotic prophylaxis is recommended for all grades of VUR in children younger than 1 year because of a very high rate of spontaneous resolution. For children 1 to 5 years old, the study panel recommended antibiotic prophylaxis for all grades of VUR, with surgical options in grades III to V if VUR is bilateral or renal scarring is present. For children older than 6 years, the study panel recommended antibiotic prophylaxis for grades I and II (unilateral or bilateral) and unilateral grades III and IV, with surgical options if renal scarring is present, and surgical repair for bilateral grades III and IV and unilateral or bilateral grade V with or without scarring because the VUR has the lowest possibility of spontaneous resolution.[46]

Medical Management

Medical management involves long-term antimicrobial prophylaxis, appropriate management of voiding dysfunction and constipation, if present, and follow-up renal imaging to assess the resolution of VUR and the potential development of renal injury. The antimicrobial agents most appropriate for prophylaxis include trimethoprim-sulfamethoxazole (TMP-SMZ), trimethoprim alone, nitrofurantoin, and cephalexin. Follow-up of patients with VUR and UTI requires rapid evaluation (within 72 hours of the onset of fever) to allow early detection and prompt treatment of UTI. The timing of follow-up VCU is not well defined, but studies have suggested time intervals of 12 to 24 months. The treatment of voiding dysfunction or dysfunctional elimination syndrome (a syndrome consisting of constipation and urinary symptoms of frequency, urgency and incontinence that is associated with recurrent UTI in toilet-trained children) may include the use of laxatives and timed frequent voiding every 2 to 3 hours. Pelvic floor exercises, behavioral modification, or anticholinergic medication may be required. A combined conservative medical and computer game–assisted pelvic floor muscle retraining has been shown to decrease the incidence of breakthrough UTI and facilitate VUR resolution in children with voiding dysfunction and VUR. Treatment of constipation by dietary measures, behavioral therapy, and laxatives helps reduce UTI recurrence and resolve enuresis and uninhibited bladder contractions.

Antibiotic Prophylaxis Versus Surveillance Only

Some studies challenge the benefit of long-term antimicrobial prophylaxis in the prevention of renal injury in patients with VUR.

Surgical Techniques for Management of Vesicoureteral Reflux (VUR)			
Technique	**Success Rates**	**Pros**	**Cons**
Open reimplantation	95%	High success rates Limited requirement for follow-up VCU Reduction in hospital stays	Surgical incision Hospitalization required Catheters needed during postoperative management Need for pain control
Endoscopic injection Dextranomer and hyaluronidase (Deflux)	70%-80%	Reasonable success rates Outpatient management Minimal pain	Expensive Lower success rates Need for repeated procedures Need for follow-up VCU
Laparoscopic or robotic reimplantation	70%-90%	Reasonable success rates Small incisions Less discomfort	Lower success rates Requires hospitalization Need for follow-up VCU Long procedure Expensive equipment Significant surgical learning curve

Table 63-5 Surgical techniques for VUR. *VCU,* Voiding cystourethrography.

Concerns have been raised regarding the potential risks of long-term antibiotic use including the possibility of development of resistance or allergy.

In the last few years, six prospective randomized trials evaluated the role of antimicrobial prophylaxis in the prevention of recurrent UTI and renal scarring in children. Altogether 1435 patients were randomized, and included were 961 (67%) female patients. Four studies[13,52-54] reported no benefit with antimicrobial prophylaxis in children with or without VUR. One study[55] reported a decrease of 6 percentage points (95% confidence interval [CI] 1-13) in the number of UTIs with prophylaxis compared with placebo. The Swedish reflux trial[56,57] demonstrated that the rate of UTI recurrence in girls was higher than in boys, and that this rate can be decreased with antibiotic prophylaxis and endoscopic procedure. None of the five studies showed any difference in the rate of renal scarring with or without prophylaxis.

These trials, although suggestive, are not conclusive. Various study design limitations were present, including small study cohorts, short follow-up, lack of blinding, no evaluation of compliance, no use of placebo, urine collection by sterile bags in non–toilet-trained children, and exclusion of patients with high-grade VUR (who are normally associated with the highest risk of renal injury) as well as the issue of interobserver variability in the interpretation of DMSA renal scans.

Hypertension and Proteinuria

Appropriate management of hypertension and proteinuria includes the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) as in other renal diseases (see Chapter 80). ACE inhibitors reduce proteinuria in patients with RN and also can reverse microalbuminuria. Combinations of ACE inhibitors and ARBs may provide additional lowering of proteinuria.[58] However, it is not known whether this antiproteinuric effect slows the progression of the renal disease. Historically, some patients also occasionally had their scarred kidney removed to help control hypertension, provided the contralateral kidney was healthy. However, this is exceptionally rare these days because of the availability of many potent antihypertensive agents.

Surgical Management

Surgical management of VUR is now a second-line management strategy and is reserved for patients whose medical management with antimicrobial prophylaxis and follow-up has failed. Current indications for surgical management of VUR are recurrent infections despite compliance with a prophylactic antibiotic regimen, worsening of renal scars, as judged by DMSA scanning, after a UTI, and repeated failure to comply with a prophylactic regimen. The recent introduction of minimally invasive modalities for the management of VUR has made some clinicians consider surgical correction a potential first-line therapy. Immediate correction could potentially offset the need for antibiotic prophylaxis in children. Although most surgical techniques have high success rates, most studies indicate that surgical correction of VUR does not prevent UTI or eventual renal scarring.[59] A review of surgical techniques is presented in Table 63-5.

CHAPTER 64

Chronic Interstitial Nephritis

Masaomi Nangaku

DEFINITION

Chronic interstitial nephritis is a histologic entity characterized by progressive scarring of the tubulointerstitium, with tubular atrophy, macrophage and lymphocytic infiltration, and interstitial fibrosis. Because the degree of tubular damage accompanying interstitial nephritis is variable, the term *tubulointerstitial nephritis* is used interchangeably with *interstitial nephritis. Tubulitis* refers to infiltration of the tubular epithelium by leukocytes, usually lymphocytes.

There are many primary as well as secondary causes of chronic interstitial nephritis (Table 64-1). Tubulointerstitial injury is clinically important because it is a better predictor than the degree of glomerular injury of present and future renal function. Although any glomerular disease can injure the tubulointerstitium secondarily through mechanisms involving the direct effects of proteinuria and ischemia, in this chapter we discuss only primary chronic interstitial nephritis.

PATHOGENESIS

The tubulointerstitium can be injured by toxins (e.g., heavy metals), drugs (e.g., analgesics), crystals (e.g., calcium phosphate, uric acid), infections, obstruction, immunologic mechanisms, and ischemia. Regardless of the initiating mechanism, however, the tubulointerstitial response shows little variation. Tubular injury results in the release of chemotactic substances and the expression of leukocyte adhesion molecules that attract inflammatory cells into the interstitium. Tubular cells express human leukocyte antigens, serve as antigen-presenting cells, and secrete complement components and vasoactive mediators, all of which may further stimulate or attract macrophages and T cells. Growth factors released by tubular cells and macrophages, such as platelet-derived growth factor and transforming growth factor β, may stimulate fibroblast proliferation and activation, leading to matrix accumulation.[1] The source of fibroblasts in renal interstitial fibrosis remains controversial but may include an intrinsic fibroblast population, migration of circulating fibrocytes from perivascular areas, and transdifferentiation of tubular cells, pericytes, and endothelial cells into fibroblasts. Over time, a loss of peritubular capillaries and decreased oxygen diffusion caused by expansion of the interstitium render the kidney hypoxic, and progressive apoptosis leads to local hypocellularity and fibrosis.[2] Renal function becomes severely decreased, and renal replacement therapies are required.

EPIDEMIOLOGY

Whereas chronic interstitial nephritis occurs with progressive renal disease of all causes, primary chronic interstitial nephritis is not a common cause of end-stage renal disease (ESRD); reports range from 42% in Scotland to 3% to 4% in China and the United States.[3-5] This variability in incidence may relate to differences in how diagnoses are made, causes and toxin or drug exposure, and treatment modalities.

In several localized regions of the world, marked increases in the incidence of chronic interstitial nephritis have been reported. These include Sri Lanka, some coastal areas of Central America, and the Balkan region in Europe.

PATHOLOGY

The pathologic features of chronic interstitial nephritis are nonspecific. They include tubular cell atrophy or dilation; interstitial fibrosis that is composed of interstitial (types I and II) collagens; and mononuclear cell infiltration with macrophages, T cells, and occasionally other cell types (neutrophils, eosinophils, and plasma cells). Tubular lumina vary in diameter but may show marked dilation, with homogeneous casts producing a thyroid-like appearance, hence the term *thyroidization.*

Whereas a noncaseating granulomatous pattern is typical of sarcoidosis, interstitial granulomatous reactions also occur in response to infection of the kidney by mycobacteria (Fig. 64-1), fungi, or bacteria; drugs (including rifampin, sulfonamides, and narcotics); and oxalate or uric acid crystal deposition. Interstitial granulomatous reactions also have been noted in renal malacoplakia, Wegener granulomatosis, and heroin abuse and after jejunoileal bypass surgery.

CLINICAL MANIFESTATIONS

The impaired renal function is often insidious, and the early manifestations of the disease are those of tubular dysfunction, which may go undetected (Box 64-1).[6] Diagnosis is often made incidentally on routine laboratory screening or during evaluation of hypertension, in association with reduced glomerular filtration rate (GFR). Proteinuria is commonly less than 1 g/day. The urinalysis may show only occasional white blood cells and, rarely, white blood cell casts. Hematuria is uncommon. Anemia may occur relatively early because of loss of erythropoietin-producing interstitial cells.

The tubular dysfunction is often generalized, but some conditions may present with proximal tubular defects including aminoaciduria, phosphaturia, proximal renal tubular acidosis (RTA), or, rarely, a complete Fanconi syndrome. Distal tubular defects can be associated with distal RTA (type 1 or type 4) (see Chapter 12). Concentrating defects (increased urinary frequency and nocturia) can be a sign of medullary dysfunction and may be severe enough to result in nephrogenic diabetes insipidus. Some patients will also have an inability to conserve salt on a low-salt diet with a subsequent salt-wasting syndrome. Others, particularly with microvascular disease, may

Major Causes of Chronic Interstitial Nephritis	
Diseases in Which the Kidneys Are Macroscopically Normal	**Diseases in Which the Kidneys Are Macroscopically Abnormal**
Drugs and toxins (e.g., aristolochic acid, lithium, cyclosporine, tacrolimus, indinavir, cisplatin)	Analgesic nephropathy
Metabolic (hyperuricemia, hypokalemia, hypercalcemia, hyperoxaluria, cystinosis)	Chronic obstruction (see Chapters 60 and 63)
Heavy metals (lead, cadmium, arsenic, mercury, gold, uranium)	Hereditary (nephronophthisis, medullary cystic kidney disease, familial juvenile hyperuricemic nephropathy, autosomal dominant polycystic kidney disease, autosomal recessive polycystic kidney disease)
Radiation	Infection (chronic pyelonephritis, malacoplakia, xanthogranulomatous pyelonephritis; see Chapter 53)
Balkan nephropathy	
Immune-mediated conditions (systemic lupus erythematosus, Sjögren syndrome, sarcoidosis, Wegener granulomatosis, other vasculitides)	
Vascular diseases (atherosclerotic kidney disease) (see Chapter 66)	
Transplantation (chronic transplant rejection)	
Hematologic disturbances (multiple myeloma, light-chain deposition disease, lymphoma, sickle cell disease, paroxysmal nocturnal hemoglobinuria) (see Chapters 27, 51, and 65)	
Progressive glomerular disease of all causes (e.g., glomerulonephritides, diabetes, hypertension)	
Idiopathic	

Table 64-1 Major causes of chronic interstitial nephritis. Note that kidneys of any clinical entity can be shrunken at end stage. Some diseases categorized as macroscopically normal can in later stages result in macroscopically abnormal kidneys. For example, kidneys of sickle cell nephropathy are macroscopically normal unless papillary necrosis is present.

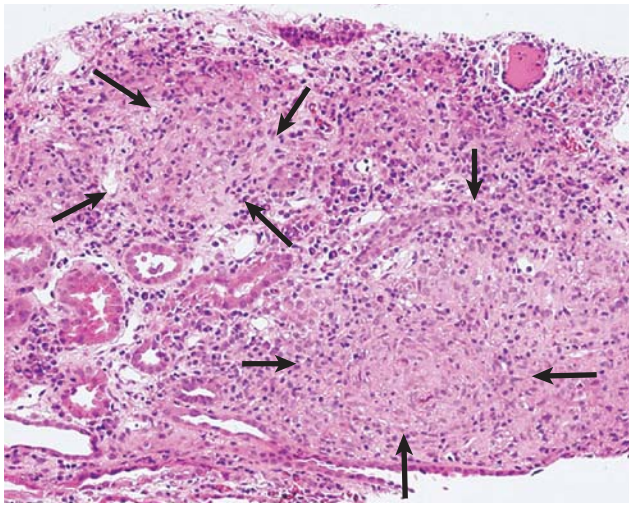

Figure 64-1 Renal tuberculosis. Noncaseating granulomas with epithelioid cells in miliary tuberculosis (arrows show the peripheries of the granulomas). Although the typical pathologic change is granuloma with caseous necrosis with Langerhans-type giant cells, these atypical granulomas can be observed in tuberculosis and should be differentiated from sarcoidosis. (Hematoxylin-eosin stain.) *(Courtesy Dr. Noriko Uesugi, Ibaraki, Japan.)*

Functional Manifestations of Chronic Interstitial Nephritis
Deterioration of glomerular filtration rate with insidious onset
Tubular proteinuria mainly composed of low-molecular-weight protein (generally <1 g/day)
Inactive urinary sediment
Renal anemia at a relatively early stage
Proximal tubular dysfunction (aminoaciduria, phosphaturia, proximal renal tubular acidosis, Fanconi syndrome)
Distal tubular dysfunction (type IV renal tubular acidosis)
Medullary dysfunction (concentrating defects)
Salt-wasting syndrome
Salt-sensitive hypertension

Box 64-1 Functional manifestations of chronic interstitial nephritis.

have a relative inability to excrete salt with resultant salt-sensitive hypertension.[7]

Clues to the causes of tubulointerstitial nephritis by history and physical examination are shown in Table 64-2.[8]

TREATMENT

Treatment includes identification and elimination of any exogenous agents (drugs, heavy metals), metabolic causes (hypercalcemia), or conditions (obstruction, infection) potentially causing the chronic interstitial lesion. Specific treatments may be required for a condition, such as corticosteroids for sarcoidosis. General measures include control of blood pressure. Most clinicians favor the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), which reduce glomerular and systemic pressures, decrease proteinuria, and increase renal blood flow. Specific therapies for each clinical entity are discussed later.

DRUG-INDUCED CHRONIC INTERSTITIAL NEPHRITIS

Several drugs and herbs can cause chronic interstitial nephritis. Cyclosporine- and tacrolimus-induced nephropathy is discussed in

Clues to Causes of Tubulointerstitial Nephritis by History and Physical Examination		
Feature	**Symptom, Sign, or Historical Clue**	**Potential Diagnosis**
Occupational history	Exposure to heavy metals (e.g., batteries, alloys)	Lead or cadmium nephropathy
Alcohol	History of moonshine ingestion	Lead nephropathy
Social history	Country of origin	Balkan nephropathy
Past history	Systemic lupus erythematosus Sjögren syndrome Sarcoidosis Inflammatory bowel disease Autoimmune pancreatitis Chronic pain syndrome Gouty attack	Disease-associated chronic interstitial nephritis Analgesic nephropathy Lead nephropathy
Medication	Prescribed Over-the-counter (NSAIDs) Herbal Indinavir	Drug-induced chronic interstitial nephritis Analgesic nephropathy Aristolochic acid–associated nephropathy Crystal nephropathy
Physical examination	Dry eyes	Sjögren syndrome
Laboratory examination	Hyperuricemia Hypokalemia Hypercalcemia High serum IgG4 levels	Chronic uric acid nephropathy Hypokalemic nephropathy Hypercalcemic nephropathy IgG4-related sclerosing disease
Radiologic examination	Decreased volume, bumpy contours, and papillary calcification on CT Microcysts on MRI or ultrasound Nephrocalcinosis on CT	Analgesic nephropathy Lithium nephropathy Hypercalcemic nephropathy

Table 64-2 Clues to tubulointerstitial nephritis by history and physical examination. *CT,* Computed tomography; *MRI,* magnetic resonance imaging; *NSAIDs,* nonsteroidal anti-inflammatory drugs. *(Modified from reference 8.)*

Chapters 101, 107, and 111; aristolochic acid as a cause of aristolochic acid–associated nephropathy (formerly known as *Chinese herbs nephropathy*) is discussed in Chapter 78.

Lithium Nephropathy

Definition and Epidemiology

Lithium is commonly used in the treatment of bipolar disorder. Complications of lithium treatment include nephrogenic diabetes insipidus, acute lithium intoxication, and chronic lithium nephrotoxicity. A meta-analysis of the data of 14 studies involving 1172 patients receiving chronic lithium therapy showed that the prevalence of reduced GFR was 15%.[9]

Pathogenesis

Diabetes insipidus results from accumulation of lithium in the collecting tubular cells after entry into these cells through sodium channels in the luminal membrane. Lithium blocks vasopressin-induced reabsorption by inhibiting adenylate cyclase activity, and hence cyclic adenosine monophosphate production, and also by decreasing the apical membrane expression of aquaporin 2, the collecting tubule water channel. Chronic lithium-induced interstitial nephritis may also occur, possibly because of inositol depletion and inhibition of cell proliferation.

Pathology

Biopsies show focal chronic interstitial nephritis with interstitial fibrosis, tubular atrophy, and glomerular sclerosis. Whereas similar histologic changes have been reported in psychiatric patients without a history of lithium therapy, patients with lithium exposure often show microcystic changes in the distal tubule; interstitial inflammation and vascular changes are relatively minor. The degree of interstitial fibrosis is related to the duration of administration and cumulative dose.

Clinical Manifestations

Lithium-associated Diabetes Insipidus The most common presentation of lithium-induced nephrotoxicity is nephrogenic diabetes insipidus, characterized by resistance to vasopressin, polyuria, and polydipsia. Impaired renal concentrating ability is found in about 50% of patients, and polyuria resulting from nephrogenic diabetes insipidus occurs in about 20% of patients chronically treated with lithium.

Lithium is also rarely a cause of hypercalcemia, which could potentially exaggerate the tubular concentrating defect and contribute to the development of chronic interstitial nephritis in lithium-treated patients. Nephrogenic diabetes insipidus in lithium treatment may be associated with distal RTA, although this partial functional defect is virtually never of clinical importance.

Chronic Lithium Nephropathy Nephrogenic diabetes insipidus induced by lithium may persist despite the cessation of treatment, indicating irreversible renal damage.

In one study, the mean serum creatinine concentration of patients with biopsy-proven chronic lithium nephrotoxicity was 2.8 mg/dl (247 μmol/l) at the time of biopsy, and 42% of patients had proteinuria greater than 1 g/day.[10] After renal biopsy, all but one patient discontinued treatment with lithium, but seven patients nevertheless progressed to ESRD. A study of 74 lithium-treated patients in France showed that lithium-induced nephropathy developed slowly during several decades, with an average latency between the start of therapy and ESRD of 20 years.[11]

Magnetic resonance imaging, in particular the half-Fourier acquisition single-short turbo spin-echo T2-weighted sequence, without the use of gadolinium, or ultrasound may help in the detection of the characteristic microcysts in the kidney.[12]

Treatment

After other potential causes of polyuria and polydipsia have been excluded, particularly psychogenic polydipsia, the first step to

consider is a reduction in lithium dosage. The potassium-sparing diuretic amiloride improves the polyuria and also blocks lithium uptake through sodium channels in the collecting duct. Thiazide diuretics should be avoided because they increase the risk for acute lithium intoxication because of the resultant volume contraction and an increase in sodium and lithium reabsorption in the proximal tubule.

Patients undergoing long-term lithium treatment should have renal function and 24-hour urine volume measured yearly (serum creatinine and estimated GFR [eGFR]). Lithium has a narrow therapeutic index, so levels should be monitored and maintained between 0.6 and 1.25 mmol/l. The severity of chronic lithium intoxication correlates directly with the serum lithium concentration and may be categorized as mild (1.5 to 2.0 mmol/l), moderate (2.0 to 2.5 mmol/l), or severe (>2.5 mmol/l). Once-daily regimens are less toxic than multiple daily administration schedules, perhaps because of the possibility of renal tubular regeneration with a once-daily administration schedule.[13] Prevention of volume depletion is also important.

Because progressive renal injury with reduced GFR in patients without prior acute lithium intoxication is relatively unusual, raised serum creatinine concentration should initially be treated by a dose reduction. If serum creatinine is persistently elevated, a renal biopsy should be considered, although the findings rarely mandate the complete cessation of lithium treatment. At all times, the risk for discontinuation in a patient with a severe unipolar or bipolar affective disorder needs to be balanced with the relatively low risk of progressive renal injury.

Analgesic Nephropathy

Definition and Epidemiology

Analgesic nephropathy resulted from the abuse of analgesics, commonly mixtures containing phenacetin, aspirin, and caffeine, that were available as over-the-counter preparations in Europe and Australia. It is now rare; indeed, some doubt that new cases are still presenting, following restrictions in compound analgesic sales.[14] Long-term use of aspirin alone is not associated with analgesic nephropathy, and although long-term nonsteroidal anti-inflammatory drug (NSAID) use has been associated with chronic interstitial nephritis in a small number of patients, a large-scale case-control study found no increased risk of ESRD in users of combined or single formulations of phenacetin-free analgesics.[15] A large study in the United States also showed no association between use of current analgesic preparations and increased risk of chronic renal dysfunction,[16] although it does increase the risk of acute kidney injury (see Chapter 69).

Pathogenesis and Pathology

The primary injury in analgesic nephropathy is medullary ischemia caused by toxic concentrations of phenacetin metabolites combined with relative medullary hypoxia, aggravated by inhibition of vasodilatory prostaglandin synthesis. The main pathologic consequence is papillary necrosis, with secondary tubular atrophy, interstitial fibrosis, and a mononuclear cellular infiltrate (Fig. 64-2).

Clinical Manifestations

Analgesic nephropathy is five to seven times more common in women than in men. Renal manifestations are nonspecific and consist of slowly progressive chronic kidney disease (CKD) with impaired urine concentrating ability, urinary acidification defects, and impaired sodium conservation. Urinalysis shows sterile pyuria and mild proteinuria. Patients with analgesic nephropathy are at increased risk for transitional cell carcinoma of the uroepithelium. Recent prospective analysis of the Nurses' Health Study and the Health Professionals Follow-up Study also showed association of regular use of nonaspirin NSAIDs with an increased renal cell carcinoma risk, whereas aspirin and acetaminophen use were not.[17]

(Masson trichrome stain; original magnification ×400.) *(Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo.)*

Diagnosis

Papillary necrosis is present histologically in almost all patients, but it can be detected radiologically only if part or all of the papilla has sloughed. Papillary necrosis is not pathognomonic of analgesic nephropathy; it is also seen in diabetic nephropathy (particularly during an episode of acute pyelonephritis), sickle cell nephropathy, urinary tract obstruction, and renal tuberculosis. Non–contrast-enhanced computed tomography (CT) demonstrates a decrease in renal mass with either bumpy contours or papillary calcifications (Fig. 64-3; see also Fig 52-3, *C*).[18]

Treatment

Management consists of stopping or at least reducing the intake of analgesic medications. Because of the increased incidence of uro-

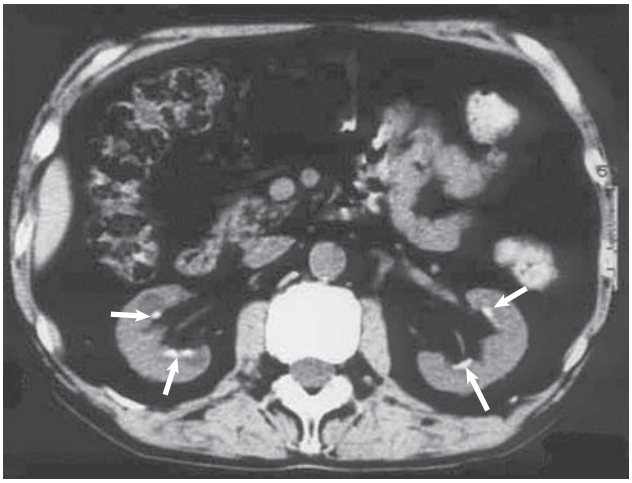

Figure 64-3 Papillary calcifications in analgesic nephropathy. Non–contrast-enhanced computed tomography scan of a patient with long-time analgesic abuse shows thinning of the renal parenchyma and typical papillary calcifications *(arrows). (Courtesy Dr. Yoshifumi Ubara, Toranomon Hospital, Tokyo.)*

epithelial tumors, close follow-up is necessary. New hematuria requires early referral for urologic evaluation.

Analgesic nephropathy associated with over-the-counter medicines is also discussed in Chapter 78.

CHRONIC INTERSTITIAL NEPHRITIS CAUSED BY METABOLIC DISORDERS

Metabolic disorders that cause interstitial nephritis are discussed here. Hyperoxaluria is described in Chapter 59 and cystinosis in Chapter 48.

Chronic Uric Acid Nephropathy

Definition and Epidemiology

Historically, chronic interstitial nephritis associated with chronic hyperuricemia was called *gouty nephropathy* and was ascribed to the medullary deposition of crystals with surrounding inflammation and fibrosis. Later this concept was challenged, and the renal disease associated with gout was thought to be secondary to coexistent hypertension, vascular disease, or aging-associated renal injury. In addition, independent of a specific chronic uric acid nephropathy with crystal deposition, recent epidemiologic studies document that an elevated serum uric acid is a risk factor for the *de novo* development of CKD.[20] These increases in risk remain significant even after adjustment for eGFR, proteinuria, age, and components of the metabolic syndrome. These studies suggest that chronic hyperuricemia may be both a true risk factor for the development of CKD and also a risk factor for progression of established CKD.[21]

Pathogenesis

Chronic gout and severe hyperuricemia can be associated with the deposition of uric acid crystals in the renal medulla (Fig. 64-4). However, independent of crystal deposition, experimental studies indicate that hyperuricemia causes chronic renal injury by activating the renin-angiotensin system (RAS) and inducing oxidative stress, resulting in glomerular hypertension and impaired renal autoregulation.[22] Although uric acid can function as an antioxidant in the extracellular environment, within the cell uric acid has pro-oxidant effects and can lead to endothelial and mitochondrial dysfunction.

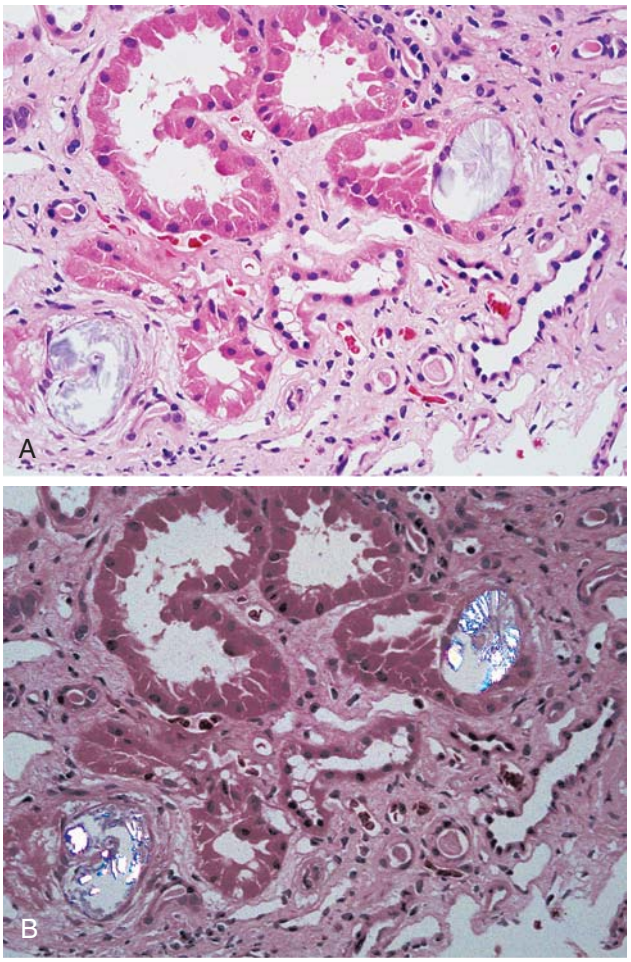

Figure 64-4 Chronic uric acid nephropathy. A, Large collections of elongated or fragmented uric acid crystals are present in association with atrophic tubules. (Hematoxylin-eosin stain; original magnification ×400.) **B,** The crystalline masses are refractile under polarized light. *(Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo.)*

Pathology

Renal functional abnormalities are observed in 30% to 50% of patients who have had gout for many years, and histologic changes are observed in more than 90%.[23] The most consistent histologic findings are arteriolosclerosis, focal or global glomerulosclerosis, and chronic tubulointerstitial disease. Uric acid crystals can also be occasionally found within both tubules and in the interstitium (see Fig. 64-4), especially in the outer medulla, and on rare occasions medullary renal tophi can be found on gross anatomic dissection. Experimental studies question whether the uric acid crystals themselves are responsible for the disease.

Clinical Manifestations

Patients with chronic uric acid nephropathy present with hypertension with mildly impaired renal function, mild proteinuria, unremarkable urinary sediment, and minor tubular dysfunction (usually impairment of urine concentrating ability manifested as isosthenuria). Uric acid nephropathy should particularly be considered if there is a disproportionate elevation in serum uric acid in relation to the degree of renal impairment (Table 64-3).[24]

Serum Creatinine and Uric Acid Levels in Chronic Kidney Disease			
Serum Creatinine		**Serum Uric Acid**	
mg/dl	**μmol/l**	**mg/dl**	**μmol/l**
<1.5	<132	9	536
1.5-2.0	132-176	10	595
>2.0	>176	12	714

Table 64-3 Serum creatinine and uric acid levels in chronic kidney disease. Uric acid levels higher than those shown should alert the clinician to the possibility of chronic uric acid nephropathy, although they are not diagnostic. *(Modified from reference 23.)*

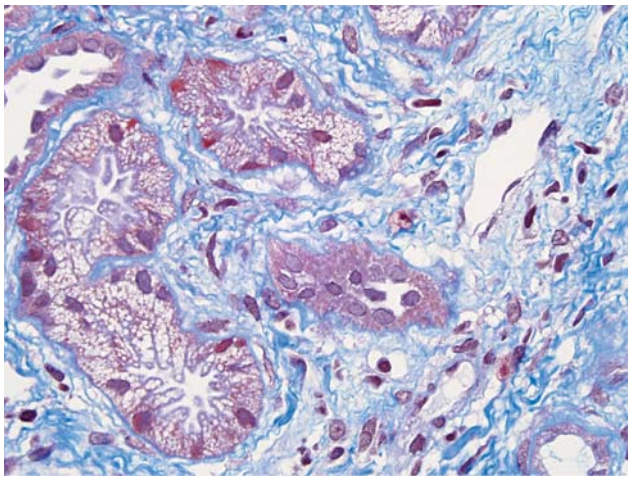

Figure 64-5 Hypokalemic nephropathy. Vacuolization of the renal tubules is observed in association with interstitial fibrosis in a patient with hypokalemic nephropathy. (Masson trichrome stain; original magnification ×400.) *(Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo.)*

Diagnosis

The most important differential diagnosis for chronic uric acid nephropathy is chronic lead nephropathy. Familial juvenile hyperuricemic nephropathy is a rare autosomal dominant disease that mimics chronic gouty nephropathy but presents in adolescence or during early childhood (see Chapter 50).

Treatment

It remains controversial whether lowering uric acid can improve kidney disease in patients with gout or hyperuricemia. One prospective, randomized trial demonstrated that allopurinol therapy is associated with preservation of eGFR in CKD, although the treatment did not show any effects on the defined study end point, which was ESRD.[25] Withdrawal of allopurinol from patients with stable CKD has resulted in worsening of hypertension and acceleration of kidney dysfunction, especially in patients who were not on ACE inhibitors.[26] Lowering uric acid in patients with asymptomatic hyperuricemia is also associated with an increase in eGFR.[27] There have also been reports that lowering uric acid may reduce the risk of cardiovascular disease in patients with CKD.[25,28] However, to date all studies have involved small numbers of patients, and more definitive studies are required before treatment of hyperuricemia with uric acid–lowering therapy can be recommended routinely.

One reason for caution is the accumulation of xanthine in renal failure, which will be aggravated by the xanthine oxidase inhibitor allopurinol and which can precipitate in the kidney and cause acute kidney injury. To minimize this complication, it is recommended to initiate allopurinol at a dose of 50 to 100 mg/day, increasing to 200 or 300 mg/day after several weeks if it is tolerated. Another adverse effect of allopurinol use is a hypersensitivity reaction (Stevens-Johnson–like syndrome) that may be more common in patients with impaired renal function. The newer xanthine oxidase inhibitor febuxostat does not require modification of dose in renal failure and appears to be less frequently associated with hypersensitivity or nephrotoxicity, but more studies are required before it can be recommended as first-line therapy.

Hypokalemic Nephropathy

Definition and Epidemiology

Hypokalemia, if persistent for prolonged periods, can induce renal cysts, chronic interstitial nephritis, and progressive loss of renal function, known as *hypokalemic nephropathy,* which can be inherited or acquired. Hypokalemic nephropathy occurs in 15% to 20% of individuals with anorexia nervosa.[29]

Pathology

The characteristic finding is vacuolation of the renal tubules as a result of dilation of cisternae of the endoplasmic reticulum and basal folding, which is usually limited to the proximal tubular segments (Fig. 64-5). This abnormality generally requires at least 1 month to develop and is reversible with potassium supplementation. More prolonged hypokalemia can lead to more severe changes, predominantly in the renal medulla, including interstitial fibrosis, tubular atrophy, and cyst formation. There is experimental evidence that hypokalemic injury may be caused by hypokalemia-induced renal vasoconstriction with ischemia. Local ammonia production stimulated by hypokalemia may also lead to intrarenal complement activation that may contribute to the renal injury. Furthermore, the associated intracellular acidosis can stimulate cell proliferation, which may account for the occasional development of cysts in hypokalemic patients.

Clinical Manifestations

Impaired urine concentration, presenting with nocturia, polyuria, and polydipsia, may occur, particularly when serum potassium concentration is consistently below 3.0 mmol/l for months or years. The average duration of hypokalemia reported in patients with chronic hypokalemic nephropathy is 3.5 to 9 years. The renal defect is associated with decreased collecting tubule responsiveness to vasopressin, possibly because of decreased expression of aquaporin 2.

Diagnosis

Although degenerative changes in proximal tubular cells are a consistent but nonspecific finding in hypokalemic nephropathy, a particularly characteristic finding is vacuolar changes in the proximal tubules (see Fig. 64-5). Similar vacuolization of the convoluted tubules is observed in ethylene glycol poisoning.

Treatment

Hypokalemia can usually be treated with oral potassium supplements. The treatment of hypokalemia is discussed in Chapter 9. Coarse cytoplasmic vacuoles may persist for some time after normalization of serum potassium values.

Hypercalcemic Nephropathy

Definition and Epidemiology

Hypercalcemia can cause both a transient and reversible renal vasoconstriction with a decrement in renal function and a chronic interstitial nephritis secondary to tubular cell necrosis and intratubular obstruction. In addition, hypoparathyroidism (especially after surgical treatment of hyperparathyroidism) can also result in marked hypercalciuria and a similar syndrome in the absence of hypercalcemia.

Pathology

Focal degeneration and necrosis of the tubular epithelium, primarily in the medulla where calcium is concentrated, develop soon with persistent hypercalcemia. Although focal degenerative and necrotic lesions of the tubular epithelium can be observed with acute hypercalcemia, the most distinctive histologic feature of longstanding hypercalcemia is calcific deposits in the interstitium (nephrocalcinosis; Fig. 64-6). Deposition begins in the medullary tubules, followed by deposition in the cortical proximal and distal tubules and within the interstitial space, and secondarily leads to mononuclear cell infiltration and tubular necrosis.

Clinical Manifestations

Macroscopic nephrocalcinosis is often detected on radiography or ultrasound. A defect in urinary concentration is the most notable tubular dysfunction and manifests as polyuria and polydipsia. The mechanism is incompletely understood, but the impairment relates both to a reduction in medullary solute content and to interference with the cellular response to vasopressin. Reversible impairment of renal function can result from either acute or chronic hypercalcemia by decreased renal blood flow and GFR. Irreversible renal failure is a rare consequence of longstanding hypercalcemia and is almost invariably associated with calcium crystal deposition in the interstitium of the kidney.

CHRONIC INTERSTITIAL NEPHRITIS CAUSED BY HEREDITARY DISEASES OF THE KIDNEY

Nephronophthisis (NPHP) and medullary cystic kidney disease (MCKD) (or the NPHP-MCKD complex) are hereditary diseases associated with renal cysts at the corticomedullary junction. These disorders are described in detail in Chapter 47.

CHRONIC INTERSTITIAL NEPHRITIS ASSOCIATED WITH HEAVY METAL EXPOSURE

Lead Nephropathy

Definition and Epidemiology

Acute lead intoxication is rare but may present with abdominal pain, encephalopathy, hemolytic anemia, peripheral neuropathy, and proximal tubular dysfunction (Fanconi syndrome). In contrast,

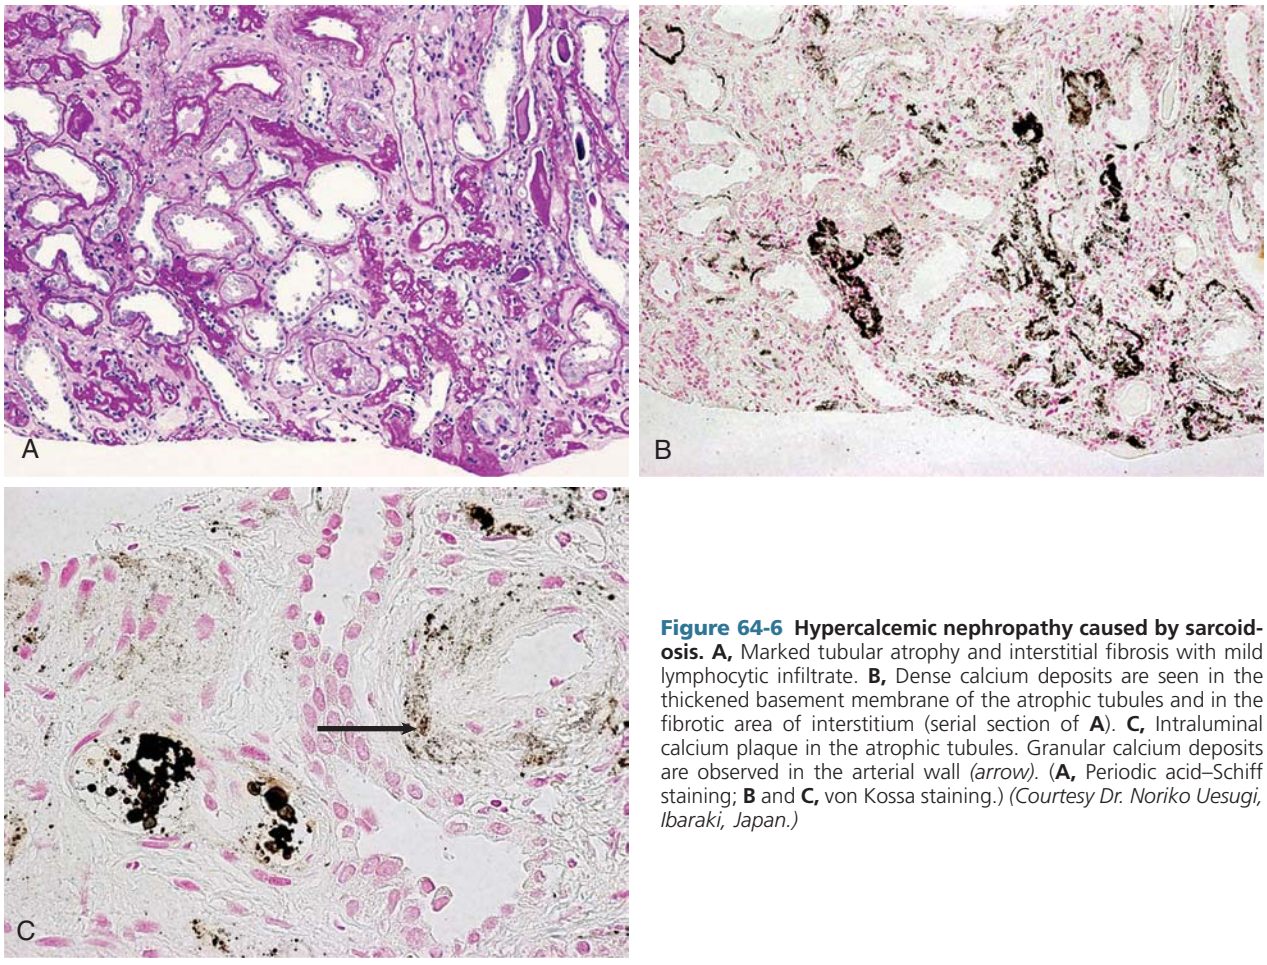

Figure 64-6 Hypercalcemic nephropathy caused by sarcoidosis. A, Marked tubular atrophy and interstitial fibrosis with mild lymphocytic infiltrate. **B,** Dense calcium deposits are seen in the thickened basement membrane of the atrophic tubules and in the fibrotic area of interstitium (serial section of **A**). **C,** Intraluminal calcium plaque in the atrophic tubules. Granular calcium deposits are observed in the arterial wall *(arrow)*. (**A,** Periodic acid–Schiff staining; **B** and **C,** von Kossa staining.) *(Courtesy Dr. Noriko Uesugi, Ibaraki, Japan.)*

chronic low-level exposure to lead has been associated with CKD, often with hyperuricemia. Because lead has a biologic half-life of several decades, both intermittent acute poisoning and low-level environmental exposure result in chronic cumulative lead poisoning.

Although some epidemiologic studies have suggested that low-level exposure may be associated with CKD or hypertension,[30-32] data indicating that lead causes CKD leading to ESRD are relatively sparse.[33] The pathogenesis of the renal disease may be related to the accumulation of reabsorbed lead in the proximal tubule cells, effects of chronic lead exposure on the vasculature, or lead-induced hyperuricemia. Additional well-controlled longitudinal studies with adequate exposure and effect variables are awaited to confirm that lead exposure causes deterioration of renal function and eventual ESRD.

Pathology

The kidneys are granular and contracted. The characteristic morphology is chronic interstitial nephritis demonstrating nonspecific tubular atrophy, interstitial fibrosis, and a paucity of inflammatory cells. The earliest histologic finding is proximal tubular injury, with intranuclear inclusion bodies composed of a lead-protein complex. Glomerular scarring can be observed as a secondary event, and arteries and arterioles demonstrate medial thickening and luminal narrowing, probably related to hypertension. Immunofluorescence studies are noncontributory.

Clinical Manifestations

Chronic lead nephropathy is usually identified when a source of high exposure is known (occupational hazard or consumption of illicitly distilled spirits [moonshine]). Hyperuricemia is common because of impaired uric acid excretion. Urine sediment is benign, and urinary protein excretion is less than 2 g/day. Hypertension is almost always present, and in the absence of appropriate testing or a careful exposure history, lead nephropathy is often misdiagnosed as hypertensive kidney disease. Gouty arthritis ("saturnine gout") affects about half of patients. Patients with chronic lead intoxication may occasionally manifest other signs, including peripheral motor neuropathies, anemia with "basophilic" stippling, and perivascular cerebellar calcifications.

Diagnosis

Lead nephropathy may be underdiagnosed because no simple diagnostic blood test is available. Lead nephropathy is easily confused with chronic uric acid nephropathy, in which uric acid deposits (tophi) may form in the renal interstitium. All patients with hyperuricemia and renal impairment should have a history of occupational lead exposure excluded. The blood lead concentration is an insensitive measure of cumulative body stores. A clinical diagnosis of lead nephropathy is based on a history of exposure, evidence of renal dysfunction, and an abnormal calcium disodium edetate ($CaNa_2$ EDTA) lead chelation test. The association with gout and CKD is strong enough to merit lead chelation screening in patients with CKD who have gout and risk of lead exposure. $CaNa_2$ EDTA is administered (two doses of 0.5 g in 250 ml 5% dextrose given 12 hours apart), and urine is collected for 3 days because urinary excretion is slowed in the setting of renal failure. Normal urinary lead levels are less than 650 µg/3 days. X-ray fluorescence, which provokes the emission of fluorescent photons from the target area, is an alternative method that detects increased bone lead levels, which are also a reflection of cumulative lead exposure. Although x-ray fluorescence measurements allow a rapid, noninvasive estimation of lead in bone, detection equipment remains available at only a small number of centers, making availability of this method limited.

Treatment

Treatment involves the infusions of $CaNa_2$ EDTA together with removal of the source of lead. The likelihood of a satisfactory response to $CaNa_2$ EDTA is influenced by the degree of interstitial fibrosis that has already occurred.

In industrial and occupational settings, such as in foundry workers and individuals working with lead-based paints and glazes, preventive measures to minimize exposure and low-level absorption are essential. Some studies in children show success with the oral chelating agent succimer (Chemet). Chelation therapy may slow progressive CKD, even in patients with mild lead intoxication.[34] However, the chelation therapy has not been widely used because of adverse drug effects and concerns about the effects of remobilized lead. It is generally not indicated for adults with blood lead concentrations of less than 45 µg/dl. Because of a lack of controlled clinical trials demonstrating efficacy of chelation and concerns about potential side effects, recommendations for treatment with chelating agents are empiric, and decisions to use chelation therapy for lead intoxication can be controversial.

Other Heavy Metal–induced Nephropathies

Cadmium is a metal with a wide variety of industrial uses, including the manufacture of glass, metal alloys, and electrical equipment. Cadmium is preferentially concentrated in the kidney, principally in the proximal tubule, in the form of a cadmium-metallothionein complex that has a biologic half-life of about 10 years. Cadmium contamination may be an important contributor to the high risk of chronic interstitial nephritis in some agricultural communities in the developing world. A major outbreak of cadmium toxicity occurred in Japan as a result of industrial contamination. The disease was called *itai-itai,* or "ouch-ouch," because bone pain was the major clinical manifestation. Other manifestations included proximal tubular dysfunction, renal stones caused by hypercalciuria, anemia, and progressive chronic interstitial nephritis. The mechanism by which cadmium elicits chronic inflammation and fibrosis in the kidney is relatively unstudied. The diagnosis is suggested by a history of occupational exposure, increased urinary β_2-microglobulin, and increased urinary cadmium levels (>7 µg of cadmium per gram creatinine). Once manifested, renal injury tends to be progressive, even if exposure is discontinued. Chelation has not been effective in humans, and prevention is the only effective treatment.

Arsenic, used as a poison gas in the First World War, is present in insecticides, weed killers, wallpaper, and paints. Chronic arsenic toxicity most commonly manifests as sensory and motor neuropathies, distal extremity hyperkeratosis, palmar desquamation, diarrhea and nausea, Aldrich-Mees lines (white bands on the nails), and anemia. In rare cases, it may cause renal disease, manifested by both proximal RTA and chronic interstitial fibrosis. Diagnosis is made by demonstration of an elevated urinary arsenic level.

Mercury is found in alloy plants, mirror plants, and some batteries, and mercury intoxication usually occurs as a result of accidental exposure to mercury vapor. Mercury has been shown to induce membranous nephropathy (MN) in experimental animals and has been reported with the use of mercury-containing skin-lightening creams.[35] Neither elemental mercury nor the mercurous salt (Hg_2Cl_2) produces sustained renal tubular injury, but mercury dichloride ($HgCl_2$) may produce acute tubular necrosis and subsequent chronic interstitial nephritis. However, a report of endemic methyl mercury poisoning in Japan revealed a clinical picture dominated by neurologic sequelae; renal disease in these patients was surprisingly benign, consisting only of tubular proteinuria without changes in serum creatinine.

ENDEMIC CHRONIC INTERSTITIAL NEPHRITIS

A number of localized epidemics of CKD caused by chronic interstitial nephritis have been reported. The longest known is Balkan endemic nephropathy, which is described in Chapter 78 along with the other manifestations of aristolochic acid nephropathy.

Another epidemic has been identified in agricultural communities on the Pacific coast of Central America, especially in Nicaragua, Honduras, and El Salvador. The disease is observed primarily in men working in the sugar cane fields, but it also occurs in others working outside in hot environments. The cause remains unknown but does not appear to relate to pesticides, aristolochic acid, or heavy metals. It has been proposed that the disease may result from leptospirosis infection or from chronic or recurrent episodes of dehydration, possibly in conjunction with the use of NSAIDs.

An epidemic has also been described recently in agricultural communities in Sri Lanka; the cause remains uncertain, but heavy metal contamination may be involved.

RADIATION NEPHRITIS

Definition and Epidemiology

Although radiation nephritis was relatively common decades ago, the incidence has decreased considerably because recognition of radiation-induced renal damage has altered protocols for the administration of therapeutic radiation. In general, direct exposure of the kidney to 20 to 30 Gy (1 Gy = 100 rad) during 5 weeks or less will produce radiation nephritis.

Pathology

The initial target of ionizing radiation within the kidney appears to be endothelial cells, leading to endothelial cell swelling. Vascular occlusion then develops with resultant tubular atrophy. Electron microscopy reveals a split appearance of the capillary wall caused by the mesangial interposition and widening of the subendothelial space by a nondescript fluffy material. These features are shared by hemolytic uremic syndrome and thrombotic thrombocytopenic purpura, suggesting a common pathogenic mechanism originating from endothelial injury. Severe disease is characterized by progressive interstitial fibrosis and the presence of interstitial inflammatory cells.

Clinical Manifestations

In general, vascular and glomerular lesions of thrombotic microangiopathy may predominate. However, tubulointerstitial changes of varying severity are also usually present. Hypertension is commonly observed. Progression to a "chronic" form of radiation nephritis may occur if resolution of acute radiation nephritis is incomplete. These patients present with proteinuria, progressive CKD, and eventual development of ESRD several years after irradiation in the absence of an acute phase.

Treatment

Prevention is the best approach. The risk for development of radiation nephritis can be minimized by shielding the kidneys or fractioning the total-body irradiation into several small doses over several days. No specific treatment is available for established radiation nephritis; consequently, the general approach is control of hypertension and supportive treatment of CKD.

INTERSTITIAL NEPHRITIS MEDIATED BY IMMUNOLOGIC MECHANISMS

Sjögren Syndrome

Definition and Epidemiology

Sjögren syndrome may be associated with chronic interstitial nephritis. The reported prevalence of renal involvement in Sjögren syndrome has varied widely, ranging from 2% to 67%, principally owing to different definitions of kidney involvement or disease. Recent analysis of 130 patients with primary Sjögren syndrome in China showed an 80% incidence of biopsy-proven chronic interstitial nephritis.[36]

Pathology

The lesion is characterized histologically by infiltration of lymphocytes and plasmacytes in the interstitium with tubular cell injury and, rarely, granuloma formation. This progresses to tubular atrophy and interstitial fibrosis over time. Immunofluorescence reveals granular deposits of IgG and C3 along the tubular basement membrane (TBM).

Clinical Manifestations

The clinical and biochemical manifestations of interstitial nephritis may be the presenting or only features of Sjögren syndrome. Serum creatinine concentration is generally only mildly elevated in association with a bland urine sediment and abnormalities in tubular function, including Fanconi syndrome, distal RTA, hypokalemia, and nephrogenic diabetes insipidus. Sjögren syndrome is one of the most common causes of acquired distal (type 1) RTA in adults, and the hypokalemia may be marked, resulting in a clinical presentation of severe weakness. Hypokalemia may occur in the absence of RTA, resulting from salt wasting and secondary hyperaldosteronism.

Treatment

Treatment with corticosteroids at the stage of cellular infiltration is frequently beneficial for protecting renal function. Although the renal disease has a slow and protracted course and CKD develops over time, progression to ESRD is rare.

Sarcoidosis

Definition and Epidemiology

Histologic evidence of interstitial nephritis with noncaseating granulomas is common in patients with sarcoidosis, but the frequency of clinically significant disease is low.[37] It may present as either an acute interstitial nephritis or a chronic interstitial nephritis.

Pathogenesis and Pathology

Renal biopsy reveals normal glomeruli; interstitial infiltration, mostly with mononuclear cells; tubular injury; and with more chronic disease, interstitial fibrosis. Whereas the classic finding is noncaseating granulomas in the interstitium, they are uncommon and nonspecific. An analysis of 18 patients with granulomatous interstitial nephritis showed that in five the disorder was associated with sarcoidosis; in two, tubulointerstitial nephritis and uveitis; in two, medication; and in nine, the condition was idiopathic.[38] Immunofluorescence and electron microscopic studies typically show no immune deposits.

Recent studies suggest that renal sarcoidosis may reflect an impaired immune response to certain bacteria, especially *Propionibacterium acnes*. Confirmatory studies are needed, and it is not known if antibiotic treatment aimed at *P. acnes* provides any benefit.

Clinical Manifestations

Most affected patients have clear evidence of diffuse active sarcoidosis, although some present with an isolated elevation in serum creatinine and only minimal extrarenal manifestations. The urinalysis, if findings are not normal, shows only sterile pyuria or mild proteinuria.

In addition, hypercalcemia induced by increased production of calcitriol (1,25-dihydroxyvitamin D_3) by activated mononuclear cells (particularly macrophages) in the lung and lymph nodes occasionally results in renal problems (see the previous discussion of hypercalcemic nephropathy).

The serum ACE level is used best not as a primary diagnostic tool but as a marker of disease activity and response to therapy. A normal serum ACE level does not exclude renal sarcoidosis.

Treatment

Corticosteroid therapy tends to improve renal function, although recovery is often incomplete. Rapid tapering of corticosteroids can result in relapse.
